Reboulia hemisphaerica (Figure 69-Figure 76) is cosmopolitan (Piippo *et al.* 1997; Kürschner 2008) and is especially distributed in subtropical and temperate regions (Nieuwkoop 1996). *Reboulia hemisphaerica* is distributed in China, India, Japan, Korea, Nepal, Afghanistan, Pakistan, Java, Boning, New Zealand, Australia, Europe, Africa, Tahiti, North America, and South America (Singh & Singh 2002; Nair & Prajitha 2016).

Janovicová and Kubinská (2001) considered *Reboulia hemisphaerica* (Figure 69-Figure 76) to be both rare and threatened in the Biele Karpaty Mountains of Slovakia.

Aquatic and Wet Habitats

Reboulia hemisphaerica (Figure 69-Figure 76) is occasionally submerged (Watson 1919) and can occur in rivers (Ferreira *et al.* 2008). Konstantinova (2011) reported it from sandy soil between rocks in a dry stream bed in Dagestan, Russia. In the Uşak province of western Turkey it occurs on wet rocks (Gökler 2017). Hong (1977) found it on wet rocks in Montana, USA.

Reboulia hemisphaerica (Figure 69-Figure 76) occurs on the bank of the Banaz stream in the Uşak province of western Turkey (Gökler 2017). In the Izarene Massif of Rocco, it occurs on clayey soil on slopes (Figure 77) beside flowing water (Laouzazni *et al.* 2021). In Cyprus, it occurs under shrubs on the bank of a gully and on a steep bank by a stream in a deep valley (Blockeel 2003). Sharp (1939) found it on moist banks (Figure 1) in eastern Tennessee, USA. Konstantinova (2011) reported that *Reboulia hemisphaerica* subsp. *australis* occurs in Dagestan, Russia, in the gorge at the source of the Gunibka River on the bank. Some of its habitats on rocks and soil banks are shown in Figure 77-Figure 82.

Figure 82. *Reboulia hemisphaerica* habitat on a soil bank. Photo by Michael Lüth, with permission.

Both streams and rivers can have floodplains. Many species have life cycles timed to take advantage of these ephemeral habitats. In the Virginia Piedmont, USA, the presence of *Reboulia hemisphaerica* (Figure 69-Figure 76) can indicate such a habitat where most of the species appear in late fall after leaf drop, regrowing from spores and dying soon after dispersing their spores (Breil 1977). These indicator species are sensitive to drying, yet typically require high light intensities.

Reboulia hemisphaerica (Figure 69-Figure 76) seems to have a preference for steep slopes (Figure 83-Figure 84). In the Netherlands, it is nearly always found on slopes up to 90° (Nieuwkoop 1996). Martin (1943) reported it from a cliff face in Ledges State Park, Iowa, USA. Miller and Thomson (1959) reported it from moist sandstone cliffs in Indiana, USA.

Figure 84. *Reboulia hemisphaerica* with archegoniophores on steep rocky slope. Photo by Michael Lüth, with permission.

Slopes and cliffs often have water trickling down them, or occur in canyons that remain humid. These provide suitable habitat for moisture-loving species of liverworts. In particular, cracks and crevices (Figure 85) provide protection and tend to remain moist longer than bare rock. *Reboulia hemisphaerica* (Figure 69-Figure 76) can occur in such locations (Sharp 1939; Crundwell & Nyholm 1979; Konstantinova 2011).

Figure 85. *Reboulia hemisphaerica* on rock ledge. Photo by Michael Lüth, with permission.

In the Netherlands, Nieuwkoop (1996) found that *Reboulia hemisphaerica* (Figure 69-Figure 76) preferred a loamy substrate (Figure 86), even if growing on a rock. These usually were on moist, loamy walls with light shade. Like the above members of the family Aytoniaceae, *Reboulia hemisphaerica* takes advantage of the cooler temperatures and greater moisture of wind holes (Figure 22) (Bakalin *et al.* 2017).

Figure 86. *Reboulia hemisphaerica* on soil. Photo by Štěpán Koval, with permission.

Reboulia hemisphaerica (Figure 69-Figure 76) exhibits a wide range of moisture tolerance, growing on slopes of ditches, on roadside banks, and along roads (Brown 1924). Jerath and Puja (2006) reported it as xeromorphic in the Shivalik Ecosystem of Punjab, India, but also growing in moist and exposed places. Nair and Prajitha (2016) found it on cut earth in the western Ghats of India. Singh and Singh (2002) found it on rocks in partially exposed places in India.

Province (2011) reported it in particular from basic schists and slate on rock outcrops among scrub vegetation in South-west Sichuan, China. Piippo and Koponen (2013) similarly found it in both primeval and secondary evergreen forests in northwestern Sichuan, China, in both open and shaded sites, on humus over rock (Figure 87) or stone, on cliffs, clay, and soil (Figure 88).

Figure 87. *Reboulia hemisphaerica* on soil over rock, Europe. Photo by Michael Lüth, with permission.

Figure 88. *Reboulia hemisphaerica* on soil. Photo by Jan-Peter Frahm, with permission.

Konstantinova *et al.* (2018) considered *Reboulia hemisphaerica* (Figure 69-Figure 76) to be a calcicole. It occurs in Russia on bare soil on mossy rock outcrops, on ledges (Figure 89-Figure 91) and in crevices, and even under rocks. Aleffi *et al.* (2005) listed it from rocks and escarpments in Italy. It finds similar habitats to be suitable in Morocco, including rock ledges with accumulated soil and bases of rocks (Ros *et al.* 2000), but Saadi *et al.* (2020) found it on siliceous soil in Morocco. Piippo and Tan (1992) found it on an abandoned wall in a shaded garden in the Philippines.

Figure 90. *Reboulia hemisphaerica* with archegoniophores on rock ledge. Photo by Michael Lüth, with permission.

Figure 91. *Reboulia hemisphaerica* with archegoniophores on rock ledge. Photo by Barry Stewart, with permission.

In Oklahoma, USA, *Reboulia hemisphaerica* (Figure 69-Figure 76) is the most frequent species of liverwort on dry rock outcrops (Little 1936) and also occurs on sandy soil (Sharp 1930). In Illinois, USA, it occurs on rocks, walls, and soil, including a sandstone wall (Spessard 1972; Simon 1977). Conard (1940) found it to be common on dry earth or rocks in Iowa, USA. At Mountain Lake, Virginia, USA, it similarly occurs on calcareous rocks and crevices (Sharp 1944).

In Myvatn, Iceland, *Reboulia hemisphaerica* (Figure 69-Figure 76) occurred as a pioneer on Krafla following the 1984 eruption (pers. obs. 1987). In just three years, it reached large populations (Figure 92-Figure 93).

Physiology

Reboulia hemisphaerica (Figure 69-Figure 76) apparently has a wide moisture tolerance. Crundwell and Nyholm (1979) considered it to be one of the most drought-tolerant of the Turkish liverworts.

Reboulia hemisphaerica (Figure 69-Figure 76) exhibits growth and branching at moisture levels ranging 40-90%, with optimum growth at 70-80% (Vishvakarma & Kaul 1988a).

Xiang *et al.* (2010a) found that water stress affects the soluble sugar and proline, but has negligible effect on MDA. Calcium stress has even greater effects on sugar and proline. Low calcium results in a reduction in the accumulation of proline and soluble sugar, but as low calcium stress worsens their content gradually increases.

Hoffman and Gates (1970) demonstrated, using *Reboulia hemisphaerica* (Figure 69-Figure 76), that water loss proceeds rapidly in moist plants, with very low resistance. But as the water loss decreases, both convection and reradiation of energy become more important. At the same time, resistance increases in proportion to water loss. *Reboulia hemisphaerica* transpired for 2 hours under a radiation regime of 2.6 to 2.8 cal cm⁻² min⁻¹.

Reboulia hemisphaerica (Figure 69-Figure 76) has a mean water conductive rate of ~0.5 mm s⁻¹ (McConaha

1941). The areolation of its thallus greatly increases the surface through which water can be lost through the atmosphere by pores. A high phlobaphene content on the ventral surfaces helps to maintain a capillary film there among the tuberculate rhizoids and prevents water loss from the upturned thallus margins. McConaha demonstrated that a single water drop at one end of the thallus became distributed through the length of the thallus by its external capillary system. This water was immediately available to all absorptive surfaces. This external system provides a much more rapid transport than any known internal system. This seems to compensate successfully for the increased water loss due to areolation. In contrast to the description of McConaha, O'Hanlon (1928) describes the species with only a mere suggestion of air chambers and no air pores.

Takio *et al.* (1990) examined the chlorophyll content and photosynthetic rate in *Reboulia hemisphaerica* (Figure 69-Figure 76). They found that it possessed high levels of chlorophyll when cultured in light ($4\text{--}34\ \mu\text{g mg}^{-1}$ dry weight). These plants likewise had a high photosynthetic rate of $10\text{--}94\ \mu\text{mol O}_2\ \text{mg}^{-1}\ \text{chlorophyll h}^{-1}$. Dark-grown cells exhibited these same high levels of chlorophyll and photosynthesis, contrasting sharply with the low chlorophyll levels in dark-grown *Barbula unguiculata* (Figure 94).

Figure 94. *Barbula unguiculata*. Photo by Kristian Peters, through Creative Commons.

Rao *et al.* (1979) reported on the assimilation of labelled carbon into amino acids for *R. hemisphaerica*. The CO_2 assimilation rate was lower than that of seed plants. The chlorophyll content of these populations (from moist locations in the Ooty Hills, India) was low, as was the chlorophyll *a:b* ratio, parameters that are typical of shade-loving species. Rao *et al.* (1979) reported that the Hill reaction rates of *R. hemisphaerica* was lower than that typically reported for seed plants.

Both dark-grown and light-grown cells of *Reboulia hemisphaerica* (Figure 69-Figure 76) exhibited high chlorophyll content ($4\text{--}34\ \mu\text{g mg}^{-1}$ dry weight) after one year of culture on 2% glucose medium (Takio *et al.* 1990). Photosynthetic activity was likewise high in both ($10\text{--}84\ \mu\text{mol O}_2\ \text{mg}^{-1}\ \text{chlorophyll h}^{-1}$).

Lei *et al.* (2010) explored the responses of photosystem II in *Reboulia hemisphaerica* (Figure 69-Figure 76) to nitrogen deposition. Increased N concentrations (40 and $60\ \text{kg h m}^{-2}\ \text{a}^{-1}$) caused changes in chlorophyll fluorescence and reduced the energy-trapping capacity per unit area. It furthermore changed the redox states, destroyed electron flow especially beyond the Q-A, disabling that energy absorption and necessitating its consumption by fluorescence and heat. Liu *et al.* (2009) also explored N effects on this species and found both photosynthetic rate and starch concentration were lower at N concentrations of 20 and $40\ \text{kg h}^{-1}\ \text{m}^{-2}$ than at the control levels or at $60\ \text{kg h}^{-1}\ \text{m}^{-2}$. On the other hand, the total N in the tissue changed inversely. Both the inducible and constituted nitrate reductase activity were very low in all treatments, suggesting that it is unable to use nitrates. Potassium ion leakage increased significantly when the N addition increased to $60\ \text{kg N h}^{-1}\ \text{m}^{-2}$, suggesting membrane damage.

Vishvakarma and Kaul (1986) explored the temperature tolerance of *Reboulia hemisphaerica* (Figure 69-Figure 76). Morais and Becker (1991) cultured *Reboulia hemisphaerica* and found that it grew best on agar with 0.5% sucrose and an 18 h light: 6 h dark regime. Callus could be induced by phytohormones ($2\ \text{mg L}^{-1}$ *n*-naphthylacetic acid + $1\ \text{mg L}^{-1}$ kinetin) or by 4% glucose. Once cultures differentiated, there was a tenfold increase in sesquiterpene production. No sesquiterpenes were produced in dark cultures, but 5-hydroxy-7,8,4'-trimethoxyflavone was present. In light cultures, apigenin *n*-7,4'-dim ethylether was the only flavonoid produced.

Xiang *et al.* (2010b) evaluated the effects of heavy metals on *Riccardia hemisphaerica* (Figure 69-Figure 76) from cavern rock and soil on walls. They found that *R. hemisphaerica* actually exhibited depletion levels of Ca in the Three Gorges karst region, whereas some mosses exhibited either strong or relative enrichment in their tissues. It exhibited no enrichment of Mg, whereas the moss *Thuidium cymbifolium* (Figure 95) did. *Reboulia hemisphaerica* did, however, show a strong enrichment by Zn.

Adaptations

One aspect that may account for the wide range of habitats for *Reboulia hemisphaerica* (Figure 69-Figure 76) is its ability to form pure mats or to grow with other bryophytes (Figure 96-Figure 97) (Konstantinova *et al.* 2018). The accompanying bryophytes can act like a sponge to retain moisture that could maintain suitable conditions for *R. hemisphaerica*, whereas pure mats can completely cover the substrate and reduce evapotranspiration.

Figure 97. *Reboulia hemisphaerica* with mosses and archegoniophores. Photo by Michael Lüth, with permission.

Reboulia hemisphaerica (Figure 69-Figure 76) has air chambers (Figure 98-Figure 100) that form an extensive system of air spaces separated by thin partitions (Dupler 1921; Haupt 1921a). These have air pores (Figure 99-Figure 101) on the upper surface, but no filaments, and thus serve primarily for gas exchange. Dupler (1921) describes them as very elongated air chambers that extend lengthwise along the midrib region. They radiate from there toward the thallus margins. They are in a single layer just below the surface and presumably facilitate CO₂ exchange in internal photosynthetic cells.

Figure 101. *Reboulia hemisphaerica* thallus pore. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Having pores (Figure 99-Figure 101) presents its own set of problems. They are advantageous for gas exchange, but not only do they allow water to leave the thallus, they also can allow water to enter. In species like *Reboulia hemisphaerica* (Figure 69-Figure 76), these pores have hydrophobic ledges that not only constrict the size of the pore, but that also repel water, preventing water from entering the plant during downpours or other water events Schönherr & Ziegler (1975). For water to enter, it must have a contact angle of 0° with the ledge. It would be interesting to see the difference in photosynthetic rate if these chambers were injected with water to fill the spaces.

Watson (1919) noted that when *Reboulia hemisphaerica* (Figure 69-Figure 76) grows on wet ground it has fewer rhizoids than when it grows in drier situations. This suggests that more rhizoids help to facilitate the movement and uptake of water, as noted above for other members of the family. Daniels (1998) cites the complex morphology along with tuberculate and smooth rhizoids, scale leaves (Figure 102), and well defined assimilatory and storage zones as xerophytic adaptations in *R. hemisphaerica*.

Reproduction

Haupt (1921a) described *Reboulia hemisphaerica* (Figure 69-Figure 76) as **monoicous** (Figure 103-Figure 107) in Midwestern USA. It is **protandrous** (antheridia develop before archegonia; Figure 105-Figure 106). Generally, 2-3 antheridial groupings develop in succession before the archegonia develop. The antheridia and archegonia occur in separate groups on the dorsal thallus surface.

Dupler (1922a) considered the male receptacle and antheridium to be plastic, including both primitive and advanced characteristics. It is typically dorsal and posterior to the female receptacle (Figure 108-Figure 118) that terminates the branch. It is sessile or on a very short stalk, a feature that places it close to the archegonial head before elongation of the latter on its stalk.

Figure 108. *Reboulia hemisphaerica* young archegoniophores in Europe. Photo by Michael Lüth, with permission.

Figure 118. *Reboulia hemisphaerica* with archegoniophores and dying thalli. Photo by Štěpán Koval, with permission.

Udar and Chandra (1964) reported anomalous female receptacles in *Reboulia hemisphaerica* (Figure 69-Figure 76). One aberrant type produced branch stalks of the archegoniophores. A second aberrant type was just the opposite, producing no stalks or nearly sessile archegonial heads. Furthermore, Chandra (1963) reported compound female receptacles.

Miduno (1937) described the spermatozooids of *Reboulia hemisphaerica* (Figure 69-Figure 76). These typically had two cilia, although they also found five with three cilia. Other variations in size of the spermatozoid and relative length of the cilia were present.

Among the variations in the life cycle of *Reboulia hemisphaerica* (Figure 69-Figure 76) are differences in oicy. Since Haupt (1921a) published his descriptions of Midwestern, USA, populations, differences among populations have led to the description of subspecies. The subspecies of *R. hemisphaerica* differ in the distribution of their sexual organs (Hicks 1992). The typical variety is **paroicus**, whereas the three more recent subspecies are **dioicus** and two **autoicus** ones with differences in male receptacle size. Konstantinova (2011) reported that populations in the eastern Caucasus of Russia were **autoicus**. However in the entire country of Russia, one can find **paroicus**, **autoicus**, and **dioicus** populations (Bakalin 2008). Schuster (1992) considered all these to be one species, but Bakalin (2008) considers them to need further study. Itouga *et al.* (2005) noted that *R. hemisphaerica* had been subdivided into seven subspecies based on sexual condition, a strong indicator of genetic diversity. They recognized three subspecies in Japan, including the autoicus subsp. *orientalis*, subsp. *acrogyna*, and a new to Japan **paroicus** subsp. *hemisphaerica*. In addition to differences in oicy, spore maturation times differed. In subsp. *acrogyna* spores matured in summer, whereas in subsp. *hemisphaerica* and subsp. *orientalis*, they matured in spring.

The emergence of the archegoniophore of *Reboulia hemisphaerica* (Figure 69-Figure 76) does not occur until the sporophytes are nearly mature (Haupt 1921a). Archegonia appear in autumn and fertilization occurs then. The embryo develops immediately, but the sporophyte

(Figure 119-Figure 123) does not mature until the following spring, necessitating survival through the winter.

Figure 119. *Reboulia hemisphaerica* with immature capsules. Photo by Jiří Kameníček (BioLib, Obázek), with permission.

Figure 123. *Reboulia hemisphaerica* archegonial head with scales and capsules that have shed their spores. Photo by Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Allsopp (1964) found that whereas male gametangiophores developed on media with 1% glucose, female gametangiophores developed on sugar-free media. Could these differences in energy needs serve to induce their formation at different times?

Rao and Das (1968) found a sharp rise in the respiratory rate and a doubling of the C:N ratio as *Reboulia hemisphaerica* (Figure 69-Figure 76) transformed from the vegetative to female reproductive phase. At that time, the plants exhibited enhanced levels of endogenous IAA (indole-3-acetic acid), RNA, and protein. During antheridial formation the plants exhibited a reverse trend and exhibited no appreciable change in the C:N ratio (see also Hartmann & Weber 1990).

As noted by Haupt (1921a), *Reboulia hemisphaerica* (Figure 69-Figure 76) is fertilized in autumn in southern Wisconsin and northern Illinois, USA (O'Hanlon 1928); Dupler (1922b) likewise reported fertilization in October. In early spring (8 March) the plants are still dormant (O'Hanlon 1928). Woodburn (1919) determined that both egg and sperm nuclei are in a resting condition in the early stages of fusion. When transplanted indoors on 29 October, *R. hemisphaerica* regenerated new branches but failed to exhibit elongation of the archegoniophore (O'Hanlon 1928). The plants exhibited an inverse relationship between amount of regeneration and development within the receptacle. Most thalli produce fewer than three mature sporophytes per head, but can produce up to nine.

As one might expect, *Reboulia hemisphaerica* (Figure 69-Figure 76) has a lower gene flow with increasing distance ($Nm = -0.0009 \times \text{km}^{1.1}$) (Itouga *et al.* 2002). The mean value for populations in East Asian populations was only 0.609. Thus, the genetic variation was high, as would be predicted for species that reproduce only by spores. Slatkin (1985) considers that Nm values <1 usually imply that genetic drift has been a major contributor to the distribution of genetic variation. Itouga and coworkers found that the break point for Nm values <1 was 125 km. Dispersal of spores beyond 100 km was negligible. Itouga and coworkers agree that the degree of genetic differentiation within monoicous marchantialean species is correlated with dispersal distances of sperm and rates of self-fertilization. Nevertheless, the dioicous *Asterella wallichiana* (Figure 124) and monoicous *R. hemisphaerica* showed similar levels of gene flow in this study.

Figure 124. *Asterella wallichiana*, a dioicous liverwort with gene flow levels similar to those of the monoicous *Reboulia hemisphaerica*. Photo by Forestowlet, through Creative Commons.

Woodburn (1919) described the union of egg and sperm and the early developmental stages of the ensuing sporophyte. Dupler (1922b) also described the early embryogeny of *Reboulia hemisphaerica* (Figure 69-Figure 76). The embryo begins immediate development following fertilization. There is considerable variation in the development of the early embryo, with accompanying variations in habitat, archegoniophore, and other morphological variations. By winter, the sporogenous tissue is becoming differentiated. However, the sporophyte does not mature until the following May or June. Brown found *Reboulia hemisphaerica* fruiting "profusely" in a variety of places in Georgia (in the Caucasus region).

Haupt (1921b) found that the archegoniophore begins to elongate in early spring (Figure 125), about the last week of March, in Indiana, USA. The sporogenous tissue resumes development, but there is no indication at that time as to which will become spores and which elaters. By the first part of May, these cells break apart from each other, form an abundance of mucilage, and spore mother cells and elaters are clearly distinguishable.

Figure 125. *Reboulia hemisphaerica* with developing archegoniophores and dying older thalli. Photo by Štěpán Koval, with permission.

Blair (1926) describes meiosis in *Reboulia hemisphaerica* (Figure 69-Figure 76). She notes only 16 chromosomes arriving at each pole. However, several authors (Sha *et al.* 2003; Itouga *et al.* 2005) have since determined the chromosome number for *R. hemisphaerica* to be $n=9$, a typical number in liverworts.

Patidar *et al.* (1987) reported 2410 spores (Figure 126-Figure 127) per capsule in *Reboulia hemisphaerica* (Figure 69-Figure 76). Schuster (1966) earlier reported 2500 per capsule (see also O'Hanlon 1930). These large (70-80 μm) spores germinate in about five days when in suitable conditions of fairly good light and plenty of moisture (O'Hanlon 1930). They remain completely viable for at least five months.

Figure 126. *Reboulia hemisphaerica* spore SEM. Photo by William T. Doyle, with permission.

Figure 127. *Reboulia hemisphaerica* distal spore wall SEM. Photo by William T. Doyle, with permission.

Reboulia hemisphaerica (Figure 69-Figure 76) produces a tangle of white, sticky filaments (Figure 128) below the capsule (Frank 2015). These appear to aid in spore dispersal in a rather unusual way. They make a bryophyte version of masking tape. The springtail *Bourletiella hortensis* (Figure 129) peruses the capsule area and comes away with bits of the sticky filaments on its body. And to these, spores are attached. Frank suggests that not only do springtails aid dispersal through these adhered filaments, but that other animals could easily contribute as well.

Figure 128. *Reboulia hemisphaerica* archegoniophores with mature sporangia in Europe. Note the white filaments hanging below the capsules. Photo by Michael Lüth, with permission.

Figure 129. *Bourletiella hortensis*, a springtail that facilitates spore dispersal in *Reboulia hemisphaerica* by getting sticky filaments with adhering spores stuck to its body. Photo by Andy Murray, through Creative Commons.

Vishvakarma and Kaul (1987) studied the effects of such conditions as duration, quality, and intensity of light on spore germination in *Reboulia hemisphaerica* (Figure 69-Figure 76). Inoue (1960) reported that blue and red light were the most effective in promoting rhizoid development, and far-red and green caused less activity. However, germ tube development was just the opposite of rhizoid development, being relatively short in blue and red light but elongating remarkably in far-red and green.

Vishvakarma and Kaul (1988b) found that the optimum pH for both germination and thallus growth was 6, but vegetative growth occurred in the range of 3.0-7.0. Germination was more restricted at pH 5-7. Differences between germination requirements and growth tolerances could explain the absences of species in some areas where we expect them.

O'Hanlon (1930) noted that the first stage in spore germination of *Reboulia hemisphaerica* (Figure 69-Figure 76) is the emergence of a germ tube and a single rhizoid. The author provides details of subsequent cell divisions

leading up to bud formation. Rhizoids form on the ventral side of the protonema, establishing its dorsiventrality. Low intensity causes the germ tubes to be extremely long or to give rise to secondary and even tertiary germ tubes. Hartmann and Weber (1990) reviewed the literature on control of germination in this and other species of liverworts.

Vishvakarma *et al.* (1987) showed that percentage spore germination of *Reboulia hemisphaerica* (Figure 69-Figure 76) was enhanced by the addition of Mg in the liquid culture medium.

Not all bryophytes are known to produce callus tissue. Allsopp (1957) reported the first success in obtaining unlimited callus-like growth in liverworts, one of which was *Reboulia hemisphaerica* (Figure 69-Figure 76). This technique is often useful for mass producing desired chemical from bryophyte tissues.

Koevenig (1973) investigated reproductive physiology of *Reboulia hemisphaerica* (Figure 69-Figure 76). Archegoniophores elongate in late spring in Kansas. Under long days (12 hr light, 12 hr dark, or 16 hr light, 8 hr dark), pre-elongation archegoniophores elongated completely within two weeks at both 15 and 25°C. But in short days (8 hr light, 16 hr dark) no elongation occurred. Cold temperature (5°C) slowed elongation. Adding plant growth hormones (IAA, NAA, BA, GA) to heads failed to stimulate to normal lengths in short days. Koevenig suggested that perhaps the hormones could facilitate elongation but could not initiate it. (See also Szein *et al.* 1997).

Brown and Lemmon (1990) elucidated the mitotic apparatus of *Reboulia hemisphaerica* (Figure 69-Figure 76). They concluded that the mitotic apparatus in this species demonstrates a transition between algae and land plants.

Nehira and Nakagoshi (1987) reported that after removal of bryophytes in an urban environment, the same community became re-established in 1-2 years. Pleurocarpous mosses and thalloid liverworts such as *Reboulia hemisphaerica* (Figure 69-Figure 76) regenerated faster than did acrocarpous mosses. This regrowth occurred primarily in spring and autumn, but there was little seasonal variation in the amount of available airborne diaspores.

Role

Bryophytes such as *Reboulia hemisphaerica* (Figure 69-Figure 76) often serve as substrates for algae, especially diatoms (Ando 1978). These algae and other micro-organisms provide food for visiting invertebrates. But the bryophytes themselves can serve as food (Konstantinov *et al.* 2019). The flea beetle *Distigmoptera borealis* (Figure 130) was recently discovered eating *R. hemisphaerica*. Imada and Kato (2016) reported on larvae of the fly *Litoleptis* on bryophytes and described six new species, all thallus-miners of liverworts. *Litoleptis kiiensis* (Figure 131), *L. niyodoensis*, *L. himukaensis*, and *L. izuensis* are all thallus miners on *Reboulia hemisphaerica* and only that species.

Biochemistry

Reboulia hemisphaerica (Figure 69-Figure 76) was an early subject of biochemical studies. Furusawa *et al.* (2006) isolated and described structures of new cyclomylytayne and ent-chamigrane-type sesquiterpenoids from *Reboulia hemisphaerica* subsp. *australis*. Morais *et al.* (1988, 1991) described a gymnomitrane-type sesquiterpenoid and two derivatives from cultures of this species. Keserü and Nogradi (1995) reported riccardins. Warmers and König (1999, 2000) reported gymnomitrone from plants in nature and described its synthesis. Wei *et al.* (1995) described five new sesquiterpenoids and three new marchantin-type compounds and elucidated their structures. Sakai *et al.* (1999) were able to describe the synthesis (+)-cyclomylytayne-5 α -ol from *Reboulia hemisphaerica* from Taiwan.

Toyota *et al.* (1999) found and described the structure of four new sesquiterpenes from *Reboulia hemisphaerica* (Figure 69-Figure 76), as well as isolating nine compounds that were already known. Warmers and König (2000) identified the biosynthesis of the gymnomitrane-type sesquiterpene in this species.

Reboulia hemisphaerica (Figure 69-Figure 76) has chemotypes (Ludwiczuk *et al.* (2008). The researchers found two "totally different chemical compositions" in two different locations in Tokushima, Japan, whereas those from the same location had very similar chemical composition, indicating genetic isolation of the two populations. They noted that *R. hemisphaerica* has sesquiterpenoids and acetogenins.

Asakawa and Matsuda (1982) isolated riccardin C from *Reboulia hemisphaerica* (Figure 69-Figure 76) – a secondary compound that appears to be widespread among thallose liverworts. Wang *et al.* (2011a) found four new phenolic glycosides in this species in China and described their structures as rebousides. Wang *et al.* (2011b) described the configuration of isoriccardin C and riccardin D isolated from this species.

Kwon *et al.* (2019) were able to describe the entire chloroplast genome of *Reboulia hemisphaerica* with its 122,596 base pairs with 87 protein-coding genes, eight rRNAs, and 36 tRNAs. These indicated a close relationship to *Dumortiera hirsuta* (Figure 132).

Figure 132. *Dumortiera hirsuta*, a close relative of *Reboulia hemisphaerica*, based on chlorophyll DNA. Photo by Lin Kyan, with permission.

There have been at least some traditional medical uses of bryophytes (Du 1997). Sabovljević *et al.* (2016) noted that *Riccardia hemisphaerica* (Figure 69-Figure 76) is sold in Chinese markets. It has been cited numerous times related to potential medicinal uses of its compounds. Belcik and Wiegner (1980) reported good antibacterial activity in culture, reinforcing the findings of Banerjee and Sen (1979), who considered it to be one of the most active bryophytes against bacteria.

Becker (1990) pointed out the need for *in vitro* plant cultures when the desired plant product has a high price or conventional production of the plant causes problems. Liverwort culture meets the second criterion, but the science is new and although many medicinally active compounds are known, development of their commercial use is negligible. Kandpal *et al.* (2016) further noted the need for new antibiotic compounds because of the increasing evolution of antibiotic-resistant bacterial strains.

While one extract may inhibit bacteria or have other medicinal properties, a different extract solvent of the same compound(s) may exhibit no activity (Zehr 1990). Although this is a serious consideration in making ecological interpretations, it is usually not a serious problem for medicinal applications. Furthermore, effectiveness differs among bacteria species. Zehr showed that *Bacillus subtilis* (Figure 133-Figure 134) and *Escherichia coli* (Figure 135) were the most susceptible bacteria tested while *Enterococcus faecalis* (Figure 136) experienced the least inhibition.

Figure 136. *Enterococcus faecalis* SEM, a species of bacteria that is more resistant than others in study to extracts of *Reboulia hemisphaerica*. Photo from CDC, through public domain.

Following these early studies, a number of additional studies confirmed antibacterial and medicinal activity in *Reboulia hemisphaerica* (Figure 69-Figure 76) (Joshi 1995; Ko *et al.* 1995; Du 1997).

Ko *et al.* (1995) isolated marchantinquinone, from *Reboulia hemisphaerica* (Figure 69-Figure 76), a compound known to inhibit lipid peroxidation and to serve as a free radical scavenger. Liao *et al.* (2000) reported that marchantinquinone from *R. hemisphaerica* inhibited platelet aggregation and ATP release stimulated by thrombin. Harrowven *et al.* (2005) found that Riccardin C, manufactured by *Reboulia hemisphaerica* exhibited cytotoxicity against nasal epidermoid carcinoma cells in culture as well as inhibiting HIV-1 reverse transcriptase.

Asakawa (1998; 2007) cited a number of potential medical uses for *Reboulia hemisphaerica* (Figure 69-Figure 76), including treatment of blotches, external wounds, and bruises, and hemostasis. Tosun *et al.* (2016) and Chandra *et al.* (2017) expanded on this list, including uses to cure cuts, burns, wounds, bacteriosis, pulmonary tuberculosis, neurasthenia, fractures, convulsions, scalds, uropathy, inflammation, fever, and pneumonia. Tosun *et al.* (2016) further elaborated on the specific means of wound healing. Önder and Özenoğlu (2019) found that extracts of *R. hemisphaerica* were effective against three different cancer cell lines.

A variety of potential uses emerged in laboratory cultures of *Reboulia hemisphaerica* (Figure 69-Figure 76) (Gao *et al.* 2009; Asakawa 2013; Tosun *et al.* 2013). Harada *et al.* (2013) reported its potential for the treatment of cardio-vascular diseases, including arteriosclerosis. Even pet treatments are possible, with *R. hemisphaerica* inhibiting carrageenan-induced paw edema (Tosun *et al.* 2013).

Kandpal *et al.* (2016) found the extract of *R. hemisphaerica* (Figure 69-Figure 76) to be the most effective bryophyte species tested against *Escherichia coli* (Figure 135), *Bacillus cereus* (Figure 137), and *Pseudomonas aeruginosa* (Figure 138). The researchers found a correlation between total phenol and flavonoid contents and the antioxidant activity.

Summary

The Aytoniaceae does not have members that are typically submersed, but several species are at least tolerant of being constantly wet from water spray or other source of water. Their habitats include waterfall spray, streamside, dripping cliffs and ledges, wet soil and wind holes, but also various substrata in mesic forests. The latter habitat provides cool, moist air that permits Arctic species to survive in temperate regions. On the other hand, many of these species occur in the mountains, especially in Macaronesia.

The members of Aytoniaceae included here tend to endure a wide range of habitats, including a wide range of moisture conditions. They have air spaces that permit CO₂ exchange and rhizoids and scales that facilitate water uptake. Sexual condition varies, even within a species, but no gemmae or other specialized asexual reproductive structures are present. Most of the species die from the posterior end after fertilization, but grow from the apex.

Acknowledgments

Lars Söderström helped me find the current acceptable names for taxa. Bryonettors helped me find images of wind holes.

CHAPTER 1-20

AQUATIC AND WET MARCHANTIOPHYTA, CLASS MARCHANTIOPSIDA: CONOCEPHALACEAE, PART 1

Figure 1. *Conocephalum conicum* s.l. habitat on emergent rock. Photo from <www.aphotofauna.com>, with permission.

Conocephalaceae

Conocephalum conicum (Figure 1-Figure 11)

Recently, genetic determinations and usable morphological characters have led to the division of *Conocephalum conicum* (Figure 1-Figure 2-Figure 11) into several species (Szweykowski *et al.* 2005; Akiyama 2022). Therefore, one must read the research attributed to this species with caution because it might actually refer to

Conocephalum salebrosum (Figure 12-Figure 13) in North America, or several species in Japan. When I can't be sure which species it is, I shall denote the species as *Conocephalum conicum* s.l. (the abbreviation s.l. refers to *sensu lato* and means in the broad sense; s.s. refers to *sensu stricto* and means in the narrow sense) (Figure 1-Figure 2-Figure 11).

Conocephalum conicum s.s. (Figure 1-Figure 11) is a smaller plant than *C. salebrosum* (Figure 12); *C. salebrosum* plants are dull, with more conspicuous thallus grooves that are more conspicuous than the air pores (Figure 13) (Stotler & Crandall-Stotler 2017).

Distribution

Sérgio *et al.* (2011) surmised that *Conocephalum salebrosum* (Figure 12-Figure 13) has a more scattered and wider distribution than does *C. conicum* (Figure 1-Figure 11). Stotler and Crandall-Stotler (2017) concluded that *Conocephalum conicum* does not occur in North America and that all of the specimens previously identified as *C. conicum* are instead aligned with *C. salebrosum*. In Russia Borovichev *et al.* (2009) found *C. conicum* to be more widespread than *C. salebrosum*. The overall distribution of *C. conicum* appears to be restricted to Europe. The photos below illustrate its presence in a number of European countries (Figure 14-Figure 18).

Aquatic and Wet Habitats

Borovichev *et al.* (2009) found that *Conocephalum conicum* (Figure 1-Figure 11) and *C. salebrosum* (Figure 12-Figure 13) have similar ecological preferences and that they can even grow intermingled (Figure 19). Both form extensive mats on streambanks and at the bases of moist rocks and cliffs. *Conocephalum conicum* tends to be more hygrophytic than *C. salebrosum*. Both species seem to specialize in colonizing spring and river micro-habitats close to running or standing water. The photographs below illustrate some of the habitats where *Conocephalum conicum* has been found in Europe (Figure 20-Figure 22).

Figure 19. *Conocephalum conicum* (left) and *C. salebrosum* (right). Photo courtesy of Michael Lüth.

Conocephalum conicum s.l. (Figure 1-Figure 11) occurs in wet places around lakes, especially in shade in Scotland (West 1910); in ground, rock, spring, and water communities associated with streams near Lacko, Western Carpathians (Mamczarz 1970); in association with the River Wear, England (Birch *et al.* 1988); associated with rivers (Ferreira *et al.* 2008). Its habitat seems to be primarily from rivers, streams, and stream banks (Figure 26). Nevertheless, it occurs often on rocky walls above streams (Figure 20) and in caves (Figure 21-Figure 22).

Figure 20. *Conocephalum conicum* growth habit on wall s.l. Photo by Allen Norcross, with permission.

Figure 22. *Conocephalum conicum* in wet, limestone cave, Traeth Glaslyn Nature Reserve, Wales. Photo by Janice Glime.

There are many reports of *Conocephalum conicum* (Figure 1-Figure 11) from streams and rivers. It is among the commonest species in English and Welsh rivers (Scarlett & O'Hare 2006). It is among the most common bryophytes in the River Tweed, UK (Holmes & Whitton 1975) and occurs throughout the River Swale, Yorkshire, UK (Holmes & Whitton 1977b). In the River Tyne, UK, it occurs mostly in mid to lower reaches (Holmes & Whitton 1981). It is part of the *Platyhypnidium-Fontinalis antipyretica* (Figure 23-Figure 24) association in Thuringia, Germany (Marstaller 1987). It occurs both in the Iskur River, Bulgaria, and its main tributaries (Papp *et al.* 2006). In Greece it is common in streams (Papp 1998). It occurs on moist stones and rocks in the streambed (Figure 1, Figure 25) in streams of Gory Stolowe Mountains, Poland (Szweykowski 1951). It is also found in mountain streams of northwestern Portugal (Vieira *et al.* 2005) and in mountainous streams on Madeira Island (Luis *et al.* 2015).

Stream and River Banks

Conocephalum conicum (Figure 1-Figure 11) is able to live on banks with frequent submergence (Figure 26) and slow water, usually on rocks just above water (Figure 27-Figure 31) (Watson 1919). It occurs in a zone above *Cratoneuron filicinum* (Figure 32-Figure 33), up to 0.9 m above the water (Gimingham & Birse 1957). Holmes and Whitton (1977a) found it on the river bank of the River Tees, UK.

Figure 33. *Cratoneuron filicinum*, a species that lives in a zone closer to the water than that of *Conocephalum conicum* s.l. Photo by Tigrente, through Creative Commons.

Luis *et al.* (2008) reported *Conocephalum conicum* s.s. (Figure 1-Figure 11) along the lower reaches of Ribeira Brava in Madeira in disturbed areas dominated by the great

reed *Arundo donax* (Figure 34). It was associated there with the mosses *Bryum dichotomum* (Figure 35), *Pohlia melanodon* (Figure 36), *Ptychostomum capillare* (Figure 37), and *Scorpiurium circinatum* (Figure 38-Figure 39) and the liverwort *Lunularia cruciata* (Figure 40).

Springs

There seem to be few reports of *Conocephalum conicum* (Figure 1-Figure 11) in or around springs. It is known at a spring in the Tara river canyon and Durmitor area, Montenegro (Papp & Erzberger 2011).

Waterfalls

Watson (1919) reported *Conocephalum conicum* (Figure 1-Figure 11) from waterfalls, but others don't seem to attribute it to this habitat. This is often a lack of detail in reporting, with the splash zone of a waterfall included with "streambank."

Non-Aquatic Habitats

Although *Conocephalum conicum* (Figure 1-Figure 11) is usually associated closely with water, it can be found on slopes (Figure 41), perhaps getting water from seepage, or occurring on canyon walls where it is shaded and humid (Figure 42).

Figure 41. *Conocephalum conicum* s.l. habitat. Photo by Michael Lüth, with permission.

Figure 42. *Conocephalum conicum* s.l. on rock of stream canyon. Photo by Michael Lüth, with permission.

Physiology

Conocephalum conicum (Figure 1-Figure 11) is more easily stressed by **desiccation** than its sibling species *C. salebrosum* (Figure 12-Figure 13) (Szweykowski *et al.* 2005; Borovichev *et al.* 2009). This explains its more aquatic habitats.

Like *C. salebrosum*, *C. conicum* (Figure 1-Figure 11) has scales (Figure 43-Figure 44) and rhizoids (Figure 45-Figure 46) that provide **capillary spaces** on the ventral surface. We can assume that like the case of *C. salebrosum*, water moves through these spaces along the thallus and is delivered to all points on the thallus where it is taken in and distributed.

Figure 43. *Conocephalum conicum* s.l. from Italy showing scales on the ventral thallus surface. Photo courtesy of Anna di Palma.

Figure 44. *Conocephalum conicum* s.l. ventral scale that aids in movement of water across the ventral side of thallus. Photo by Ralf Wagner at <www.dr-ralf-wagner.de>, with permission.

Figure 45. *Conocephalum conicum* s.l. thallus with rhizoids and thallus; rhizoids help to move water across the ventral side of the thallus and facilitate uptake. Photo by Ralf Wagner at <www.dr-ralf-wagner.de>, with permission.

Figure 46. *Conocephalum conicum* rhizoids showing the capillary spaces where they are massed. Photo by Paul Davison, with permission.

The shade habitat of *Conocephalum conicum* s.l. (Figure 1-Figure 11) is supported by its reaction to supplemented **UV-B radiation** (Ihle & Laasch 1995; Ihle 1997). This radiation causes a drastic decrease in the reaction center proteins D1 and D2 as well as the outer light-harvesting antenna. Streptomycin inhibited the repair process of PS II, indicating that only chloroplastic protein synthesis is needed for recovery. A specimen from India suggests that under the right conditions this species can produce protective pigments (Figure 47).

Figure 47. *Conocephalum conicum* from India showing brown pigmentation. Photo courtesy of Muhammet Ören.

At the other end of the light intensity range, **low light** causes **etiolation**. Ken Adams (pers. comm.) demonstrated this by growing *Conocephalum conicum* in the dark (Figure 48).

Figure 48. *Conocephalum conicum* etiolation (3 weeks in dark). Photo by Ken Adams, with permission.

The **pH** seems to be important in the distribution of *Conocephalum*, but most reports of preference can only be applied to *Conocephalum conicum* s.l. (Figure 1-Figure 11). Trębacz (1992) found that pH is also important within the cells of *Conocephalum conicum* s.l. It responds to the onset of **light** by decreasing its internal pH by about 0.15 units, followed by a slow increase. Respiration also can exhibit up to a 100% increase in response to excitation, but

the pH seems not to be involved. Dziubińska *et al.* (1989) found that cutting the thallus or providing an electrical stimulus elicited a transient rise in the rate of respiration. If the stimulation fails to produce any excitation, the respiration does not increase. The differences in response depend on the character of the excitation and the area of the thallus stimulated. Erdtmann and Mueller Stoll (1983) investigated the relationship between respiration and regeneration in *Conocephalum conicum* s.l.

Trębacz and Fensom (1989) found that in *Conocephalum conicum* s.l. (Figure 1-Figure 11) labelled carbon travelled cell to cell at a rate of $\sim 2.0\text{--}1.7\ \mu\text{m}\ \text{s}^{-1}$, a rate that is the same as that of cytoplasmic streaming. **Photosynthesis** occurs in the thallus cells (Figure 49); CO_2 is obtained from the air through the pores on the thallus surface (Figure 50-Figure 51) and oxygen is released there. Below these openings are chambers with chlorophyllous cells where photosynthesis occurs (Figure 51). Starch can be stored in the cells and can be densely clumped in the stalk portion of the archegoniophore (Figure 52).

Figure 49. *Conocephalum conicum* photosynthetic cells in thallus. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Figure 50. *Conocephalum conicum* s.l. showing pore openings on the thallus surface in the UK. Photo by Dick Haaksma, with permission.

Figure 52. *Conocephalum conicum* s.l. archegoniophore stalk section showing stained dense starch grains. Photo from Botany Website, UBC, with permission.

In addition to whatever benefit may be derived from neighbors, *Conocephalum conicum* s.l. (Figure 1-Figure 11) has anatomical adaptations that may permit it to live where it can become inundated with water. The **air pores** (Figure 50), which are quite large in this genus, have hydrophobic cuticular ridges (Figure 51) surrounding them (Schönherr & Ziegler 1975). This allows only liquids with a contact angle of zero degrees with the ledges to enter the air pore. This presumably permits the internal air chambers of the species to maintain the air space needed to obtain CO_2 . One would assume that this is necessary for rapid recovery once the water recedes and to allow continued photosynthesis when kept wet on the exterior by splash.

Dilks and Proctor (1975) found that *Conocephalum conicum* s.l. (Figure 1-Figure 11) was killed by **rapid cooling** to -5°C , whereas many of the bryophytes tested could withstand such rapid cooling. Nevertheless, it certainly can survive freezing temperatures in caves, where the temperature is not likely to drop suddenly (Figure 53). Dilks and Proctor surmised that the ability to survive long periods at low temperatures, as exhibited by many species, seems to relate to desiccation resistance.

Figure 53. *Conocephalum conicum* s.l. on wet cave roof with ice. Photo by Allen Norcross, with permission.

Krol *et al.* (2003) found that *Conocephalum conicum* (Figure 1-Figure 11) s.l. exhibits all-or-none action potentials in response to **sudden temperature drops**. Calcium is important in these potentials, with its inhibition or decrease resulting in the inhibition of voltage transients. The researchers concluded that the temperature drop causes a change in membrane potential due to calcium influx from both internal and external stores.

Conocephalum conicum s.l. (Figure 1-Figure 11) produces **Heat Shock Protein 70** in response to atmospheric pollution (Basile *et al.* 2013). The **heavy metals** accumulate in cell walls, accompanied by a strong increment in the Heat Shock Protein 70. Cadmium and lead accumulate in the parenchyma and are absorbed to cell walls or concentrated in vacuoles. The pollutants result in severe alterations to the organelles. The researchers concluded that *C. conicum* s.l. is tolerant of heavy metals and can serve as a bioindicator (see also Maresca *et al.* 2020). Nevertheless, Iqbal *et al.* (2011b) expressed concern that it was threatened by changes in the environment in Bhaderwah as well as in the Kumaon Himalaya.

Trębacz *et al.* (1994) compared the activities of Ca^{2+} , K^+ , Cl^- , and NO_3^- in *Conocephalum conicum* (Figure 1-Figure 11). The free cytosolic Ca^{2+} did not exhibit any light-dependent changes when no action potential was triggered. However, action potentials typically caused a 2-fold increase in free cytoplasmic Ca^{2+} concentration. Action potentials cause little change in K^+ activity. For both Cl^- and NO_3^- the vacuolar activity was 5 to 6 times that of the cytoplasmic activity. Changes in illumination had little effect on the concentrations of the two ions.

Samecka-Cymerman *et al.* (1997) found that the ecological differentiation between the liverwort species *Conocephalum conicum* (Figure 1-Figure 11), *Marchantia polymorpha* (Figure 54), and *Pellia epiphylla* (Figure 55) correlates closely with the soil chemistry. They found a high correlation between the soil concentrations of heavy metals as well as macroelements and the thalli of these liverworts. *Conocephalum conicum* s.l. proved to be a good biomonitor of chromium and cobalt.

Figure 54. *Marchantia polymorpha* with gemmae cups. Photo by Hermann Schachner, through Creative Commons.

Figure 55. *Pellia epiphylla*, a species of similar locations near stream water, but differs in soil chemistry from that of *Conocephalum conicum*. Photo by Hermann Schachner, with permission.

Adaptations

Gimingham and Birse (1957) concluded that thalloid mats such as those in *Conocephalum* occur at the most moist end of the spectrum. *Conocephalum conicum* s.l. (Figure 1-Figure 11) often occurs in **association** with other liverworts, such as *Chiloscyphus kashyapii*, *Dumortiera hirsuta* (Figure 56), *Marchantia* spp. (Figure 54), *Pellia endiviifolia* (Figure 57), *Preissia quadrata* (Figure 58), *Reboulia hemispherica* (Figure 59), and occasionally with *Aneura pinguis* (Figure 60), *Clevea hyalina* (Figure 61), *Mannia triandra* (Figure 62), and as well as the mosses *Myurella sibirica* (Figure 63) and *Thuidium delicatulum* (Figure 64) (Iqbal *et al.* 2011a). *Conocephalum conicum* is also associated with fungi, ferns, flowering plants, and even insects. These associations might prove to be beneficial, perhaps by maintaining moisture or in helping the liverworts to obtain it. They could also result in competition.

Levine (1999) explored the "indirect facilitation" in a riparian community where *Conocephalum conicum* s.l. (Figure 1-Figure 11) (see Shevock *et al.* 2021) was a member. "Indirect facilitation occurs when the indirect positive effect of one species on another, via the suppression of a shared competitor, is stronger than the direct competitive effect." In a northern California, USA, riparian community, Levine conducted field experiments. Using a factorial design, he found three qualitatively different interactions between *Carex nudata* (Figure 65) and three target species. The *Carex* facilitated *Conocephalum conicum* s.l. in the presence of *Mimulus guttatus* (Figure 66) by suppressing the latter. On the other hand, when *M. guttatus* was absent, *Carex nudata* was a competitor with *Conocephalum conicum* s.l.

Reproduction

Conocephalum conicum s.l. (Figure 1-Figure 11) has been of interest to bryologists in a number of studies related to reproduction. However, some of these have been done in North America, so I must assume they actually refer to *Conocephalum salebrosum* (Figure 12-Figure 13). Thus, I have discussed them under that species in the next subchapter.

One of the mechanisms of spread of *Conocephalum* species is its ability to **overwinter** and produce new growth in spring. The overwintering buds are protected by scales (Figure 67-Figure 69). But young plants (Figure 70-Figure 71) also arise with no apparent connection to plants from a previous year.

Figure 67. *Conocephalum conicum* s.l. overwintering bud scales. Photo from Botany Website, UBC, with permission.

Figure 68. *Conocephalum conicum* s.l. with scales covering winter buds. Photo by Allen Norcross, with permission.

Figure 71. *Conocephalum conicum* s.l. young plants. Photo by Dick Haaksma, with permission.

Benson-Evans (1964) found that *Conocephalum conicum* s.l. (Figure 1-Figure 11) from Wales grew best and produced **gametangia** (Figure 72-Figure 75) at 21°C, but not at 10°C. It grew and produced gametangia best in long days (18 hours), but not in short days (6 hours).

Figure 74. *Conocephalum conicum* s.l. males with mature antheridial receptacles, Nichinan, Japan, June 1983. Photo by Janice Glime.

Yamazaki (1981) discovered that even within a population of *Conocephalum conicum* (Figure 1-Figure 11) the **genetic variation** was abundant, a condition that suggests that sexual reproduction predominates in the natural populations. It is not unusual to see reproductive populations (Figure 76-Figure 78), and for the most part

bryologists have not reported asexual structures. Since *C. conicum* can grow together with *C. salebrosum* (Figure 12-Figure 13), it is possible that some of the variation Yamazaki observed was really that of what we now consider to be two species.

Figure 78. *Conocephalum conicum* s.l. sporangia ready to release spores. Photo from Botany Website, UBC, with permission.

More recently, **tubers** have been verified on *Conocephalum conicum* s.l. (Figure 1-Figure 11) in Sussex, England (Paton 1993). These were found so uncommonly that their presence was often omitted from descriptions of the species. They may, however, be more common than assumed because they are located on **moribund** (in terminal decline; lacking vitality or vigor; Figure 79) thalli – a part of the plant often overlooked or discarded in the preparation of specimens. Furthermore, they are on the ventral surface, hidden among the rhizoids. Nevertheless, when they become detached, they germinate to produce a new thallus.

Figure 79. *Conocephalum* cf. *salebrosum* dead and new growth on population at Hocking Hills, Ohio, USA. It is on the ventral side of such moribund tissues where tubers have been found in *Conocephalum conicum* s.l. Photo by Janice Glime.

Bhagat *et al.* (2012) suggested that sexual reproduction is a less important means of reproduction in *Conocephalum* than is asexual reproduction. They based this on the relatively constant ratio of spores to elaters (Figure 80) (0.40-0.43:1) over the past 54 years, a ratio that is much lower than that known in other **Marchantiales**.

Figure 80. *Conocephalum conicum* s.l. spores and elaters at maturity. Photo from Botany Website, UBC, with permission.

Fungal Interactions

Carré and Harrison (1961) reported a species of *Pythium* (Figure 81), a parasitic fungus, invading *Conocephalum conicum* s.l. (Figure 1-Figure 11). This endophyte invades the rhizoids (Figure 82) and then the thallus, but is limited to the area adjoining the midrib. A species of *Pythium* was consistently isolated from infected rhizoids and thalli. Other fungal species were in cultures with sterile thalli, but none was able to form the typical **vesicular-arbuscular** (Figure 83) condition. Some were, however, able to penetrate the rhizoids and lower cells of the thallus.

Figure 83. **Vesicular arbuscular mycorrhizae** in root cells, showing the form that might also show up in the thallus of *Conocephalum conicum*. Photo by Rit Rajarshi, through Creative Commons.

Ligrone and Lopes (1989) reported a highly branched fungus that colonizes the smooth-walled rhizoids (Figure 82) of *Conocephalum conicum* s.l. (Figure 1-Figure 11). The fungus is able to enter the thallus through these rhizoids to the parenchyma of the midrib, where it is entirely intracellular. The fungus forms vesicles (see Figure 83) in the rhizoids and a few ventral layers of the parenchyma cells. The fungal hyphae spread from cell to cell. More internal cells have prominent arbuscules (Figure 83) formed by the infecting hyphae. The infected host cells experience proliferation of the ribosomes, plastids, and mitochondria. The arbuscules ultimately degenerate, leaving clumps of collapsed hyphae, and these cells have not been observed to become reinfected.

Later, Ligrone *et al.* (2007) reported **Glomeromycotean** associates in liverworts. *Glomus mosseae* (Figure 84) was identified in axenic thalli of both *Conocephalum conicum* (Figure 1-Figure 11) and *C. salebrosum* (Figure 12-Figure 13) and produced an association with these liverworts similar to that seen in the wild. These fungi suppressed cell wall autofluorescence in Marchantialean liverworts and triggered the deposition of a

new wall layer that specifically bound the monoclonal antibody CCRC-M1 against fucosylated side groups associated with xyloglucan and rhamnogalacturonan I.

Figure 84. *Glomus mosseae* spores cultured with tomato root. Photo by Samson90, through Creative Commons.

Nevertheless, *Conocephalum conicum* s.l. (Figure 1-Figure 11) exhibited some antifungal activity. Asakawa (2007) reported antimicrobial, antifungal, antipyretic, and antidotal activity from *Conocephalum conicum* s.l.. It can be used to cure cuts, burns, scalds, fractures, swollen tissue, poisonous snake bites, and gallstones. We don't know which cryptospecies was used in the study.

Animal Interactions

Imada *et al.* (2011) found that there are ~25 East Asian endemic members of the micropterigid moths (Figure 85) that occur exclusively on *Conocephalum* (Figure 1-Figure 11, Figure 86). These moth species are separated by geographical isolation. It would be interesting to know if these moth species have any correlations with the chemical differences among cryptospecies of this liverwort.

Biochemistry

Conocephalum conicum s.l. (Figure 1-Figure 11) has had more than its share of biochemical analyses. Only a few are included here. Unfortunately, most of these predate the breakup of the species into multiple species and cryptospecies.

Markham *et al.* (1976) found that flavonoids differed between a German sample and one from the USA. This difference might be the forerunner of our understanding that the North American populations are actually *Conocephalum salebrosum* (Figure 12-Figure 13). They also found that the flavonoids they identified did not change qualitatively with seasonal changes. Using 280 samples, Toyota *et al.* (1997) compared three chemotypes of *Conocephalum conicum* s.l. (Figure 1-Figure 11).

Ludwiczuk *et al.* (2013) identified cryptic species in *Conocephalum conicum* s.l. using volatile components. Using 13 samples, they identified four cryptic species of *C. conicum* and the species *C. salebrosum* (Figure 12-Figure 13). The chemical differences correlated with the geographic distribution of the samples.

Ghani *et al.* (2016) used Japanese material of Type-II *Conocephalum conicum* s.l. (Figure 1-Figure 11) to release a phenyl propanoid, trans-methyl cinnamate as a stress response. Although they used it to show that this type had this compound, only previously known from Type III, it is interesting ecologically to know that phenyl compounds can be released in response to stress. Are these similar to the herbivory responses known from many tree leaves?

Asakawa and Takemoto (1979) identified tulipinolide as the compound causing the pungency one can sense in the female gametophyte of *Conocephalum conicum* s.l. (Figure 1-Figure 11); the compound and the smell are absent in the males. The guaianolides were inhibitory toward germination and growth of roots of rice in the husk.

Castaldo-Cobianchi *et al.* (1988) reported antibiotic activity in *Conocephalum conicum* s.l. (Figure 1-Figure 11) against both Gram+ and Gram- bacteria.

Odrzykoski and Szweykowski (1991) described three new sesquiterpenoids from *Conocephalum conicum* s.l. (Figure 1-Figure 11). They found that the compounds varied in their cytotoxicity, but that they could exert immunosuppressive effects on rat splenocytes at lesser concentrations than those that were toxic. Melching and König (1999) identified three new sesquiterpenes from *Conocephalum conicum* s.l. in Germany.

Lu *et al.* (2006) identified four new monoterpene esters and elucidated a number of known compounds in *Conocephalum conicum* s.l. (Figure 1-Figure 11). Two compounds were moderately cytotoxic to human HepG2 cells and one of these also exhibited antibacterial activity against *Pseudomonas aeruginosa* (Figure 87).

Figure 87. *Pseudomonas aeruginosa*, a bacterium that is inhibited by compounds from *Conocephalum conicum* s.l. Photo from CDC, through public domain.

Himanshu *et al.* (2007) tested several bryophytes, including *Conocephalum conicum* s.l. (Figure 1-Figure 11) for activity against the human pathogens *Escherichia coli* (Figure 88) and *Salmonella typhi* (Figure 89) and two fungi, *Aspergillus niger* (Figure 90), *Candida albicans* (Figure 91). None of the water-soluble extracts was effective on the pathogens. However, the acetone-soluble extract was inhibitory against all the pathogens. *Candida albicans* was strongly inhibited by the extract from *Conocephalum conicum* s.l.

Figure 91. *Candida albicans* pseudohyphae in a fresh and unstained urine sediment. Photo from Controllab, through Creative Commons.

Ivković *et al.* (2021) found that methanol extracts of terpenes, oils, sugars and bis-bibenzylys were absent in *Conocephalum conicum* s.l. (Figure 1-Figure 11), whereas these are present in both *Marchantia polymorpha* (Figure 54) and *Pellia endiviifolia* (Figure 57).

Negi *et al.* (2020) found that *Conocephalum conicum* s.l. (Figure 1-Figure 11) acetone extracts were active against *Aspergillus flavus* (Figure 92) and *A. parasiticus* (Figure 93-Figure 94), with the highest activity coming from populations collected at Mukteshwar (2100 m asl). Negi and Chaturvedi (2021) further evaluated the usefulness of *Conocephalum conicum* s.l. and found that methanol extracts were highly effective against the fungal wilt disease caused by *Fusarium oxysporum* f. *lycopersici* (Figure 95-Figure 96), a disease that makes it unprofitable to grow tomatoes in the tropics. Since *C. conicum* is an "efficient" source of the Riccardin C that is active in inhibiting the fungi on tomatoes, it could be an eco-friendly alternative to the more conventional fungicides.

***Conocephalum orientalis* (Figure 97-Figure 100)**

In 1994, Akiyama and Hiraoka (1994a, b) noted allozyme variation in the *Conocephalum* in Japan. This

led to later studies on the differences among the Japanese forms. In 2022 Akiyama has published several new species, some of which occur in wet habitats.

One of these new species is *Conocephalum orientalis* (Figure 97-Figure 100), a segregate of *C. conicum* (Figure 1-Figure 11) previously known as J type (Figure 97) (Akiyama 2022). The thallus of *Conocephalum orientalis* is shiny and light green (Figure 98-Figure 99), but becomes yellowish when growing in the shade; the air chambers (visible as polygons at the surface) increase in size toward the center of the thallus (Figure 100) The grooves are deep (Figure 101-Figure 102), like those of *C. salebrosum* (Figure 97). It forms the largest plant bodies of any *Conocephalum* species in Japan.

Figure 99. *Conocephalum orientalis* showing thallus grooves and pores. Photo courtesy of Hiroyuki Akiyama.

Figure 100. *Conocephalum orientalis* showing thallus grooves and pores, with polygons larger toward the center. Photo courtesy of Hiroyuki Akiyama.

Thallus variation occurs within as well as between populations of *Conocephalum orientalis* (Figure 97-Figure 100) (Akiyama 2022). These can include differences in thallus size (Figure 101), degree of purplish pigments on ventral surface (Figure 102-Figure 104), wavy margins (type J2; Figure 105), and blackish thallus grooves (type J3; Figure 106-Figure 109).

Figure 109. *Conocephalum orientale* type J3 with purplish ventral side and dark grooves. Photo courtesy of Hiroyuki Akiyama.

Although the separation of the species names is new, some natives of Japan have distinguished them for some time (Akiyama 2022). The plants now known as *Conocephalum orientale* (Figure 97-Figure 100) are heated in oil and eaten like potato chips. The distinctive aroma is lost during heating. They taste similar to the dried seaweed **nori** (Figure 110).

Figure 110. Nori, a red alga used to wrap sushi; fried *Conocephalum orientale* tastes much like this alga. Photo by Kropsoq, through Creative Commons.

Distribution

Conocephalum orientale (Figure 97-Figure 100) is described as a segregate of *C. salebrosum* (Figure 111), another recent segregate from *C. conicum* (Akiyama 2022). *Conocephalum orientale* is known from Japan and Taiwan, where it is the largest of the Japanese species and is the *Conocephalum* species most likely to be encountered on stream banks.

Figure 111. *Conocephalum salebrosum* from Japan. Photo courtesy of Hiroyuki Akiyama.

Aquatic and Wet Habitats

Conocephalum orientale (Figure 97-Figure 100) forms large plants on streamsides (Figure 112) (Akiyama 2022). It occurs in slightly shaded places along streams and seepage slopes along forest trails.

Figure 112. *Conocephalum orientalis* on rock. Photo courtesy of Hiroyuki Akiyama.

Conocephalum orientalis (Figure 97-Figure 100) avoids rock surfaces with no soil, except where there is an extreme amount of rainfall (Akiyama 2022). It becomes quite succulent in areas with good moisture conditions. By contrast, populations in direct sunlight, such as concrete retaining walls along sunlit roadways, can become hard and yellowish. The J2 type becomes very thick with wavy margins in dry conditions (Figure 113). The J3 type is more common in mountain areas such as Hokkaido; these thalli can be orange to purplish on the ventral side, even in summer (Figure 114), most likely a response to higher UV light. Thalli in these mountainous areas are also larger than the streamside populations of lower elevations.

Figure 113. *Conocephalum orientalis* type J2 with wavy margin. Photo courtesy of Hiroyuki Akiyama.

Figure 114. *Conocephalum orientalis* type J3 showing variation in orange to purplish ventral side. Photo courtesy of Hiroyuki Akiyama.

Physiology

Although there has not been time for separate physiological studies to be done on the newly named species *Conocephalum orientalis*, we can infer some of its physiology from its structures and their known functions in other members of the *C. conicum* species complex. In other cases, Akiyama (2022) was able to link earlier studies with the new species through voucher specimens.

The color of *Conocephalum orientalis* (Figure 97-Figure 100) also changes with the seasons. The thallus is pale green in spring through autumn (see Figure 115), although there is a pale reddish purple coloration at the basal part of the midrib. In the shade the thallus can become dark green (Figure 116). However, in late autumn and through winter, the entire under surface becomes reddish purple.

Figure 115. *Conocephalum orientalis* pale color at one location in the sun. Photo courtesy of Hiroyuki Akiyama.

Figure 116. *Conocephalum orientalis* dark color at one location in the shade. Photo courtesy of Hiroyuki Akiyama.

Akiyama (2022) found that plants of *Conocephalum orientalis* (Figure 97-Figure 100) grown in good moisture conditions become succulent and have clear slimy contents of polysaccharides flowing from the cut across mucilage canals (Figure 117). But it often lacks mucilage cells, suggesting that it is best adapted for a wet habitat (Akiyama 2022). It does, however, have abundant rhizoids (Figure 118-Figure 119) that form capillary spaces suitable for movement of water. We can surmise that its rhizoids and scales (Figure 118-Figure 119) move water along the ventral surface, as in other *Conocephalum* species, facilitating the uptake of water. In addition, it often has symbiotic fungi that can help in obtaining nutrients.

Figure 117. *Conocephalum orientalis* from Japan showing leak of mucilage from cross section of mucilage canals. Photo courtesy of Hiroyuki Akiyama.

Figure 118. *Conocephalum orientalis* from Taiwan, ventral side showing rhizoids. Photo courtesy of Hiroyuki Akiyama.

Figure 119. *Conocephalum orientalis* type J3 rhizoids and purplish ventral side. Photo courtesy of Hiroyuki Akiyama.

Adaptations

Plants of *Conocephalum orientalis* (Figure 97-Figure 100) seem to be quite plastic in nature. When plants grow in darker places, such as the entrance of a cave, thalli become very thin and yellowish (Figure 120), resembling Japanese forms of *C. salebrosum* (Akiyama 2022). Hard, leathery thalli can form in the sun, accompanied by dense ventral scales (Figure 119); their appendages are large and strongly colored reddish purple, a color that is also seen on the upper side of the thalli. These population differences can relate to altitude and shading, but the differences seem not to be linked to any genetic differences.

Figure 120. *Conocephalum orientalis* thin thalli produced under diffuse light. Photo courtesy of Hiroyuki Akiyama.

Akiyama (2022) described the thallus of *Conocephalum orientalis* (Figure 97-Figure 100) as having a light green ventral surface (Figure 118). However, this becomes reddish purple toward late autumn. This is a pattern seen in other bryophytes, including *Sphagnum* (Figure 121) species, presumably in response to the greater light intensity due to loss of canopy leaves, and to the cold nights. The cold nights and warm days are also responsible for the red colors seen on trees in the autumn (Kyne & Diver 2012).

Figure 121. *Sphagnum capillifolium* showing a color transition from green to red. Photo by Bernd Haynold, through Creative Commons.

Akiyama (2022) noticed that smaller plants of *Conocephalum orientalis* (Figure 97-Figure 100) tended to be the most common along the lower elevation streams, whereas at higher elevations they were larger, more "normal" plants.

Reproduction

Conocephalum orientalis (Figure 97-Figure 100) is **dioicous** (Figure 125-Figure 128) and **perennial** (Akiyama 2022). The antheridia appear as clusters in antheridial receptacles on the upper surface of the thallus at the tips of the thallus branches (Figure 122-Figure 124). In the spring, these receptacles appear at tips of newly formed lobes. These antheridial receptacles may appear on stalks created by the midrib because the thallus tissue ceases growth when the receptacle forms (Figure 125). These stalks differ from those of *Marchantia* in which the thallus folds and encloses the rhizoids.

Figure 122. *Conocephalum orientalis* male with antheridial receptacles. Photo courtesy of Hiroyuki Akiyama.

Figure 123. *Conocephalum orientalis* male with immature antheridial receptacle. Photo courtesy of Hiroyuki Akiyama.

Figure 124. *Conocephalum orientalis* male showing antheridial receptacle. Photo courtesy of Hiroyuki Akiyama.

Figure 125. *Conocephalum orientalis* male with stalked thallus, a condition that can sometimes be seen in new growth. Photo courtesy of Hiroyuki Akiyama.

Shimamura *et al.* (2008) described the dispersal of sperm (Figure 126) in *Conocephalum conicum* (Figure 1-Figure 11), providing photographs of their discovery in Japan. Shimamura now considers that the species is probably the newly described *Conocephalum orientalis* (Figure 97-Figure 100). Shimamura and coworkers found that as the sperm were discharged, they became airborne (Figure 126), a phenomenon they were able to verify in the field. They postulated that this explosive behavior, along with the elevated receptacles, would increase the efficiency of fertilization in this (and probably many other) liverwort species, particularly in a drought environment.

Figure 126. *Conocephalum orientalis* explosive sperm dispersal. Photo courtesy of Masaki Shimamura.

The archegonial heads begin growing near the growing tips (Figure 127). At maturity the archegonial heads are large and are perched on a stalk (Figure 128) up to 9 cm tall (Akiyama 2022).

Figure 127. *Conocephalum orientalis* with young archegoniophore. Photo courtesy of Hiroyuki Akiyama.

Figure 128. *Conocephalum orientalis* with mature archegoniophore. Photo courtesy of Hiroyuki Akiyama.

Conocephalum orientalis (Figure 97-Figure 100) produces spores that may be dispersed while small, or they may remain in the capsule, dividing into **endosporic** sporelings (Akiyama 2022). Spore germinability is 40-100% among the smaller spores. The remaining spores

divide within the spore walls (Figure 129) while still in the sporangium, thus increasing the number of chloroplasts. These larger spores lose their germinability within 30 days under room conditions (Inoue 1966 in Akiyama 2022). Such a two-size strategy permits immediate long distance dispersal of small spores, whereas the larger, short-lived spores have a size advantage that permits them to get a rapid start near the location of their parents. Spore sizes range 65-130 μm in longer diameter (Akiyama 2022).

Figure 129. *Conocephalum conicum* s.l. multicellular spores and elaters. Photo by Hugues Tinguy, with permission.

Conocephalum orientale (Figure 97-Figure 100) has no known asexual reproductive structures (Akiyama 2022), but presumably it can reproduce by fragments. It is able to overwinter and produces bud scales (Figure 130-Figure 131) that protect the growing points. The thallus produces winter buds at the tip of the thallus in autumn, developing new shoots in the following spring. It can afford to lose some older cells, with other cells remaining viable, but cells that give rise to new tissue are few in number and vulnerable at the tip of the plant, so the bud scales help to protect them. These scales are absent in tropical populations, where the thallus grows throughout the winter, but a few populations in more northern locations of Japan also lack the buds, and these have been aligned with unique alleles (Isono *et al.* 1999; Akiyama 2022).

Figure 130. *Conocephalum orientale* with young overwintering bud. Photo courtesy of Hiroyuki Akiyama.

Figure 131. *Conocephalum orientale* with overwintering bud. Photo courtesy of Hiroyuki Akiyama.

Biochemistry

Conocephalum orientale (Figure 97-Figure 100) produces large amounts of methyl cinnamate, giving it a pleasant odor (Toyota *et al.* 1997; Toyota 2000; Ab Ghahi *et al.* 2016; Miyatake *et al.*, 2018). It would be interesting to see if this compound has any role in discouraging herbivores.

Other biochemical studies on *Conocephalum orientale* likely exist, but the task remains to link the studies with their current species concept.

Summary

Conocephalum conicum s.l. has recently been divided into multiple species in addition to several cryptospecies. Some studies indicate that *Conocephalum* s.s. does not exist in North America or Asia and is confined to Europe. This reconfiguration of the *Conocephalum conicum* complex has made it difficult to link many published studies with the modern species concepts.

Several of these newly defined species occur in wet habitats. *Conocephalum conicum* tends to be in wetter habitats than those of *C. salebrosum*, a widespread species and possibly the only one in most of North America. Nevertheless, both of these species occur near water (streambanks, springs, splash of waterfalls, canyon walls) and can grow intermixed in Europe. *Conocephalum conicum* prefers shade and can grow in running water or on emergent rocks. It can also occur on slopes where it may get water from seepage.

Members of *Conocephalum* often occur in large mats or mixed with other bryophytes. They have scales and rhizoids on the ventral surface that aid in movement and uptake of water. Air pores have hydrophobic cuticular ridges that prevent water from entering to the internal air chambers through the pores. Rapid cooling kills the cells of *C. conicum* s.l., but apical buds of members of the genus survive winter under the

protection of bud scales. Heat Shock Proteins help to protect the cells from heavy metals, where the latter can accumulate and serve as biomonitors.

Conocephalum conicum can experience **indirect facilitation** from other species, in some cases in which another species outcompetes a species that is a strong competitor to the *C. conicum*.

Little is known about the tubers that grow among the rhizoids, but fragmentation occurs as new growth and branching occur and older parts die. Sexual reproduction is common. Gametangia of *C. conicum* s.l. are produced best at 21°C in long days.

Conocephalum conicum s.l. is often infected by vesicular-arbuscular fungi and a species of *Glomus*, but benefits and harmful effects need to be evaluated. The species does produce antifungal and antibacterial compounds, some of which could be used commercially.

There are ~25 East Asian micropterigid moths that occur exclusively on species of *Conocephalum*.

Conocephalum orientalis is a newly described species from Japan that has deep grooves unlike those of *C. conicum* s.s. It is sometimes eaten in Japan, where it is the most common *Conocephalum*, especially along streams. This species changes color with the seasons, becoming pale reddish purple in late autumn, and becoming dark green in the shade. It becomes succulent in good moisture conditions, but very thin in low light of caves.

Conocephalum orientalis expels its sperm explosively, presumably facilitating their dispersal to nearby female plants. Like other species of *Conocephalum*, some spores are small and dispersed early, whereas others are larger due to **endosporic** development.

Acknowledgments

Bryonettors provided a wonderful array of images to illustrate this chapter. Thank you to Masaki Shimamura for providing me with the image of the explosive sperm dispersal in *Conocephalum* cf. *orientalis*. And thank you to Hiroyuki Akiyama for sending me his 2022 paper on the new species in Japan and providing me with original images. I appreciate Guido Bursa's notification that one of my images was not the species indicated, and supplying me with a new, correct image.

CHAPTER 1-21

AQUATIC AND WET MARCHANTIOPHYTA, CLASS MARCHANTIOPSIDA: CONOCEPHALACEAE, PART 2

Figure 1. *Conocephalum* cf. *salebrosum* at water's edge, Wahkeena Historical Preserve, Ohio, USA. Photo by Janice Glime.

***Conocephalum purpureorubrum* (Figure 2-Figure 14)**

Conocephalum purpureorubrum (Figure 2-Figure 14) was previously designated as *Conocephalum conicum* F type (Akiyama 2022). The lower surface of the thallus is reddish purple (Figure 2-Figure 4) even in summer, although this coloration may be confined to the midrib (Figure 5). The upper surface of the thallus mat is yellowish green (Figure 6-Figure 9) in western Japan or slightly shiny and blackish green (Figure 10-Figure 11) in eastern Japan. Upper epidermal cells of thalli can have thin or thick walls. The grooves outlining the **areolae** (air chambers) are deep and distinct (Figure 12-Figure 13). These air chambers do not differ in size between the margins and central portions (Figure 14).

Distribution

Conocephalum purpureorubrum (Figure 2-Figure 14) is known from southern China, South Korea, Taiwan, and Japan (Akiyama 2022).

Aquatic and Wet Habitats

Conocephalum purpureorubrum (Figure 2-Figure 14) can grow in drier habitats than those of *C. orientale* (Figure 15), but it can also grow intermixed with that species (Figure 16). It occurs at some waterfall sites. It tends to grow in more humid habitats when it grows with *C. salebrosum* (Figure 1, Figure 30-Figure 49) (Akiyama 2022), a behavior suggesting possible **indirect facilitation** as discussed in the previous subchapter under *C. conicum* (Figure 17). It is also possible that these behavioral differences in habitat preference relate to differences in genetic races (see Akiyama & Hiraoka 1994).

Figure 17. *Conocephalum conicum* from Scotland, with distinct thallus grooves. Photo courtesy of David Long.

Figure 15. *Conocephalum orientale* type J2 with wavy margin. Photo courtesy of Hiroyuki Akiyama.

Non-Aquatic

The eastern populations of *Conocephalum purpureorubrum* (Figure 2-Figure 14) usually occur on soil of valley slopes where they are far from water (Figure 18), but they can sometimes grow along streams (Akiyama 2022).

Figure 18. *Conocephalum purpureorubrum* from Mt. Takao, Japan, showing terrestrial habitat. Photo courtesy of Hiroyuki Akiyama.

Figure 16. *Conocephalum purpureorubrum* (FW) and *C. orientale* (J) growing intermixed in Japan. Photo courtesy of Hiroyumi Akiyama.

Physiology

Plants of *Conocephalum purpureorubrum* (Figure 2-Figure 14) tend to be thick and pale in sunny conditions (Figure 19) and thin and dark in shaded conditions (Figure 20) (Akiyama 2022). The reddish ventral condition seems to persist all year, but does its intensity relate to low light? In some flowering plants on tropical forest floors this ventral purplish coloring helps in the back-scattering of sunlight to the photosynthetic tissue (Lee *et al.* 1979). Such a role has not been explored in bryophytes. It seems likely that it would mostly work in liverworts among the bryophytes because they have a dorsiventral orientation.

Figure 19. *Conocephalum purpureorubrum* pale form typical of populations in western Japan. Photo courtesy of Hiroyuki Akiyama.

Figure 20. *Conocephalum purpureorubrum* from Japan, showing dark form typical of shade, with deep thallus grooves. Photo courtesy of Hiroyuki Akiyama.

Rhizoids are abundant on the ventral surface of *Conocephalum purpureorubrum* (Figure 21-Figure 23) (Akiyama 2022). These undoubtedly facilitate the movement and uptake of water into the thallus.

Figure 21. *Conocephalum purpureorubrum* showing rhizoids along the midrib. Photo courtesy of Hiroyuki Akiyama.

Figure 22. *Conocephalum purpureorubrum* showing numerous rhizoids. Photo courtesy of Hiroyuki Akiyama.

Figure 23. *Conocephalum purpureorubrum* showing numerous rhizoids. Photo courtesy of Hiroyuki Akiyama.

Conocephalum purpureorubrum (Figure 2-Figure 14) may have mucilage canals (Figure 24), but mucilage cells are often absent (Akiyama 2022). The mucilage may help to keep the cells moist, but experiments are needed to verify this. They are often absent in populations in dry habitats.

Figure 24. *Conocephalum purpureorubrum* from Japan, showing mucilage canals. Photo courtesy of Hiroyuki Akiyama.

Reproduction

Conocephalum purpureorubrum (Figure 2-Figure 14), like other species of *Conocephalum*, is **dioicous**. The antheridial receptacles form at the apex of the male thallus (Figure 25-Figure 26). Bud scales can often be seen at their margins (Figure 25).

Figure 25. *Conocephalum purpureorubrum* young antheridial receptacle. Note the remaining reddish brown bud scales. Photo courtesy of Hiroyuki Akiyama.

Figure 26. *Conocephalum purpureorubrum* young antheridial receptacle. Photo courtesy of Hiroyuki Akiyama.

Female plants of *Conocephalum purpureorubrum* (Figure 2-Figure 14) form archegoniophores at the apex of the female plants (Figure 27-Figure 28). When sporangia mature, the stalks elongate to 3-6 cm with bluntly conical archegonial heads (Figure 28-Figure 29). The sporangia hang down from the archegonial heads.

Figure 27. *Conocephalum purpureorubrum* with young archegoniophore. Photo courtesy of Hiroyuki Akiyama.

Figure 28. *Conocephalum purpureorubrum* with young archegoniophores beginning to elongate. Note that the black sporangia are already visible. Photo courtesy of Hiroyuki Akiyama.

Figure 29. *Conocephalum purpureorubrum* with mature archegoniophores and sporangia. Photo courtesy of Hiroyuki Akiyama.

Biochemistry

Biochemical analysis may reveal some interesting compounds in *Conocephalum purpureorubrum* (Figure 2-

Figure 14). This species has a fresh, earthy odor, usually not a mushroom odor (Akiyama 2022).

***Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49)**

Conocephalum salebrosum (Figure 1, Figure 30-Figure 49) is a relatively recently described species and is a segregate of *Conocephalum conicum* (Figure 17) (Szweykowski *et al.* 2005). It appears that many of the North American records of *Conocephalum conicum* should be placed here (Stotler & Crandall-Stotler 2017), with populations in California (Figure 50) being potential exceptions (see Shevock *et al.* 2021). The latter, for now, are best designated as *Conocephalum conicum* s.l.

In Europe, the distinction of the species in older literature is not so simple, if even possible without checking voucher specimens. Both species occur there. For example, Poponessi *et al.* (2014) have reported *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) from Italy. Sérgio *et al.* (2011) reported it from Portugal and Madeira and Azores Islands. Other records are documented in Figure 30-Figure 36. Figure 37 shows the similarities of a British Columbia, Canada, population to *Conocephalum salebrosum*.

Figure 37. *Conocephalum conicum* s.l. showing distinct thallus grooves and less distinct pores. These thallus grooves of a western North American population fit more closely with those of *C. salebrosum*. Photo from Botany Website, UBC, with permission.

Distribution

The distribution of *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) remains sketchy because of the long treatment of the species as part of *Conocephalum conicum* (Figure 17) (Szweykowski *et al.* 2005). It is definitely known from North America (Figure 38-Figure 41), but can also be found in Europe (Figure 42-Figure 43) (e.g. Tacchi *et al.* 2009) and eastern Asia (Figure 44-Figure 49) (Sérgio *et al.* 2011). Sérgio and coworkers consider it to be Holarctic.

Aquatic and Wet Habitats

Conocephalum, presumably *C. salebrosum* (Figure 1, Figure 30-Figure 49), occurs on wet, sandy streambanks and on moist rock surfaces (Figure 51-Figure 53) or springy banks of ravines in Connecticut, USA (Nichols 1916). On Cape Breton Island, Canada it also occurs on streambanks (Nichols 1918).

Figure 49. *Conocephalum salebrosum* thallus from Japan, showing pores and distinct grooves. Photo courtesy of Hiroyuki Akiyama.

Populations in California (Figure 50), however, are similar, but not identical, to *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) (Shevock *et al.* 2021).

Figure 52. *Conocephalum* cf. *salebrosum* at Scott Falls, Michigan, USA. Photo by Janice Glime.

Figure 54. *Conocephalum* cf. *salebrosum* on canyon wall at Hocking Hills, Ohio, USA. Photo by Janice Glime.

Conocephalum salebrosum (Figure 1, Figure 30-Figure 49) can be found along stream banks in the Appalachian Mountain, USA, streams (Glime 1968). In another humid environment, it is known from the base of the Flume wall and ledges in the flume at Franconia Notch, New Hampshire, USA (Glime 1982). It is likely the species that is a restricted terrestrial species in montane streams and on streambanks in western Canada (Vitt *et al.* 1986; Glime & Vitt 1987). It seems to avoid the submersion that is common for *C. conicum* (Figure 17).

Stephenson *et al.* (1995) reported its preferred pH as 7.9 in West Virginia, USA, mountain streams. Sérgio *et al.* (2011) considered *Conocephalum conicum* (Figure 17) to be less hygrophytic than *C. salebrosum* (Figure 1, Figure 30-Figure 49), being more tolerant of desiccation and preferring limestone areas.

Stream and River Banks

In North America, Porter (1933) reported *Conocephalum* (now probably *C. salebrosum* – Figure 1, Figure 30-Figure 49) from shady streambanks on soil in Wyoming, USA. Little (1936) described its habitat as constantly moist, shaded rock outcrops within a few feet of water in Oklahoma, USA. There it is one of the commonest species on moist, shaded bases of walls near water, occurring on both sandstone and limestone, as well as chert bluffs near water and especially in canyons and by springs.

In Europe, Tacchi *et al.* (2009) found it in ravines in the Apennines of Italy. Antkowiak *et al.* (2008) reported *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) synusia overgrowing high escarpments below the headstream at the River Kamionka in eastern Poland. Borovichev *et al.* (2009) found that *C. salebrosum* formed extensive mats on stream banks as well as on the bases of moist rocks and cliffs.

Canyon Walls

I have found *Conocephalum* cf. *salebrosum* (Figure 1, Figure 30-Figure 49) in extensive mats on canyon walls (Figure 54-Figure 67). These canyons were sandstone and humid.

Floodplains

Because of its need for high humidity and tolerance of submersion, *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) commonly occurs in floodplains of streams and rivers (Figure 69-Figure 68), including periodically flooded bases of canyons (Figure 70-Figure 71).

Figure 71. *Conocephalum* cf. *salebrosum* at base of canyon rock where it is flooded during high water, Hocking Hills, Ohio, USA. Photo by Janice Glime.

Waterfalls

Among its moist habitats, *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) can form large, dense patches on dripping rocks and wet soil where it is in close contact with water (Sérgio *et al.* 2011), including those areas wet by the splash of waterfalls (Figure 72) (personal observation).

Figure 72. *Conocephalum* cf. *salebrosum* beside Hungarian Falls at Tamarack City, Michigan, USA. Photo by Janice Glime.

Conocephalum salebrosum (Figure 1, Figure 30-Figure 49) was locally abundant at the entrance to Grotta degli Innamorati in central Italy at the Marmore Waterfalls Regional Park (Pononessi *et al.* 2020). I have seen the species in several locations in Michigan, USA, growing on a rock wall behind a waterfall (Figure 73).

Figure 73. *Conocephalum salebrosum* behind waterfall at Scott Cave, Michigan, USA. Photo by Janice Glime.

Non-Aquatic Habitats

Akiyama (2022) considered rather dry habitats (Figure 74) to be included among those of *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49). This fits with my own experience in North America. Other somewhat dry habitats are shown in Figure 75-Figure 79.

Physiology

McConaha (1939) determined that the water absorption of *Conocephalum salebrosum* is limited to the ventral appendages, which are restricted to the underside of the midrib (Figure 80). The scales (Figure 80) increase the surface area by ~380% and the rhizoids (Figure 80-Figure 83) increase it by 5100%. The rhizoid strands and scales create an extensive capillary system (that is able to move water ventrally along the entire length of the thallus).

Figure 83. *Conocephalum conicum* s.l. showing **pegged** (upper) and **smooth** (lower) rhizoids. Photo from Botany Website, UBC, with permission.

Schott *et al.* (2021) found that *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) from west Germany had ice-nucleating proteins that differed in ice-nucleating temperature and seasonal concentration from those of *Marchantia polymorpha* subsp. *ruderalis* (Figure 84). Ice formed in the air chambers of both species, and crystals grew out of the air chamber pores (Figure 85). Crystals also formed in various locations on the ventral side of the thallus. This crystal formation resulted in dehydration of the thallus cells and permitted survival of low temperatures and frost (Figure 86). Presumably, this is a means of preventing crystal formation within the cells where it can damage membranes.

Adaptations

Although no specific adaptations have been attributed to *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49), it is likely that many are similar to those of *Conocephalum conicum* (Figure 17). However, *C. salebrosum* does have more conspicuous pores (Akiyama 2022) that could be an advantage is gas exchange and hence, photosynthesis.

Conocephalum salebrosum (Figure 87-Figure 88) from Japan has more mucilage canals and mucilage cells

than most other members of the *Conocephalum conicum* complex there (Akiyama 2022). These most likely help it to conserve moisture in its drier habitats.

Figure 87. *Conocephalum salebrosum* from Japan, showing mucilage cells and canals. Photo courtesy of Hiroyuki Akiyama.

Figure 88. *Conocephalum salebrosum* from Japan, showing mucilage cells and canals in thallus cross section. Photo courtesy of Hiroyuki Akiyama.

In addition to its rhizoids and scales (Figure 80-Figure 83) for water movement and uptake, *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) often occurs in large mats (Figure 1) or mixed with other bryophytes (Figure 89-Figure 90) (Akiyama 2022). These closely intermingled plants can help to maintain moisture on the lower side of the plant where uptake occurs.

Reproduction

Showalter (1921) determined that the male and female chromosomes of *Conocephalum* cf. *salebrosum* (Figure 1, Figure 30-Figure 49) in Wisconsin and New York, USA, and in Copenhagen, Denmark, did not differ as they do in some **dioicous** liverworts, but that 1 of the 9 chromosomes was considerably smaller, a condition that apparently led to some earlier researchers finding only 8.

Antheridia in *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) are borne in receptacles on the thallus surface (Figure 91-Figure 94) and apparently not elevated by an elongated midrib as they are in *C. orientalis* (Figure 15) (see Conocephalaceae part 1 subchapter).

Graham (1909) described the development of both the gametophyte and sporophyte of *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49). In New York, USA, the gametangiophore (Figure 95-Figure 105) begins development early in June. Archegonia are mature by the first of July. The development of the sporangia (Figure 104-Figure 105) is rather slow, with spores and elaters

maturing by the onset of winter. At that time, growth ceases. The stalk of the gametangiophore is still very short, with the conical head appearing to be sessile on the thallus. In the warmth of the following May, this archegoniophore elongates rapidly, lifting the receptacle well above the thallus surface (Figure 100-Figure 103). When the stalk of the sporangium elongates, the spores are released when the capsule ruptures. A surrounding sheath may protect the overwintering capsule from excessive radiation and transpiration.

Taylor and Hollensen (1984) elaborated on this cycle for plants of *Conocephalum* cf. *salebrosum* (Figure 1, Figure 30-Figure 49) in Michigan, USA. Growth is initiated in March. The full reproductive cycle requires 21 months. Archegonia are initiated in August and fertilized the following June. The sporophyte matures in that autumn and spores are shed in the next spring. The thalli are under snow and dormant from December through February.

Ellen (1920) described the germination of the spores of *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) in Sinsinawa, Wisconsin, USA. Here, the spore mother cells are well developed before the beginning of September and the spores are freed from the mother cell walls about mid September. In Early October, growth and a heavy deposit of starch precede the cell division. Each sporeling has up to eight cells that remain in the spore wall (Figure 106). Before winter, the partition cell walls thicken, starch is deposited, and growth occurs by division of the spores. These multicellular sporelings remain through the winter. When warm weather returns, cell division resumes and continues until the stored food is gone. Cell division pauses and the cells expand, accompanied by a rapid development of chlorophyll and starch. This is followed by a second series of cell divisions until the sporelings become a spherical mass of 30-40 cells. As this mass matures, the archegoniophore elongates rapidly in 4-5 days to attain a height of 5-6 cm. At the same time, the seta on each capsule elongates and the capsule emerges through the calyptra and sheath. The capsule wall ruptures and sporelings and elaters are dispersed. Most of the sporelings are short-lived, but some survive up to 38 days of desiccation.

Figure 106. *Conocephalum salebrosum* multicellular spores resulting from endosporic development. Photo courtesy of Leica Chavoutier.

It appears that some spores of *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) might be dispersed while they are still small – one-celled (Ellen 1920). This strategy of multicellular spore spheres (sporelings) and single-celled spores would permit achieving a good start in the nearby habitat by dispersed spheres while permitting long-distance dispersal of the one-celled spores.

At the end of the growing season, apical buds form and older portions become moribund (Figure 107). In the spring, these buds expand and develop new plants (Figure 107-Figure 114), increasing the area covered due to branching.

Figure 107. *Conocephalum salebrosum* dead (moribund) and new growth at Hocking Hills, Ohio, USA. Photo by Janice Glime.

Figure 114. *Conocephalum salebrosum* dead with new growth at Hocking Hills, Ohio, USA. Photo by Janice Glime.

Figure 112. *Conocephalum* cf. *salebrosum* new growth on canyon walls at Hocking Hills, Ohio, USA. Photo by Janice Glime.

By whatever mechanism, when *Conocephalum* cf. *salebrosum* (Figure 1, Figure 30-Figure 49) was growing in my garden room, it managed to appear in new locations around the room. It never had sexual structures. I attributed its dispersal to the movement of my box turtle, but I have no real proof. Unfortunately, I never caught anybody in the act.

Ainsworth (1965) reported bulbils in *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) from New York, USA, that had been kept in the dark for 28 days. These occur anywhere on the ventral surface, but when the midrib has bulbils still attached, these seem to inhibit the production of bulbils elsewhere on the thallus. An average of ~1.3 bulbils can occur in 1 mm² of thallus. This is not the first report of these structures. Karsten (1887) found them on thalli of *Conocephalum conicum* s.l. (Figure 17) that had been so completely overgrown by other thalli that they too, were in complete darkness.

These "bulbils" have been somewhat controversial. Paton (1993) referred to the tubers of *Conocephalum conicum* s.l. (Figure 17). that occur on the ventral surface of the midrib and become detached to form new plants, as described by MacVicar (1926) and again by Paton from Sussex, England. These likewise occurred on moribund

thalli (Figure 107). Paton noted that these dark-produced structures, termed bulbils by Ainsworth (1965), germinated in ~5 days when placed in moist conditions in the light.

Animal Interactions

When growing in my garden room, *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) had nibbles around its edges. These were triangular and best fit the hypothesis that they were eaten by the Society Finches or the Canary in the room.

In the field I have found evidence of herbivory, but in these cases the removal was not triangular. Instead, it occurred not only on the margins but also mid thallus and the eaten areas were of irregular shape (Figure 115-Figure 117). These could be the product of insects, isopods, or possibly snails.

Figure 117. *Conocephalum* cf. *salebrosum* eaten in Houghton County, Michigan, USA. Nibbling on the edges suggests a large arthropod, perhaps an isopod. Photo by Janice Glime.

Fungal Interactions

Liepiņa (2012) reported that both *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49) and *C. conicum* (Figure 17) were "moderately" mycorrhizal. Both liverworts have Glomeromycotean endophytes and these fungi form nonseptate hyphae, vesicles, and arbuscules (see Figure 118), indicating that they created a functional symbiosis with the liverworts. The hyphae entered through the rhizoids and passed directly through the cell walls of the liverworts.

Figure 118. Vesicular arbuscular mycorrhizae in root cells, showing the form that might also show up in the thallus of *Conocephalum salebrosum*. Photo by Rit Rajarshi, through Creative Commons.

Biochemistry

It is likely that some of the biochemical work attributed to *Conocephalum conicum* (Figure 17) actually applies to *C. salebrosum* (Figure 1, Figure 30-Figure 49), but unless it is recent or in North America, voucher specimens from the study would need to be verified. Even then, since the two liverworts grow together, the assays might have included both species without having both represented in the voucher specimens.

Craft *et al.* (2016) attempted to demonstrate chemotypes in the *Conocephalum* complex in the southern Appalachian Mountains, USA. They used a common garden experiment, but found that the experiment became a common stress experiment that significantly altered the compositions of volatile compounds in *Conocephalum salebrosum* (Figure 1, Figure 30-Figure 49). This phenomenon might provide antiherbivory compounds in response to herbivory, as already known from tree leaves (see, for example, Moreira *et al.* 2012). It would also be interesting to know the cost of producing such compounds relative to the cost of herbivory.

Summary

When chemical and genetic analyses were done on the *Conocephalum conicum* complex, the researchers decided that division into multiple species was warranted. From that division, *C. salebrosum* was identified and determined to be holarctic, seemingly replacing what was known as *C. conicum* in North America. Then, in 2022, several Japanese species were segregated from *C. conicum*, including *C. purpureorubrum*.

Ecological information on *Conocephalum purpureorubrum* is scant due to its recent consideration as a different species. It occurs in both damp habitats and dry ones, sometimes occurring streamside or on steep slopes. Its life cycle seems to be the same as that of *C. conicum*, with no asexual structures known. It is unusual in always having at least some purplish color present on the ventral surface. It has mucilage canals, but it often lacks mucilage cells.

Conocephalum salebrosum occurs near water, but extends into drier habitats than those typical of *C. conicum*. Most of the North American populations may belong to this species, often occurring on rock in canyons, near waterfalls, and along stream margins. Scales and rhizoids facilitate water movement and uptake along the ventral surface. The species can suffer from herbivory, but it contains compounds that are potentially antiherbivorous. It also frequently has vesicular arbuscular mycorrhizae.

Acknowledgments

Bryonetters provided a wonderful array of images to illustrate this chapter. Thank you to Masaki Shimamura for providing me with the image of the explosive sperm dispersal in *Conocephalum cf. orientalis*. And thank you to Hiroyuki Akiyama for sending me his 2022 paper on the new species in Japan and providing me with original images.

CHAPTER 1-22

AQUATIC AND WETLAND

MARCHANTIOPHYTA, CLASS

MARCHANTIOPSIDA – CYATHODIACEAE, DUMORTIERACEAE

Figure 1. *Dumortiera hirsuta* habitat in Europe. Photo by Michael Lüth, with permission

Marchantiidae – Marchantiales

Cyathodiaceae

There have been several taxonomic considerations of the genus *Cyathodium* (Schiffner 1938; Srivastava & Dixit 1996; Salazar Allen & Korpelainen 2006).

This family often occurs in moist habitats such as caves and stream banks. *Cyathodium* habitats are typically shaded and include river banks on soil or rocks, in waterfalls, caves, cement floors, stairs, and flowerpots, with some occurring as epiphytes (Salazar Allen & Korpelainen 2006). Large communities can occur on

unstable river banks where they can become submerged and sometimes become detached by flooding or drying. They are often associated with filamentous *Cyanobacteria* (Figure 32), but these are not endophytic. Endophytic fungi are known from wild populations of *C. spruceanum* (Figure 2) and *C. cavernarum* (Figure 3) in Panama (Salazar Allen unpublished data). Riverbank plants often provide substrate for diatoms, including *Surirella* (Figure 4), *Nitzschia* (Figure 5), *Amphora* (Figure 6), *Rhopalodia* (Figure 7), *Eunotia* (Figure 8), and possibly *Diploneis* (Figure 9) (Allen & Korpelainen 2006). The most aquatic of *Cyathodium* species is *Cyathodium bischlerianum* (Figure 10).

Figure 9. *Diploneis ovalis*, in a genus of diatoms that often grows on species of *Cyathodium*. Photo by Kristian Peters, through Creative Commons.

Members of *Cyathodium* prefer moist, shady habitats (Daniels 1998). Large communities of *Cyathodium* occur on unstable river banks in Costa Rica and Panama, and here they often experience submergence or become detached by floods. In other locations they are subject to drying on soil along cement road ditches in humid areas (Salazar Allen & Korpelainen 2006). The genus endures weak light intensities where it is able to grow on rock, soil, or in two species on bark. *Cyathodium* sp. (Figure 10) occurs over (overhanging?) water and in waterfalls in the tropics (Ruttner 1955). Although there are several semi-aquatic species in *Cyathodium*, Cavers (1910), citing Lang (1905) regarded it as a genus primarily adapted to shade, rather than as a hygrophyte.

Daniels (1998) noted that *Cyathodium* species lack the complex structure of many thallose liverworts, such as well-defined assimilatory and storage zones or scales.

Tiwari (1929a,b, 1935) studied the spore germination of *Cyathodium* spores. Crum (1976) noted that some of the species have spores that emit a yellowish luminescence. There are few spores in *Cyathodium* species, numbering 20-100 per capsule (Bischler-Causse *et al.* 2005).

Cyathodium bischlerianum (Figure 10)

Distribution

Cyathodium bischlerianum (Figure 10) is a Neotropical species known only from Panama (Salazar Allen 2001). Because of its small size and association with other *Cyathodium* species, it can easily be overlooked, and Salazar Allen suspects that it is more widely distributed in the Neotropics. For these reasons, information on it is also rather scant.

Figure 10. *Cyathodium bischlerianum* habit on tree near water. Photo by José Gudiño L., courtesy of Noris Salazar Allen.

Members of *Cyathodium* have a simple, slender, dichotomously branched thallus with no purple coloring (Figure 2-Figure 3). The pores are simple with a single ring of cells and no hyaline inner ring (Salazar Allen 2001; Bischler-Causse *et al.* 2005). The air chambers are empty. Most rhizoids are smooth, but some may be tuberculate. It has 2 rows of ventral scales, often restricted to the apex. Its asexual reproduction includes fragmentation of thallus segments and ventral tubers in some.

Aquatic and Wet Habitats

Cyathodium bischlerianum (Figure 10) is one of two species that can be corticolous (Salazar Allen & Korpelainen 2006). It typically grows mixed with other species of *Cyathodium* in very moist, shaded locations, particularly on rocks near or even in creeks, along eroding river banks, and in other locations subject to partial submergence during high water levels (Bischler-Causse *et al.* 2005). It is more mesic than *C. spruceanum* (Figure 2).

Cyathodium bischlerianum (Figure 10) occurs on stream and river banks, along with *C. cavernarum* (Figure 3), in the shaded, more moist habitats close to the rivers and seepage, whereas *C. spruceanum* (Figure 2) occurs on more upper slopes (Salazar Allen & Korpelainen 2006). *Cyathodium bischlerianum* also can occur on bark (Figure 11-Figure 12) near streams and rivers and in seepages and on moist rocks.

Figure 11. *Cyathodium bischlerianum* habit on bark. Photo by José Gudiño L., courtesy of Noris Salazar Allen.

Figure 12. *Cyathodium bischlerianum* on bark. Photo by José Gudiño L., courtesy of Noris Salazar Allen.

Reproduction

Cyathodium bischlerianum (Figure 10) is **monoicous** (Salazar Allen 2001; Bischler-Causse *et al.* 2005). The involucre can have 1 or 2 archegonia and sporophytes (Figure 13); male receptacles occur on the sides of the thallus. The species lacks any specialized asexual reproductive structures, with no tumors as found in dioicous members of the genus (Salazar Allen & Korpelainen 2006).

Figure 13. *Cyathodium bischleriana* thallus with sporangia. Photo by Noris Salazar Allen, with permission.

Cyathodium bischlerianum (Figure 10) is an **r-selected** species (Salazar Allen & Korpelainen 2006). This means that it has a high reproductive rate, its population size varies through time, and recolonization occurs every year, creating competition with itself and other species (Pianka 1970).

Biochemistry

Despite the newness of the species and its limited distribution, the biochemistry of *Cyathodium bischlerianum* (Figure 10) has been evaluated. It is unique among the *Cyathodium* species, containing mostly aromatic monoterpenes (Salazar Allen *et al.* 2017). It has less than 3% of the sesquiterpenes germacrene D and bicyclogermacrene.

Nerolidol is the main compound among these (Salazar Allen *et al.* 2017). This compound has a floral and woody fragrance (Padalia *et al.* 2015). Already known from other plants, it has been approved for use in fine fragrances, cosmetics, shampoo, soaps, detergents, and cleaning products (Padalia *et al.* 2015; Boskabady *et al.* 2014). The industry level consumption is 10-100 tons per year (Queiroga *et al.* 2014).

Cyathodium cavernarum (Figure 14-Figure 15)

syn. = *Cyathodium africanum*, *C. barodae*, *C. mexicanum*

Distribution

Cyathodium cavernarum (Figure 14-Figure 15) is a widespread pantropical species (Lye & Pócs 1997) and is the most widespread species in the genus (Bischler-Causse *et al.* 2005). It is known from China (Zhang *et al.* 2004a), Japan (Furuki *et al.* 2012), India, Java, Africa, Madagascar (Srivastava & Dixit 1996; Reeb *et al.* 2018), western Australia (Meagher 2002), and the American tropics in Colombia (Winkler 1976), Mexico, Costa Rica, Panama, Cuba, and Brazil (Srivastava & Dixit 1996; Salazar Allen 2005; Salazar Allen & Korpelainen 2006; Gradstein *et al.* 2016; Reeb *et al.* 2018). Shah and Gujar (2016) reported that *Cyathodium cavernarum* was the most widely distributed liverwort species in Gujarat, India.

Figure 14. *Cyathodium cavernarum* on roof of cave. Photo by Célio Moura Neto, through Creative Commons.

Figure 15. *Cyathodium cavernarum* showing young and old thalli. Photo by Eric Hough, through Creative Commons.

Aquatic and Wet Habitats

Lye and Pócs (1997) reported *Cyathodium cavernarum* (Figure 14-Figure 15) growing on overhanging, dripping, or sprayed rocks as well as temporarily inundated muddy forest floor low areas of Uganda. On river banks, it occupies lower positions than does *C. spruceanum* (Figure 2), preferring more shaded, damper sites or those with seepage (Bischler-Causse *et al.* 2005; Salazar Allen & Korpelainen 2006). In the Northern Western Ghats it is usually found in low altitudes where there is human habitation or shaded disturbed areas (Nair & Prajitha 2016). Glenny (2002) similarly reported it from stream and river banks in Australia.

Cyathodium cavernarum (Figure 14-Figure 15) usually occurs on calcareous substrata but it can also occupy slightly acidic substrates with underlying calcareous bedrock (Bischler-Causse *et al.* 2005). Its substrata include soil, wet rocks, walls, and termite mounds in moist deciduous, semi-evergreen, or evergreen forests (Nair & Prajitha 2016). In exposed habitats it is typically associated with members of the **Pottiaceae** (Figure 16); in ravines and river banks with species of *Philonotis* (Figure 17), *Fissidens* (Figure 18), *Notothylas* (Figure 19), *Racopilum tomentosum* (Figure 20), *Cyathodium spruceanum* (Figure 2), and **Lejeuneaceae** (Figure 21) (Bischler-Causse *et al.* 2005).

Figure 21. *Lejeunea flava*, member of a family that is often associated with *Cyathodium cavernarum*. Photo by Scott Zona, through Creative Commons.

Although caves are not aquatic habitats, they are often wet and at least damp, providing suitable habitat for *Cyathodium cavernarum* (Figure 22-Figure 25) including the Birds'-Nest Cave near Niah, Sarawak, Borneo (Holtum 1938). Reeb *et al.* (2018) likewise found this species at cave entrances in Madagascar, occupying naked, compact soils that were shady. And Furuki *et al.* (2012) found it on soil of a limestone cave in Japan and Zhang *et al.* (2004a,b) in karst caves of China.

Figure 24. *Cyathodium cavernarum* in cave. Photo by Cédric de Foucault, through Creative Commons.

Figure 25. *Cyathodium cavernarum* on cave ceiling. Photo by Célio Moura Neto, through Creative Commons.

Adaptations

Cyathodium cavernarum (Figure 14-Figure 15) exhibits a bright metallic-green color (Figure 26-Figure 27) (Bischler-Causse *et al.* 2005). Reeb *et al.* (2018) described it as iridescent, with colors that change when viewed from various angles. Zhang *et al.* (2004b) described it as luminous with a "peculiar light-reflecting power which produces a kind of starry effect, so that the plants seem to flood the dark caves where they grow with a luminous, golden-green light."

Figure 26. *Cyathodium cavernarum* iridescence in Bombay. Photo ©Patrick Blanc, with permission.

Figure 27. *Cyathodium cavernarum* showing iridescent colors. Photo by Jan-Peter Frahm, with permission.

But what does this peculiar light reflection mean for the liverwort? Does it increase the ability to capture light for photosynthesis? Does it attract some sort of invertebrate that henceforth carries sperm or fragments, thus aiding in dispersal? This is a mystery that needs to be investigated.

Water can collect on the thallus and remain there for some time (Figure 28), helping the plant to remain hydrated. This may be the mechanism that permits it to live in caves where it doesn't rain.

Figure 28. *Cyathodium cavernarum* with accumulated water droplets. Photo from Idleggraphics, through Creative Commons.

Cyathodium cavernarum has pores in the thallus that increase the loss of water (Figure 29). As with many liverworts, *C. cavernarum* (Figure 14-Figure 15) often benefits from the added water retention of living among mosses (Figure 30).

Reproduction

Cyathodium cavernarum (Figure 14-Figure 15) is **monoicous** (Srivastava & Dixit 1996; Bischler-Causse *et al.* 2005). Salazar Allen and Korpelainen (2006) demonstrated that *C. cavernarum* and *C. spruceanum* (Figure 2) have more similar genetics from nearby geographic areas than those from more distant areas, suggesting a role of sexual reproduction. Sporelings in culture develop initial filamentous growth followed by apical development into the thallus.

In addition to sexual reproduction, it can reproduce by fragments and spread by branching (Figure 31) (Bischler-Causse *et al.* 2005). Tubers are unknown in this and other monoicous species (Salazar Allen & Korpelainen 2006).

Figure 31. *Cyathodium cavernarum* showing young thalli mixed with old ones. Some show branching. Others may be derived from fragments or spores. Photo by Eric Hough, through Creative Commons.

Interactions

Cyanobacteria (Figure 32) are common associates of *Cyathodium cavernarum* (Figure 14-Figure 15) (Bischler-Causse *et al.* 2005). Fungal endophytes are known from *Cyathodium cavernarum* in Panama (Salazar Allen & Korpelainen 2006).

Figure 32. *Nostoc commune*, one of the **Cyanobacteria** often associated with bryophytes. Photo by Kristian Peters, through Creative Commons.

Biochemistry

Salazar Allen *et al.* (2017) found that *Cyathodium cavernarum* (Figure 14-Figure 15) has a distinct chemical composition with an octane derivative as its major compound, suggesting that this could be used as a chemical marker for the species. Nevertheless, Ulka and Karadge (2010) found little antimicrobial activity by extracts of *Cyathodium cavernarum*. Furthermore, Surendra Kumar *et al.* (2014-15) found that extracts of *C. cavernarum* were ineffective, compared to a standard drug, in causing paralysis or death in the Indian earthworm *Pheretima posthuma* (see Figure 33). It is interesting that this widespread species seems to lack the usual liverwort ability to inhibit potentially deadly organisms. Could it be that these other organisms seldom occur where it lives? Or does it have associated bacteria or fungi that accomplish this purpose?

Figure 33. *Pheretima praepinguis* from China; *P. posthuma* is unaffected by extracts of *Cyathodium cavernarum*. Photo by Panzer VI-II, through Creative Commons.

Cyathodium foetidissimum (Figure 34)

Cyathodium foetidissimum (Figure 34) is the largest of the *Cyathodium* species (Lang 1905).

Figure 34. *Cyathodium foetidissimum*. Photo by Philippe Birnbaum, with permission.

Distribution

Cyathodium foetidissimum (Figure 34) is Asiatic with limited records in the Neotropics (Salazar Allen *et al.* 2004). It is known from Java, Sumatra, Tahiti, Nukahiva (Srivastava & Dixit 1996), Cameroon (Wigginton 2002; Wigginton & Grolle 1996), Costa Rica (Salazar Allen *et al.* 2004), Ecuador (Bischler-Causse *et al.* 2005), and Colombia (Gradstein *et al.* 2016). The specimens from Ecuador might represent an error in identification. They have tubers (otherwise unknown in *C. foetidissimum*) and the uppermost thallus cells exceed the size of those found in specimens from Costa Rica (Bischler-Causse *et al.* 2005).

Duckett and Ligrone (2006a) reported the first record of *Cyathodium* in Europe. This they identified as *Cyathodium foetidissimum* (Figure 34). It was located in southern Italy, outside its normal tropical range. They suggested that it was probably a pre-glacial relic rather than a recent arrival from sub-Saharan Africa.

Aquatic and Wet Habitats

Lang (1905) described the habitat of *Cyathodium foetidissimum* (Figure 34) in Perak, Malaysia, as one on rocks in deep forest shade, especially on vertical faces of damp rocks. Salazar Allen and Korpelainen (2006) found that it is more mesic than is *C. spruceanum* (Figure 2). Lang (1905) considers it to be more adapted to shade conditions, rather than being a **hygrophyte** (plant that grows in wet conditions). Angeles *et al.* (2020) described the species as rupestrine, occurring as **chasmophytes** (plants growing in fissures and cracks of limestone) on rock.

In Costa Rica this species forms small patches in depressions in very shady conditions on sandy limestone rock (Bischler-Causse *et al.* 2005); it also occurred in a limestone valley in Italy (Duckett & Ligrone 2006a). Its common associates include *Dumortiera hirsuta* (Figure 35), *Marchantia* (Figure 36), *Fissidens flaccidus* (Figure

37), *Taxiphyllum taxirameum* (Figure 38), and *Lejeuneaceae* (Figure 21).

Figure 38. *Taxiphyllum taxirameum*, a common associate of *Cyathodium foetidissimum* in Costa Rica. Photo by Bob Klips, with permission.

In Mali, Philippe found it in small caves on rocks (Figure 39-Figure 41).

Figure 39. *Cyathodium foetidissimum* in cave in Mali. Photo by Philippe Birnbaum, with permission.

Figure 40. *Cyathodium foetidissimum* in Mali. Photo by Philippe Birnbaum, with permission.

Figure 41. *Cyathodium foetidissimum* in small cave in Mali. Photo by Philippe Birnbaum, with permission.

Adaptations

Cyathodium foetidissimum (Figure 40) has a multistratose region of cells in the mid region of the thallus (Salazar Allen *et al.* 2004). These could give the thallus greater strength or act as a storage region, but the function needs to be explored. The oil cells have a single oil body. Unlike some species in the genus, this one has strongly dimorphic rhizoids (smooth and pegged) and large ventral scales, both adaptations that could facilitate water movement and uptake.

Srivastava and Dixit (1996) described the thalli as brownish-green and delicate, but usually larger than those of other species in *Cyathodium*. They likewise described large ventral scales, occurring just behind the involucre.

When Duckett and Ligrone (2006a) found this species in Italy, they discovered internal cells in the air chambers, the only report of such internal cells in the genus.

Cyathodium foetidissimum (Figure 40) has a phosphorescent appearance (Figure 42) – another mystery (Lang 1905; Salazar Allen *et al.* 2004). Duckett and Ligrone (2006a) suggested that this might enhance its light interception.

Figure 42. *Cyathodium foetidissimum* in cave in Mali. Photo by Philippe Birnbaum, with permission.

Reproduction

Cyathodium foetidissimum (Figure 40) is **monoicous**, but can also produce unisexual male plants in the same population (Salazar Allen *et al.* 2004). The male receptacle is apical with archegonia, wrapped in undulate laminar involucre, flanking it. It is **protandrous** (antheridia appear before archegonia).

The antheridia occur on short, disc-shaped antheridiophores (Srivastava & Dixit 1996). Archegonia are enclosed by an involucre that sits below the apex at the base of a sinus. Like those in *Targionia hypophylla* (Figure 43), antheridial receptacles occur not only on ventral shoots, but also on the main shoot along the midrib (Kashyap 1914).

Figure 43. *Targionia hypophylla*, a species that, like *Cyathodium foetidissimum*, has antheridial receptacles arising from both ventral shoots and main shoots. Photo by Ken-Ichi Ueda, through Creative Commons.

The capsule has an operculum of only 12 cells. Spores are verrucose (Salazar Allen *et al.* 2004). The spores initially germinate into a filamentous phase in culture (Salazar Allen & Korpelainen 2006). This is followed by apical development of thalli.

Cyathodium foetidissimum (Figure 40) grows in the rainy season, dying back when the dry season begins (Salazar Allen & Korpelainen 2006). Where the habitat is wetter and shaded on the banks of creeks and rivers, it is able to persist for more than one year.

Interactions

Cyanobacteria (Figure 32) are known associates of all species of *Cyathodium* (Salazar Allen & Korpelainen 2006).

Fungi are known to associate with *Cyathodium foetidissimum* (Figure 40) in the Malay Peninsula (Lang 1905) and in Italy (Duckett & Ligrone 2006a).

Biochemistry

Many liverworts have distinctive odors. As its name suggests, *Cyathodium foetidissimum* (Figure 40) is recognizable by its bad smell (Gradstein 2011). Sakurai *et al.* (2018) described it as the smell of an old person or old chest of drawers, but also called it a nostalgic odor. Collections from Tahiti were described as having a pleasant odor, whereas those in the Marquesas Islands smelled like urine and feces.

Ludwiczuk *et al.* (2009) found skatole, a well known compound produced by biodegradation of tryptophan and responsible for the fecal odor of *Cyathodium foetidissimum* (Figure 40). This species also biosynthesized izolepidozene (3.1%) and lunularin (2.4%). Izolepidozene is the main volatile component of *Conocephalum japonicum* (Figure 44) and *Marchantia emarginata* ssp. *tosana* (Figure 45). Among the six species of Polynesian liverworts tested, Ludwiczuk *et al.* (2010) found that each had a unique combination of volatile compounds.

Figure 44. *Conocephalum japonicum*, a species that, like *Cyathodium foetidissimum*, has the compound izolepidozene. Photo by David Long, with permission.

Figure 45. *Marchantia emarginata* ssp. *tosana*, a species that, like *Cyathodium foetidissimum*, has the compound izolepidozene. Photo by Lin Shanxiong, through Creative Commons.

Sakurai *et al.* (2018) identified three volatile components [4-methoxystyrene (24.4%), 3,4-dimethoxystyrene (28.7%), and skatole (15.9%)], as well as several aliphatic aldehydes [n-octanal, n-nonanal, and n-decanal] from Tahitian specimens. However, they did not find (E)-2-nonenal, a recognized compound causing an aged foul odor. Sakurai *et al.* (2018) found that a methanol extract ($100 \mu\text{g mL}^{-1}$) showed no activity against *Bacillus subtilis* (Figure 46), *Staphylococcus aureus* (Figure 47), *Escherichia coli* (Figure 48), or *Klebsiella pneumoniae* (Figure 49), although a number of bryophytes do show activity against these. Perhaps the volatile compounds have a role in antiherbivory?

Of four species of *Cyathodium*, Salazar Allen *et al.* (2017) found indole compounds only in *C. foetidissimum*. The researchers suggested that indole compounds could be used as species markers.

***Cyathodium spruceanum* (Figure 50)**

Among four Neotropical species they examined, Salazar Allen and Korpelainen (2006) found the greatest genetic differences between *Cyathodium foetidissimum* and *C. spruceanum* (Figure 50).

Figure 50. *Cyathodium spruceanum*. Photo by Jose De Gracia, through Creative Commons.

Distribution

Cyathodium spruceanum (Figure 50) is endemic to South America (Srivastava & Dixit 1996) in the Neotropics (Salazar Allen & Korpelainen 2006).

Aquatic and Wet Habitats

Cyathodium spruceanum (Figure 50) typically grows in homogeneous patches on exposed places (Salazar Allen & Korpelainen 2006). Proskauer (1951) reported the original *C. spruceanum* at the edge of a forest stream. The populations are usually rather large in years experiencing high rainfall. The species is less mesic than *C. cavernarum* (Figure 3) or *C. bischlerianum* (Figure 10), with *C. spruceanum* growing farther up the banks in less shaded, less damp habitats that are less mesic. At the Ratu Boko temple in Java, *Cyathodium spruceanum* occurs on limestone (Aryani 2014).

Adaptations

Cyathodium spruceanum (Figure 50) has a thallus that is light-green to whitish-green (Srivastava & Dixit 1996). However, Proskauer (1951) described it as iridescent with light-reflecting lens cells in the roofs of the air chambers. Other than the dark colors that protect against bright sun, little seems to be known about the adaptive values, if any, of some of the colors in bryophytes.

The thalli are overlapping (Srivastava & Dixit 1996), potentially helping to conserve water. Scales provide protection of the growing points (Proskauer 1951).

This species has numerous rhizoids, but the straight, smooth ones predominate (Proskauer 1951; Srivastava & Dixit 1996).

Reproduction

Cyathodium spruceanum (Figure 50) is **dioicous** (Srivastava & Dixit 1996). The female receptacles are ventral pouches. Male (Figure 51) and female plants can grow close to each other, permitting frequent fertilization success (Salazar Allen & Korpelainen 2006). Salazar Allen *et al.* (2017) found that the chemical composition of males and females was very similar, with three compounds found only in females [12-norcyercene-B, longifolenaldehyde and 1(5)-3-aromadenedraidene were found only in female plants].

Figure 51. *Cyathodium spruceanum* males. Photo by José Gudiño L., courtesy of Noris Salazar Allen.

Sporophytes are produced in abundance (Salazar Allen & Korpelainen 2006). Spores are numerous (>400 in a capsule). In culture, these can produce males and female gametophytes in the same year as produced, but there are no field observations to demonstrate germination in the same year as production. Salazar Allen and Korpelainen suggested that this delay in germination is due to soil dryness when the spores are released, a phenomenon that occurs because they are released at the onset of the dry season.

Figure 52. *Cyathodium spruceanum* with sporangia (S). Photo courtesy of Noris Salazar Allen.

The species of *Cyathodium* are **r-selected species** (Salazar Allen & Korpelainen 2006). **R-selected species** generally have high growth rates, produce many offspring, but have a low probability of survival to adulthood. The numerous offspring are able to exploit niches that are less crowded. The abundant sporophytes and spores permit *C. spruceanum* (Figure 50) to be among the better of the *Cyathodium* species at achieving high levels of reproduction. Long-term studies on individual populations are lacking.

The spores of *Cyathodium spruceanum* (Figure 50) are lamellate-reticulate (Salazar Allen *et al.* 2004). The sporeling initially produces a budlike protonema (Salazar Allen & Korpelainen 2006). From this structure, a thallus develops.

Cyathodium spruceanum (Figure 50) is one of the species in the genus to produce ventral tubers (Salazar Allen & Korpelainen 2006). These generally develop in the middle of the rainy season and remain attached to the parent thallus until the thallus decays. In culture, tubers are produced in abundance when nutrients are depleted. The tubers produce numerous rhizoids on their distal portion.

They germinate on agar, but germination in the field has thus far not been observed. Salazar Allen and Korpelainen suggest that when the tubers are covered by mud, they may remain dormant until the next season or become part of the diaspore bank to recolonize if the population is destroyed or if the growing season is extended with plentiful water.

Fungal Interactions

In Panama, fungal endophytes are known from *Cyathodium spruceanum* (Figure 50) (Salazar Allen & Korpelainen 2006). These interactions have barely been explored by bryologists, but mycological literature is not so scarce.

Biochemistry

As in *Cyathodium bischlerianum* (Figure 10), *C. spruceanum* (Figure 50) has less than 3% of the sesquiterpenes germacrene D and bicyclogermacrene (Salazar Allen *et al.* 2017). Oil bodies are present in all cells with the chloroplasts in this species, but the odor is not as offensive as that of *C. foetidissimum*. Nevertheless, the researchers identified far more volatile compounds in *C. spruceanum* than in the other four *Cyathodium* species assessed. Salazar Allen and coworkers identified 12-norcyercene B (70.2%), germacrene D (1.6%), and longifolinaldehyde (1.4%).

Dumortieraceae

Dumortiera hirsuta (Figure 53-Figure 55)

Most bryologists seem to recognize only one species of *Dumortiera* (Figure 53-Figure 55). However, Forrest *et al.* (2011) found two very distinct lineages, represented by ssp *hirsuta* (Figure 53-Figure 55) and ssp *nepalensis* (Figure 102-Figure 103). One (ssp. *hirsuta*) is restricted to Central America and the other (ssp. *nepalensis*) is more widely distributed throughout the range of the genus. See also the discussion of Taiwan populations (Akiyama *et al.* 2003). Forrest and coworkers concluded that there are at least two distinct species, a conclusion reached by O'Hanlon in 1934, but that the molecular basis for naming these is not known for much of the distribution. Therefore, in this chapter I will treat all as *Dumortiera hirsuta* (Figure 53-Figure 55) since most of the publications cited here do not distinguish these.

More recently, the chloroplasts (Kwon *et al.* 2019a) and mitochondria (Kwon *et al.* 2019b) of Korean populations of this liverwort have been sequenced.

Distribution

Dumortiera hirsuta (Figure 53-Figure 55) is widely distributed in tropical and subtropical regions, extending into some temperate regions (O'Hanlon 1934; Forrest *et al.* 2011). It is rare in Europe (Aleffi *et al.* 1998), reaching its northernmost distribution in the UK (Callaghan 2020). In the same year Gaston (2020) found it in France.

This distribution includes more humid and warmer regions of the temperate zones of India, Nepal, Japan, Brazil, México, Jamaica, North and South America, Europe, British Isles, New Zealand, Hawaii, and Africa (O'Hanlon 1934; Nair *et al.* 2005). In the USA it is found in southeastern states, including Arkansas (Timme & Redfearn 1997).

Aquatic and Wet Habitats

Reeb *et al.* (2018) describe the habitat of *Dumortiera hirsuta* (Figure 53-Figure 55) as a shady, humid environment. Tosun *et al.* (2015) considered it to be a large thalloid on wet rocks. Gaston (2020) described it as a pantropical hydrophile.

Dumortiera hirsuta (Figure 53-Figure 55) occurs on dripping rocks (Watson 1919). Ruttner (1955) reported it in water spray, tuff wall, <40 cm above water level, and waterfalls (Figure 1) in the tropics. McAllister *et al.* (2019) found it to be common on rocks in deep canyons, in riparian habitats, on seepy hillsides, and abundant on shale near seepages. It could occur near tributaries, on slopes near or on the underside of sandstone ravines, and at springs (Figure 56-Figure 60).

Vieira *et al.* (2005) found that in Portugal it was not extensive but seemed stable in steep, water-dripping granite surfaces next to waterfalls. It was also found at the margin of fast flow in a streambed, where it was submerged for long periods and grew associated with *Plagiothecium nemorale* (Figure 61), *Aneura pinguis* (Figure 62), *Pellia epiphylla* (Figure 63), and *Riccardia multifida* (Figure 64), in mountain streams of northwest Portugal (Vieira *et al.* 2005).

In the UK, Callaghan (2020) found all colonies in close association with flowing and moderately alkaline water, including springs, flushes and streams (Figure 56-Figure 60). It never occurred within the **spate zone** (zone suddenly flooded) of larger rivers. It occurs almost entirely on rocks (mudstone, sandstone, slate), predominantly in deciduous woodland and only in lowland sites. In these locations, it occurs with *Thamnobryum alopecurum* (most frequent associate; Figure 65), and *Conocephalum conicum* (Figure 66), as well as *Chrysosplenium oppositifolium* (flowering plant; Figure 67). Ottley (2014) reported a "strong colony" from dripping rocks at Rolvenden in the UK.

In the western Himalayas, Pant and Tewari (1984) found *Dumortiera hirsuta* (Figure 53-Figure 55) in tufaceous aquatic habitats, perennial springs, **Gadheras** (small river tributaries; active only during rainy season and stay wet and damp throughout year for growth of bryophytes), and the muddy banks of **Gadhs** (broad rivulets that never dry, resulting from joining of Gadheras). Srinivasan (1968) reported that in India it is often seen in very wet, shady situations where the flow is continuous or at least dripping.

In Java, Indonesia, Nadhifah *et al.* (2018) reported that in the Cibodas Botanical Garden this liverwort occurred on soil in wet areas such as rivers, waterfalls, and ponds. Gradstein (2006) reported that *Dumortiera* sp. was successfully cultivated in association with a small river and pond at the Cibodas Botanical Garden.

In China, *Dumortiera hirsuta* (Figure 53-Figure 55) occurs on brook sides, valleys, or slopes, in wet, mesic, or moist localities, usually in partial or full shade of forested habitats in **orotemperate** (temperate mountain climate) of deciduous and warm temperate evergreen primeval or secondary forests (Piippo & Koponen 2013).

Colon (2000) found it in limestone sinkholes in the karst zone of Puerto Rico, where it had the highest importance value among species in the Empalme Sink.

Not all of its habitats are aquatic. It occurs in oak-hickory forests with shale and sandstone, but still near streams (McAllister *et al.* 2019).

Physiology

Dumortiera hirsuta (Figure 53-Figure 55) is shade adapted (Callaghan 2020). The linear flow of electrons in photosystem II experiences a sharp decline when the photon flux density is greater than $200 \mu\text{mol m}^{-2} \text{s}^{-2}$. The chlorophyll *a:b* ratio was 1.61, contrasting with that of 2.04 in *Phaeoceros carolinianus* (Figure 68), a species of somewhat sunny habitats (Zhang *et al.* 2018). This means that the *D. hirsuta* has more chlorophyll *b*, an adaptation to low light. Duckett and Ligrone (1993, 2006b) reported massive grana and stromal crystals in the chloroplasts and considered it to be a species of extreme shade. The thylakoids in the grana often exceeded 100 (Duckett & Ligrone 2006b). All of these characteristics are consistent with adaptations to shade conditions.

Figure 68. *Phaeoceros carolinianus*, a somewhat sunny species with a higher Chlorophyll *a:b* ratio. Photo by Hermann Schachner, through Creative Commons.

Devi *et al.* (2015) found seasonal variation in the photosynthetic pigments of *Dumortiera hirsuta* (Figure 53-Figure 55). They found that chlorophyll *a* remained higher than chlorophyll *b* in *Dumortiera hirsuta* in all seasons. Chlorophyll *a* is at its lowest levels in winter, whereas there was no seasonal pattern for chlorophyll *b*. Total chlorophyll reaches its greatest levels at the end of the growing season. The carotenoid content was much lower in winter ($0.06 \pm 0.005 \text{ mg g}^{-1}$ fresh weight) than in the rainy season ($0.16 \pm 0.005 \text{ mg g}^{-1}$ fw) or the end of the growing season ($0.15 \pm 0.005 \text{ mg g}^{-1}$ fw).

Bold (1938) demonstrated that the sporophyte is strongly photosynthetic during development in *Dumortiera hirsuta* (Figure 53-Figure 55), exhibiting chloroplasts in the immature foot cells, seta cells, capsule wall cells, and elaters. This photosynthetic ability would provide greater energy for developing spores.

Beckett (1993) found that the turgor of *Dumortiera hirsuta* (Figure 53-Figure 55) correlates well with the other indicators of water stress damage, including photosynthesis, respiration, and potassium loss. The rate of respiration dropped to zero following desiccation and the plants did not recover. This was similar to results of other desiccation-intolerant liverworts such as *Conocephalum conicum* s.l. (Figure 66) (Slavik 1965). However, such measures of intolerance must be reviewed because we now know that the rate of desiccation can have a profound effect on the survival and recovery from desiccation. He developed a successful method, using a thermocouple psychrometer, to correct for apoplastic water. Nevertheless, he found that the error introduced by apoplastic water was negligible.

Loo (2005) noted the difficulties in studying the cytology of *Dumortiera hirsuta* (Figure 53-Figure 55). Nevertheless, Loo *et al.* (2005a) presented a cytological study on this species. In a separate publication (2005b), they reported that *Dumortiera hirsuta* survived at 47-1511 lux, 15-27°C, and relative humidity of 60-95% on Mt. Kinabalu. Frahm *et al.* (1996) considered the minimum light level for photosynthesis to be 400 lux. The numbers presented by Loo and coworkers suggest that this species has a good tolerance range of the physical parameters of the environment.

Proctor *et al.* (1998) found that the full-turgor water content reached 1400% in *Dumortiera hirsuta* (Figure 53-

Figure 55). In a different study it was 1636% (Proctor 1999). These are much higher figures than those in the mosses *Syntrichia ruralis* (Figure 16) or *Andreaea alpina* (Figure 69) (Proctor *et al.* 1998). Beckett (1993) found that *D. hirsuta* was very sensitive to desiccation. The cells lost potassium, and during drying the thallus continued respiration while shutting down photosynthesis, causing the thalli to lose weight. He used this species to show that turgor loss correlated with other indicators of stress-induced damage.

Figure 69. *Andreaea alpina*, a species with a much lower full-turgor water content than that of *Dumortiera hirsuta*. Photo by Stephen Moores, through Creative Commons.

Marschall and Beckett (2005) found that ABA and partial dehydration hardening can increase desiccation tolerance, with *Dumortiera hirsuta* (Figure 53-Figure 55) being much more responsive to ABA treatment than was *Atrichum androgynum* (Figure 70). Furthermore, unlike *A. androgynum*, *D. hirsuta* did not exhibit increased NPQ (non-photochemical quenching) or decreased PSII efficiency with dehydration hardening. It also had little change with partial dehydration hardening before the onset of stress, but following rehydration it displayed a 22% improvement in PSII activity within an hour.

Figure 70. *Atrichum androgynum*, a species that is more resistant to cadmium damage than is *Dumortiera hirsuta*. Photo by Niels Klazenga, through Creative Commons.

Many bryophytes are now known to produce superoxide during rehydration. *Dumortiera hirsuta* (Figure 53-Figure 55) is among those that produce extracellular superoxide rapidly, even when not stressed (Beckett *et al.* 2004). Nevertheless, the production of superoxide increases greatly in this species during rehydration even after a mild desiccation stress. There are indications that this production provides an important protection against invasion of bacteria and fungi during the period of membrane repair. (See Chapter 19 in Volume 2.)

Li *et al.* (2010) determined that cell wall peroxidases are responsible for the extracellular burst of superoxide in *Dumortiera hirsuta* (Figure 53-Figure 55). They also found that this oxidative burst may have roles in formation of protective substances such as suberin, melanin, and lignin, supporting the hypothesis that the burst of superoxide enhances protection against pathogens. These peroxidases might also have a role in signal transduction and protection against abiotic stress and Yadav *et al.* (2022) looked at seasonal changes in chemical constituents of *Dumortiera hirsuta* (Figure 53-Figure 55), particularly changes in oxidative stress responses. In the fruiting season, the plants had their highest level of malondialdehyde (MDA) and H_2O_2 , with the lowest levels occurring during the premonsoon and monsoon seasons. Protein content and pigment concentrations were maximal during the monsoon season and minimal during the fruiting season. On the other hand, the enzymatic activity and content of superoxide dismutase, catalase, and glutathione reductase and non-enzymatic antioxidants were higher during the fruiting season and low during the pre-monsoon and monsoon seasons. During the fruiting season, the temperature is very low and nutrient availability is diminished. Hence these activities provide a defense in neutralizing or suppressing the increased ROS (reactive oxygen species) during the fruiting season. The researchers suggested that the antioxidative defence system may have a role in the adaptation of the species against oxidative stress, mediated by seasonal changes.

Heavy metals are often a component in aquatic and semi-aquatic environments. These are often toxic to plants, including bryophytes, but the latter seem to have at least some coping mechanisms. Heavy metals can interact to provide varying responses in *Dumortiera hirsuta* (Figure 53-Figure 55). It exhibits both internal and external cadmium uptake (Mautsoe & Beckett 1996). The intracellular uptake is linear with time, displaying Michaelis-Menten kinetics, whereas the extracellular uptake exhibits saturation kinetics [$K(m)$ and $V(max)$ $149 \pm 19 \mu M$ & $11.0 \pm 0.8 \mu M g^{-1} h^{-1}$ respectively]. Both are temperature dependent and intracellular uptake is light stimulated, increasing by about 15. Incubation with Cd and equimolar concentrations of Ca, Mg, or Zn reduced both intracellular and extracellular uptake. Pretreating the thalli with KNO_3 stimulated Cd uptake, most likely due to the ability of the K to remove competing ions from the cell walls, a technique used to measure cation exchange. All of this suggests the involvement of cation exchange in the uptake of cadmium. The researchers suggested that such exchange sites might protect the liverworts by securing the heavy metal ions outside the cell.

When Mautsoe and Beckett (1996) explored the effects of Cd on *Dumortiera hirsuta* (Figure 53-Figure 55), they

found that intracellular Cd uptake was linear, but extracellular uptake exhibited saturation kinetics. These uptake processes were temperature dependent. Light also stimulated intracellular uptake, but storage for 20 days in the dark did not affect it. Uptake decreased when the plants were incubated with additional Mg, Zn, or Cd, whereas pretreatment with KNO increased uptake, indicating cation exchange with the KNO clearing the exchange sites of cations. Such exchange sites might protect the liverworts by securing the heavy metal ions outside the cell.

Mautsoe (1997) found that photosynthesis of *Dumortiera hirsuta* (Figure 53-Figure 55) was more sensitive to Cd than it was in *Atrichum androgynum* (Figure 70), with differences directly related to intracellular Cd concentrations. These concentrations were considerably higher in *D. hirsuta*. Furthermore, in *D. hirsuta* the Cd caused K loss, but this did not occur in *A. androgynum*. Intracellular uptake in *D. hirsuta* was affected by thallus age, K pretreatment, and site characteristics.

Loo *et al.* (2005b) described the tolerance range of *Dumortiera hirsuta* (Figure 53-Figure 55) to occur within the 480-1740 m asl on Mt. Kinabalu. Here it experienced ranges of 47-1511 lux, 15-27°C, and 60-95% humidity. Hence we should expect it to be adapted to stresses within these ranges.

Adaptations

Butt and Anima (2011) found that *Dumortiera hirsuta* (Figure 53-Figure 55) in Bhaderwah, northwest Himalayas, exhibits great diversity of habitat, pH, and altitude, with accompanying diversity of morpho-anatomical characters of both gametophyte and sporophyte. Piippo and Koponen (2013) noted that this species is likely to include many cryptic taxa.

Although *Dumortiera hirsuta* (Figure 53-Figure 55) occurs in moist habitats, those are not always moist (Figure 71). Thus, the plants need mechanisms to protect vulnerable life cycle stages that coincide with less favorable seasons. Perhaps one such adaptation is that the archegonial head is covered with hairlike appendages (O'Hanlon 1934), suggesting an adaptation that protects the critical archegonia and developing sporophytes from drying out. The adult thallus has no lacunae (unfilled space or interval; gap) and no definite demarcation between the chlorophyllous and colorless cells, the latter being mostly in the central part of the thallus. Does the lack of lacunae suggest faster drying, or does the absence of these air spaces slow it down? Based on movement of water through stomata of tracheophytes, we can hypothesize that the absence of lacunae would slow down water loss. Researchers have demonstrated that stomatal-derived water loss from plants is ~50% of the total terrestrial evaporation and 80-90% of the continental evaporation (Hetherington & Woodward 2003; Jasechko *et al.* 2013).

There are only vestigial ventral scales (Figure 72) (McAllister *et al.* 2019) – structures that usually help in water movement, uptake, and conservation, perhaps causing the restriction of *Dumortiera hirsuta* to moist habitats. Watson (1919) considered that having few or no ventral scales is an adaptation or characteristic of a species from an aquatic habitat.

Figure 71. *Dumortiera hirsuta* with thallus showing signs of drying. Photo by Blanka Aguero, with permission.

Figure 72. *Dumortiera hirsuta* ventral side showing absence of or vestigial scales. Photo by Nicola van Berkel, through Creative Commons.

Adaptations may differ between lineages. The Central American lineage has plants with a light green velvety appearance, caused by abundant papillae on the upper surface (Forrest *et al.* 2011). The role of papillae has been controversial and unproven, including movement of water into cells in some species, scattering light, and reducing water loss. The more widespread lineage is dark green and papillae range from absent to dense; marginal hairs are usually abundant. It appears that these two lineages might have different adaptations to surviving periods of drought and receding water.

Dumortiera hirsuta (Figure 53-Figure 55) is polyploid, with populations exhibiting monoploid or diploid gametophytes (Tatuno 1938, 1939). It is likely that the differences between monoploid and diploid gametophytes of *Dumortiera hirsuta* might confer some differences in adaptations. In some cases, some alleles of diploids were missing among monoploids, but both types shared the character of upright, short hairs scattered on the dorsal surface (Akiyama *et al.* 2003). In Taiwan populations, Akiyama and coworkers found that monoploids could grow on non-calcareous substrata, a single population could have different levels of ploidy, heterozygosity is fixed in diploids, and there are at least four monoploid lineages ("species" according to Akiyama *et al.*). The evidence suggests that these diploids are **allopolyploids** (two or more chromosome sets originating

as complete sets from different species or lineages). The presence of multiple chromosome sets and lineages would provide greater variation, thus permitting the species to survive a wider range of conditions.

Storage compounds can vary with seasons. Kapila *et al.* (2014) compared three liverworts and found that the more hydric *Dumortiera hirsuta* (Figure 53-Figure 55), with a habitat near streams or other hydric locations, exhibits higher carbohydrate and protein content with little seasonal change compared to *Marchantia emarginata* (Figure 73) and *M. paleacea* (Figure 74), both of mesic habitats. All three species experienced a decrease in α -amylase, β -amylase, and invertase near the end of the primary growth season due to carbohydrate accumulation in their tissues. There was an inverse relationship between protein and free amino acids. Protease activity, associated with protein metabolism, peaked in the rainy season.

Reproduction

Mcallister *et al.* (2019) considered *Dumortiera hirsuta* (Figure 53-Figure 55) to be **monoicous**. But Bischler-Causse *et al.* (2005) considered it to be **monoicous** or **dioicous** (Figure 75-Figure 77). It has no known asexual propagules.

Figure 75. *Dumortiera hirsuta*, with emerging archegoniophores. Photo by Cheng-Tao Lin, through Creative Commons.

Figure 76. *Dumortiera hirsuta* with archegoniophores. Photo by Luis Funez, through Creative Commons.

Shimamura (2015) reported that the sperm possessed four flagella and experienced aerial dispersal. This species was the first to be documented with explosive sperm dispersal. Small droplets with sperm cells are expelled several centimeters into the air from the antheridial disk. Even in monoicous plants, this explosive dispersal facilitates the cross-fertilization between male and female reproductive structures on different individuals.

From South Carolina, USA, Patterson (1933) reported that male receptacles were initiated 11-19 August, with female receptacles (Figure 77) appearing 5-12 September. Fertilization occurred primarily 25 September to 5 October. Young embryos appeared 5 October to 15 October. Sporophytes developed in November and December, with meiosis occurring 26 January to 4 February. Meanwhile, the antheridial branches withered 20 December to 20 January. Spores matured in February. In March, the capsules blackened, fertile thalli were dying, and the receptacles elongated. In April the setae elongated and the spores were dispersed. Precipitation modified this schedule from year to year. Patterson detailed the development of the reproductive structures. One unusual character is that some receptacles have both male and female gametangia,

but these do not occur on the same radii, with radii of the same sex grouped together. These receptacles with both sexes were relatively common in populations from Jamaica, but were rare in the North Carolina populations.

Figure 77. *Dumortiera hirsuta* young archegoniophores. Photo by Lin Kyan, with permission.

All the archegonia within an involucre may experience fertilization, but only one will get beyond the 2-8 cell stage (Patterson 1933).

In the UK the production of sporophytes is rare (Callaghan 2020). Since the seasons there are quite different from those in the tropics, temperature, day length, and rainy season might modify the reproductive timing so that it is unlikely to be successful.

Patterson (1933) reported the species producing sporophytes (Figure 78-Figure 80) on the bank of a small stream near Columbia, South Carolina, USA. O'Hanlon (1934) found that only one or two sporophytes (Figure 81) in each of the typically eight groups of archegonia are able to reach maturity. In Florida, USA, O'Hanlon found ripe spores (Figure 82-Figure 83) in the middle of April. They remain viable for only a short time after dehiscence. In the lab they germinate within 6-7 days on a liquid medium.

Figure 81. *Dumortiera hirsuta* with mature sporangia, showing only 1-3 mature sporangia per archegonial head. Photo by tigris 8, through Creative Commons.

The young sporocyte has a single large plastid, but the plastid divides before the nucleus divides, resulting in four plastids (Shimamura *et al.* 2000). These often continue to divide before nuclear division. The cytoplasm forms lobes around the four plastid domains, enclosing at least one plastid. This monoplastidic meiosis is rare among liverworts.

O'Hanlon (1934) found that *Dumortiera hirsuta* (Figure 53-Figure 55) produces 1-2 sporophytes (Figure 82) that reach maturity among the eight groups of archegonia. Spores reach maturity in mid April in Florida, USA. They remain viable only a short time after the capsule dehisces. These spores germinate within 6-7 days after culturing in a liquid medium. The spore first produces a rhizoid; then a bud forms from the spore.

The young sporocyte has a single large plastid, but the plastid divides before the nucleus divides, resulting in four plastids (Shimamura *et al.* 2000). These often continue to divide before nuclear division. The cytoplasm forms lobes around the four plastid domains, enclosing at least one plastid. This monoplastidic meiosis is rare among liverworts.

Miyoshi (1973) described the spore wall structure of *Dumortiera hirsuta* (Figure 53-Figure 55). Kamimura (1973) used the electron microscope to help describe the

fine structure of the spore walls. Pyramidal or rectangular planks or columnar protuberances have irregular patterns on the surfaces of the spore walls. Two-three of these protuberances frequently form lamellae. The foundation of the spore wall is nearly smooth.

Role

This species surely plays a greater role in housing invertebrates than the examples we know (Figure 84). And what might its role be in stabilizing the banks of streams during high water? The ecosystem role of *Dumortiera hirsuta* (Figure 53-Figure 55) remains mostly unexplored.

Figure 84. *Dumortiera hirsuta* with snail, a potential herbivore on this species. Photo by Chaturvedi, with permission.

Interactions

Iqbal *et al.* (2011) enumerated the wide array of organisms associated with *Dumortiera hirsuta* (Figure 85), including fungi, other bryophytes, pteridophytes, gymnosperms, angiosperms, and insects. In Bhaderway in the Doda district of Jammu, India, in the range of 1230-2600 asl *Conocephalum conicum* (Figure 66) formed the most frequent associations, but these researchers found 12 species of plants and one insect that were frequently associated with *D. hirsuta*.

Figure 85. *Dumortiera hirsuta* with the moss *Sematophyllum* sp. in India. Photo by Syamal L, through Creative Commons.

Fungal Interactions

The fungi associated with *Dumortiera hirsuta* (Figure 53-Figure 55) remain unexplored. The species has antifungal properties (Alam *et al.* 2011), but that is not usually enough to deter all fungi. And are those antifungal compounds produced by the liverwort, or by associated bacteria?

Alam *et al.* (2011) found that treatment of *Aspergillus niger* (Figure 86) by extracts from *Dumortiera hirsuta* (Figure 53-Figure 55) caused distinct morphological changes in the fungus. These included anomalies in the hyphae, flaccid cell wall, and cytoplasm leaking through cell wall and becoming granulated.

Figure 86. *Aspergillus niger*, a species that exhibits morphological aberrations after exposure to extracts of *Dumortiera hirsuta*. Photo from CDC, through public domain.

Egertová *et al.* (2018) described a new species of Ascomycetes growing on *Dumortiera hirsuta* (Figure 53-Figure 55). *Octosporopsis erinacea* (Figure 87) parasitizes the thallus, exhibiting tiny, light yellow, rimless apothecia. The hyphae develop both on and within the cells of the thallus, especially near a waterfall.

Figure 87. *Octosporopsis erinacea*, a species of Ascomycetes that parasitizes the thallus of *Dumortiera hirsuta*. Photo by Z. Egertová, through Creative Commons.

Animal Interactions

Among the inhabitants of *Dumortiera hirsuta* (Figure 53-Figure 55) is the odonate *Epiophlebia superstes* (Figure

88) (Asahina & Sugimura 1981). This odonate is intermediate between dragonflies and damselflies. It injects its eggs into the thallus of *D. hirsuta*. Later, Carle (2012) described the new species *Epiophlebia diana* from naiads in China. However, Büsse and Ware (2022) have considered it to be a synonym of *Epiophlebia laidlawi* (Figure 89), occurring in Nepal, India, Bhutan, and Vietnam. Members of this genus in China typically choose plants growing in wet and mostly shaded areas less than a meter from a stream.

Figure 88. *Epiophlebia superstes* on bryophytes. Photo by Tom Kompier, with online non-commercial permission.

Figure 89. *Epiophlebia laidlawi* naiad, an inhabitant of *Dumortiera hirsuta* in China. Photo modified from Robert John Tillyard, through public domain.

Lien (1989) suggested that species of biting midges (*Ceratopogonidae*: *Lasiohelea*) that rest on *Dumortiera hirsuta* (Figure 53-Figure 55) and other bryophytes are likely to be feeding on the *Cyanobacteria* (Figure 32) that are growing there. Lien found that *Anabaena* sp. (Figure 90) is especially beneficial for *Forcipomyia anabaenae* (see Figure 91), in a closely related genus.

Figure 90. *Anabaena circinalis*; the genus *Anabaena* is a beneficial food for some biting midges that visit bryophytes. Photo by B D Carl, through Creative Commons.

Biochemistry

Dumortiera hirsuta (Figure 53-Figure 55) has been the subject of a number of biochemical studies. Matsuo *et al.* (1976) reported 10 sesquiterpene hydrocarbons from *Dumortiera hirsuta*. Toyota *et al.* (1997a,b) reported on a new sesquiterpene compound and 13 additional known compounds from the species and described their structures. Saritas *et al.* (1998) added additional sesquiterpenes to this list, some of which were rare or unusual. To these, Lu *et al.* (2006) added more compounds (terpenoids and bisbibenzyls from Chinese populations, including riccardin D) and described their structure. Some of these were cytotoxic to the human HepG2 cells. One was also active against *Pseudomonas aeruginosa* (Figure 95).

Figure 95. *Pseudomonas aeruginosa*, a species that experiences toxicity from one of the compounds produced by *Dumortiera hirsuta*. Photo by Janice Haney Carr, CDC, through public domain.

Liu *et al.* (2012) found that riccardin D (a macrocyclic bisbibenzyl compound), a product of *Dumortiera hirsuta* and other liverworts, was effective at inhibiting intestinal adenoma from forming in mice. Its effectiveness is through multiple mechanisms, including anti-proliferative, apoptotic, anti-angiogenic, and anti-inflammatory activity. Xue *et al.* (2012) found that the riccardin D also induces apoptosis of human leukemia cells.

Xie and Lou (2008) identified two calamenane-type sesquiterpenoids (5,7-dihydroxycalamenene and 7-hydroxycalamenene) from *Dumortiera hirsuta* (Figure 53-Figure 55). Bardón *et al.* (1999) isolated dumortane sesquiterpenes, four new, from Argentine populations of *Dumortiera hirsuta* (Figure 53-Figure 55). Linde *et al.* (2016) considered that the presence of dumortane-type sesquiterpenoids in *D. hirsuta* from South Africa indicated that this species is similar in chemistry to an Argentinean sample.

Xie *et al.* (2007) reported an unusual phenylethyl cyclohexadienone (dumhirone A) from Chinese populations of *Dumortiera hirsuta* (Figure 53-Figure 55).

Alam *et al.* (2011) found that aqueous extracts of *Dumortiera hirsuta* (Figure 53-Figure 55) were effective against seven plant pathogens. Six of seven plant pathogenic fungi were completely inhibited by the extract at 550-600 ppm. Joshi (1993) also found extracts to be effective against bacteria. Kumar *et al.* (2007) likewise found that extracts of this liverwort in Indian Himalayas were effective in enhancing wound healing due to its antibacterial properties.

Setyati *et al.* (2021) found that extracts from *Dumortiera hirsuta* (Figure 53-Figure 55) were able to prevent infection by pathogenic bacteria, including flavonoids, alkaloids, and steroids. These were able to inhibit the bacteria *Escherichia coli* (Figure 48), *Staphylococcus aureus* (Figure 47), and *Salmonella typhi* (Figure 96), causing weak to moderate responses (see also Luthfiah *et al.* 2021). Junairiah *et al.* (2015) similarly found that ethylacetate extracts of *D. hirsuta* from Indonesia contained flavonoids, alkaloids, and steroids that can inhibit the pathogenic bacteria *Staphylococcus aureus* and *Escherichia coli* and the yeast *Candida albicans* (Figure 97).

Figure 96. *Salmonella typhi*, a species that is inhibited by extracts from *Dumortiera hirsuta*. Photo by CDC, through public domain.

Figure 97. *Candida albicans* SEM, a yeast species that is inhibited by extracts from *Dumortiera hirsuta*. Photo by Vader1941, through Creative Commons.

An aqueous extract from *Dumortiera hirsuta* (Figure 53-Figure 55) exhibited fungitoxicity against seven plant pathogenic fungi, inhibiting their ability to produce germinable spores (Alam *et al.* 2011). Morphological aberrations were present in *Aspergillus niger* (Figure 86) treated with extracts of *Dumortiera hirsuta*.

Mukherjee *et al.* (2012) examined antibacterial activity of *Dumortiera hirsuta* (Figure 53-Figure 55) against *Serratia marcescens* (Figure 98) from various altitudes in the Himalayas. Those plants from higher altitudes exhibited slightly less antibacterial activity than those from lower altitudes. The reproductive thallus extracts exhibited less antibacterial activity than did the vegetative thallus.

Figure 98. *Serratia marcescens* on bread, a bacterial species that is inhibited less by populations of *Dumortiera hirsuta* from higher elevations than by those at lower elevations. Photo by DBM, through Creative Commons.

Noting that *Dumortiera hirsuta* contains the bioactive alkaloids, terpenoids, flavonoids, and saponin, Sari (2014) explored its usefulness in the treatment of malaria. It was effective in treating parasitemia caused by *Plasmodium berghei* (Figure 99) in mice, so its usefulness against *Plasmodium malariae* (Figure 100) was worth exploration. Unfortunately, in their further experiments against *P. berghei* in mice, they found that it damaged microanatomical structures in the liver and kidneys at levels of 300 mg kg⁻¹ BW and above.

Figure 99. *Plasmodium berghei*, a species that can be inhibited successfully by extracts of *Dumortiera hirsuta*. Photo by C. J. Janse, through Creative Commons.

Figure 100. *Plasmodium malariae*, a species that might be inhibited by extracts of *Dumortiera hirsuta*. Photo by Mae Melvin, CDC, through public domain.

Shirzadian *et al.* (2009) found that ethanolic extracts of *Dumortiera hirsuta* (Figure 53-Figure 55) exhibited one of the broadest spectra of antifungal activities shown by the 23 bryophytes tested. Luthfiah *et al.* (2021) noted that this species can be used medically to prevent bacterial infection.

Asakawa (1982) used the terpenoids and aromatic compound differences to argue for separation of *Wiesnerella denudata* (Figure 101) and *Dumortiera hirsuta* (Figure 53-Figure 55) into different families. Those sesquiterpene lactones and monoterpenoids occurring in *W. denudata* appear to be absent in *D. hirsuta*. This supports the morphological differences also known between these two species. Kraut *et al.* (1996) reported several carboxylated α -pyrone derivatives and flavonoids from *Dumortiera hirsuta* and elucidated structures.

In their attempts to distinguish differences in secondary compounds between *D. hirsuta* ssp. *hirsuta* (Figure 53-Figure 55) and *D. hirsuta* ssp. *nepalensis* (Figure 102-Figure 103). Durant-Archibold *et al.* (2018) reported 34 compounds for the first time in the species *Dumortiera hirsuta*. They found that the two subspecies differed biochemically.

Figure 101. *Wiesnerella denudata* in Bhutan, a species wherein chemical differences separate it from *Dumortiera hirsuta*. Photo by David Long, with permission.

***Dumortiera hirsuta* ssp. *nepalensis* (Figure 102-Figure 103)**

(syn. = *Dumortiera trichocephala*)

Figure 102. *Dumortiera hirsuta* ssp. *nepalensis*. Photo courtesy of David Wagner.

Figure 103. *Dumortiera hirsuta* ssp. *nepalensis* from Bhutan. Photo courtesy of David Long.

In most cases, the subspecies *nepalensis* is considered as part of *Dumortiera hirsuta*, but it has been classified as a variety, a subspecies, and even a species. In the foregoing discussion I have considered *Dumortiera hirsuta sensu lato*. However, since I did find some separate information on it, I shall comment on that with the anticipation that it might be officially removed from *D. hirsuta* in the future.

Distribution

In 1919, Evans considered this to be the separate species *Dumortiera nepalensis* (Figure 102-Figure 103). He described its distribution as close to that of *D. hirsuta* (Figure 53-Figure 55), but absent in Europe and Africa. But it is rare in much of its range, especially the southern United States and West Indies, and David Long (pers. comm. 26 June 2022) considers these populations to belong to *Dumortiera hirsuta* ssp. *hirsuta* (Figure 53-Figure 55). *Dumortiera hirsuta* ssp. *nepalensis* (Figure 102-Figure 103) is most abundant in southeastern Asia.

Aquatic and Wet Habitats

Dumortiera hirsuta ssp. *nepalensis* (Figure 102-Figure 103) occurs submersed under water jets, above the water level, and in waterfalls in the tropics (Ruttner 1955). David Long (pers. comm. 26 June 2022) reports the subspecies from the slope of dry rocky side valley and under overhanging dripping rocks by roads in the Tashigang districts south of Tashi Yangtse, Bhutan.

Biochemistry

Durant-Archibold *et al.* (2018) found that the major volatile compounds in *Dumortiera hirsuta* ssp. *nepalensis* (Figure 102-Figure 103) from Panama were ledene, α -gurjunene, β -caryophyllene, and α -guaiene, differing from those of the subspecies *hirsuta*.

Summary

Cyathodium is **r-selected**. It has several species that occupy wet habitats in mostly tropical areas. Several species occur on stream and river banks, with *C. bischlerianum* and *C. cavernarum* typically closer to the water than is *C. spruceanum*. Species often have pungent odors, attesting to their unique secondary compounds. Others, such as *Cyathodium bischlerianum*, have pleasant odors suitable for cosmetics and soaps. Some species, such as *Cyathodium cavernarum*, have iridescent colors, but the function of those, if any, is unknown.

Dumortiera hirsuta has a similar distribution and occurs in splash zones of streams and waterfalls and on otherwise wet rocks. It is a shade-adapted species that otherwise occupies a wide range of habitat conditions, pH, and altitude. There are flies in **Agromyzidae** and **Ceratopogonidae** that are specialists on it. In some cases, the invertebrates occur there to consume associated **Cyanobacteria**. The secondary compounds of *D. hirsuta* possess antibiotic and medicinal properties.

Acknowledgments

Lars Söderström helped me find the current acceptable names for a number of older taxa.

CHAPTER 1-23

AQUATIC AND WET MARCHANTIOPHYTA, CLASS MARCHANTIOPSIDA: MARCHANTIACEAE, PART 1

Figure 1. *Marchantia debilis* on emergent rocks in Madagascar. Photo courtesy of Catherine Reeb.

Marchantiaceae

Marchantia

Marchantia is widespread in the world. In the western Cascade Mountains, Oregon, USA, it is a pioneer **riparian** (relating to wetlands adjacent to rivers and streams) genus (Campbell & Franklin 1979). Several species in this genus are associated with wet habitats, with some occasionally becoming submersed.

Like most of the older taxa, this genus has a history of species synonyms (Bischler-Causse 1993). For example, of the 28 species described in Africa, Bischler-Causse reduced them to only 6, although another 8 remained unresolved.

Zheng *et al.* (2020a) have suggested that the morphology of the gemmae can be used to help in separation of the taxa, and that molecular analyses support these separations.

Bischler-Causse (1993) suggested that dispersal of at least some of the species seems to be limited by temperature extremes, but the species also require water throughout the year, free space, and light, thus limiting their success in much of the dry parts of the African continent. This distribution is further limited by the low level of sexual reproduction, relying on vegetative multiplication – a means that is more limited in dispersal distance.

Although *Marchantia polymorpha* (Figure 2) is by far the liverwort of choice, other species have been important

in unravelling the genetic and evolutionary history of liverworts. Marks *et al.* (2019a,b) presented the genome assembly for *Marchantia inflexa* (Figure 3-Figure 4) and found evidence suggesting that dehydration tolerance may be related to sex-specific genes in *Marchantia*. They found that the genes on the sex chromosomes experience greater diversifying selection than do the autosomal and organellar genes.

Figure 3. *Marchantia inflexa* females, a species where dehydration tolerance may be related to sex-specific genes. Photo by Amelia Merced, with permission.

Figure 4. *Marchantia inflexa* with gemmae. Photo by Alan R. Franck, through Creative Commons.

Ahmad (1981) described the historical studies on spore germination and gametophyte development in *Marchantia*.

Marchantia berteriana (Figure 5-Figure 7)

(syn. = *Marchantia cephaloscypha*, *Marchantia tabularis*)

Campbell (1965) reviewed some of the history of the nomenclature for this species. Another species recorded for New Zealand and described by Stephani (1883), namely *M. cephaloscypha*, is considered by Evans after examination of an original specimen to correspond with *M. berteriana* (Evans 1917). In Columbia, Herzog (1934) described the variety *polylepida*, but that is now considered to be *M. berteriana* as well.

Distribution

Marchantia berteriana (Figure 5-Figure 7) is known in Australia, New Zealand (Campbell 1965; Wikipedia 2021), Southern Africa (Perold 1995; Lüth & Schafer-Verwimp 2004; Phephu 2012a,b), South America (Costa Rica to the Antarctic Peninsula) (Hassel de Menendez 1962; Campbell 1965; Lüth & Schafer-Verwimp 2004), Antarctica (Davey 1997), and non-continental locations such as Papua New Guinea, Java, New Caledonia, and various smaller islands (Driessen 2009; Wikipedia 2021). Phephu (2012a) noted that this species is prevalent in the winter-rainfall region of South Africa, but it also grows in regions that receive summer rain in KwaZulu-Natal, Mpumalanga and Limpopo provinces.

Figure 7. *Marchantia berteriana* vegetative thallus with gemmae cups. Photo by Clive Shirley, Hidden Forest, with permission.

Aquatic and Wet Habitats

Marchantia berteriana (Figure 5-Figure 7) lives in constantly damp, shaded areas (Figure 8) (Wikipedia 2021), including fresh water, waterfall splash zones, forest floors, and streambanks (Phephu 2012a,b). The species is widespread in New Zealand, especially near hot springs, and in southern Africa in swampy areas, **kloofs** (steep-sided wooded ravine or valley in Africa), gorges, and burned areas (Campbell 1965; Perold 1995). Li Zhang (pers. comm. 4 August 2022) found it growing in peatlands in Chile (Figure 9). It also occurs in peatlands in Colombia (Campos 2014). On the Juan Fernández Islands, it grows in expansive colonies on the mountain tops (Figure 10-Figure 11) where clouds most likely maintain its needed moisture levels.

Figure 11. *Marchantia berteriana* habitat on Alejandro Selkirk Island, Juan Fernández Archipelago, Chile. Photo by Pato Novoa, through Creative Commons.

In geothermal areas in the Antarctic, *M. berteroa* (Figure 5-Figure 7) can occur at surface temperatures of 25-35°C and subsurface temperatures of 50-60°C, although these underground temperatures have no direct effect on the bryophytes (Convey & Lewis Smith 2006). Lewis Smith (2005a,b) found that on Deception Island in the South Shetland Islands, a geothermal gully included *Marchantia berteroa* (Figure 5-Figure 7) as one of the colonizers, forming a peripheral zone at the margin of the primary moss vegetation, living on fine moist compacted clay. He attributed its abundance to the "copiously produced and widely dispersed gemmae."

Halloy (1991) reported *Marchantia berteroa* (Figure 5-Figure 7) from heated areas (Figure 12) in the Andes, at 6000 m asl. These communities comprised the highest elevation of the known autotrophic communities on the planet.

Figure 12. Geothermal fissure and *Sphagnum*; heated areas in the Andes can be suitable habitats for *Marchantia berteroa*. Photo from a geothermal vent in Iceland, by Janice Glime.

Despite its seeming preference for wet habitats, it is a colonizer on soil following fire in Tasmanian mixed forests (Duncan & Dalton 1982) and also in southern Africa (Perold 1995). The rapid germination of the spores and rapid development of the gametophyte gives the species an advantage in this habitat. Brasell and Mattay (1984) found it as a colonizer in burned *Eucalyptus* forest (Figure 13) in Tasmania, where it accumulated a high concentration of potassium. In these forests, N, P, K, and Ca, but not Mg, all decreased with time following the fire. Brasell *et al.* (1986) found that *Marchantia berteroa* contributed significantly to nitrogen fixation in burned sites of southern Tasmania, greatly exceeding rates of bryophytes in unburned forests.

Figure 13. *Eucalyptus* forest at Sherbrooke, Victoria, Australia – fire-adapted forest where *Marchantia berteroa* often appears after fire. Photo by Patche99z, through public domain.

Duncan and Dalton (1982) showed that *Marchantia berteroa* spores germinated well on burned ground. The protonemal growth is more rapid than that of the non-colonizing species, giving the *M. berteroa* a chance to establish before other, more competitive species arrive.

Phephu (2012a) considers *Marchantia berteroa* to be important in nutrient cycles and erosion control, thus stabilizing the soil.

Physiology

Davey (1997) used measurements of respiration, photosynthesis, irradiance, and temperature to model the year-round net productivity of *Marchantia berteroa* (Figure 5-Figure 7), estimating a yearly net productivity of $823 \pm 75 \text{ mg C g}^{-1}$ ash-free dry weight. Desiccation was highly adverse to the thalli (Figure 14). Below a water content of 12 g g^{-1} ash-free dry weight the photosynthetic capacity was reduced. Recovery was only ca. 10% after dehydration and rehydration. Freezing also caused great photosynthetic reduction, although the model indicated that this species should be able to photosynthesize at sub-zero temperatures. Davey suggested that the photosynthetic capacity and freezing tolerance were likely to be seasonal.

Figure 14. *Marchantia berteroa* showing dying edges, suggesting drought damage. Note its low-lying habit on the mosses. Photo by Andrew Hodgson, with permission.

Despite that fact that the model indicates that freezing causes a great reduction in photosynthesis, the model suggests that photosynthesis at sub-zero temperatures is, nevertheless, likely (Davey 1997). It is suggested that seasonality in the photosynthetic capacity and the survival of these plants subjected to sub-zero temperatures might be important. However, their distribution is likely to be limited by available moisture.

Green and Lange (1995) found that the CO_2 compensation point is much lower for *Marchantia berteroa* (Figure 5-Figure 7) in 2% oxygen than for the other bryophytes they tested, and that the compensation points rise with a rise in temperature, resulting in inhibition (Figure 15). Photosynthesis at 21% oxygen [usual atmospheric oxygen concentration on Earth (National Geographic 2022)] is depressed compared to that at 2% oxygen (Figure 16), with the depression increasing at higher temperatures.

Figure 15. Temperature effect on oxygen inhibition in *Marchantia berteroana*. Modified from Green & Lange 1995.

Figure 16. Temperature effect on CO₂ compensation point in *Marchantia berteroana*. Modified from Green & Lange 1995.

Adaptations

Marchantia berteroana (Figure 5-Figure 7) has scales on the lower surface, a common feature of the genus, but in this case they extend nearly to the margins (Phephu 2012a, b). These may be hyaline or colored reddish-brown (Campbell 1965). The thallus itself helps to maintain its moisture by its low-lying habit (Figure 14) that keeps it closer to the water in the soil and by reducing evaporation from the soil.

Like other members of *Marchantia*, the thalli have apical growing tips that are covered by scales (Figure 17). Presumably, these protect the important growing region from desiccation. When the older thallus dries out and dies, these apical areas can still retain living cells that can resume growth when favorable conditions return.

Figure 17. *Marchantia berteroana* thallus showing apical growing regions with apical scales covering them. Photo by Jan-Peter Frahm, with permission.

Reproduction

Marchantia berteroana (Figure 5-Figure 7) is **dioicous**, with a chromosome number of $n=9$ (Perold 1995; Phephu 2012a).

Males (Figure 18) are a bit larger than females (Figure 19-Figure 23) (Campbell 1965). In New Zealand, the antheridiophores (Figure 18) appear in August, followed in September by the archegoniophores (Figure 19-Figure 23).

Figure 18. *Marchantia berteroana* antheridiophore heads. Photo by Tom Thekathyl, with permission.

Figure 24. *Marchantia berteroana* archegoniophore heads with emerging open sporangia. Photo by Tom Thekathyl, with permission.

Markham *et al.* (1978) found that there is a "dramatic" change in flavonoid pattern of *Marchantia berteroana* (Figure 5-Figure 7) that accompanies sexual reproduction. Is this a consequence or an adaptation? It would be interesting to know the role of the change in compounds in reproduction. Markham and Porter (1975, 1978) found that the aurone aureusidin 6-O-glucuronide occurs in antheridiophores (Figure 18) of at least two species of *Marchantia*, one of which is *M. berteroana*. It is unknown from any other organ of the liverworts. In flowering plants it gives brighter yellow colors to the flowers (Nakayama 2022). Markham and Porter suggested parallel evolution in bryophytes and flowering plants, although the compound is not common even in flowering plants.

The sporophyte begins development the following spring, continuing through the summer (Phephu 2012a). Once it matures, its stalk elongates by absorbing water, causing the cells to stretch. This causes the sporangia to protrude from the archegonial head (Figure 24-Figure 25). When the sporangium breaks open, it exposes the spores and elaters (Figure 25). Wiggling of the elaters in response to humidity changes helps to disperse the spores. Once the spores are dispersed, the fragile stalk disintegrates.

Figure 25. *Marchantia berteriana* mature sporangia with elaters protruding. Photo by Tom Thekathyl, with permission.

On the Falkland Islands, *Marchantia berteriana* (Figure 5-Figure 7) forms extensive patches several meters in diameter, from sea level to mountain tops (Duckett *et al.* 2012). Although it seems typical for females of this species to dominate elsewhere (Garcia-Ramos *et al.* 2007; Groen *et al.* 2010a), these populations produced males and females in about equal proportion. Perhaps this sex ratio is regulated by environmental/climatic conditions?

We know that gemmae (Figure 26-Figure 27) are produced when the sexual reproduction is inactive. High humidity suppresses the production of these gemmae cups, but high temperatures (ca. 15°C) promote greater production of the cups (Chopra & Kumra 1988). Gemmae, and probably at times spores, are dispersed by water (Phephu 2012a).

Figure 26. *Marchantia berteriana* thallus forming a rosette, with gemmae cups. Photo by Tom Thekathyl, with permission.

Scott (1963) observed that plants of *Marchantia berteriana* (Figure 5-Figure 7) failed to produce gemmae cups (Figure 26-Figure 27) in New Zealand when pots were covered with glass or polyethylene sheets. He experimented with plants growing in a saturated atmosphere and demonstrated that it was indeed moisture that inhibited the development of gemmae cups. This

behavior permits the liverwort to divert its resources to sexual reproduction at a time when conditions are most favorable for that type of reproduction.

Figure 27. *Marchantia berteriana* thallus showing distinct pores and gemma cups. Photo by Tom Thekathyl, with permission.

Interactions

Marchantia berteriana (Figure 5-Figure 7) has close associations with at least several other organisms. Meeks (2018) reported associations with **Cyanobacteria**. Brasell *et al.* (1986) found that *Marchantia berteriana* exhibited high rates of acetylene reduction, indicating a high rate of nitrogen fixation, in populations from burned sites in southern Tasmania. **Cyanobacteria** are important contributors to nitrogen fixation. Activity was considerably greater than that for the same species when they occurred in the adjacent undisturbed forest. There was no significant relationship with temperature, moisture, organic matter, nitrogen, or phosphorus in these associations. I found no studies regarding nitrogen fixation association in wet habitat populations, but I would expect it to occur there as well.

Fungal Interactions

Baylis (1970) found that *Marchantia berteriana* (Figure 5-Figure 7) formed mycorrhizal associations on unsteamed phosphorus-deficient soil. Baylis suggested that the fungi entered through the rhizoids. Johnson (1977) demonstrated that infection by members of the **Enogonaceae** in a New Zealand forest occurred in the lower part of the thallus and in rhizoids in *Marchantia berteriana*. These endophytes seemed to lack specificity, occurring in a variety of the tracheophytes tested. It is likely that many associations remain to be identified.

Biochemistry

This species does not have the large number of biochemical studies reported for some of the other *Marchantia* species. Markham and Porter (1975) provided early reports on the flavones isoscutellarein and hypolaetin 8-glucuronides in *Marchantia berteriana* (Figure 5-Figure 7). The composition and concentration of these change in response to seasonal changes and reproductive stage of the plant. Acacetin and its glycosides are absent when

gametangia are present (Markham *et al.* 1978). Instead, during the sexually active stage, the predominant flavonoids are 8-hydroxyapigenin and 8-hydroxyluteolin glycosiduronic acids. These latter flavonoids are absent during the stage of asexual reproduction when the acacetin and its glycosides achieve their most active concentrations.

Asakawa and Campbell (1982) found that the major components of terpenoids and bibenzyls in *M. berteriana* (Figure 5-Figure 7) are cuparene and (–)-2-hydroxycuparene. Cuvertino-Santoni *et al.* (2017) described a number of the volatile constituents.

***Marchantia debilis* (Figure 1, Figure 28-Figure 32)**

(syn. = *Marchantia chevalieri*)

Distribution

Marchantia debilis (Figure 28-Figure 32) is widespread in tropical Africa (Pócs & Lye 1999), where it is common north to south in the drier areas (Reeb *et al.* 2018).

Figure 28. *Marchantia debilis* on rock near water in Madagascar. Photo courtesy of Catherine Reeb.

Figure 31. *Marchantia debilis* in Madagascar, showing numerous, overlapping thalli that help to conserve water. Photo courtesy of Catherine Reeb.

Figure 32. *Marchantia debilis* in Madagascar, growing on wet soil and rocks. Photo courtesy of Catherine Reeb.

Aquatic and Wet Habitats

Marchantia debilis (Figure 28-Figure 32) is more closely associated with water than some of the other species of *Marchantia* included here. It occurs on the edges of water in habitats like waterfalls, slow rivers (Figure 33-Figure 34), and ponds, on damp soil or rocks,

and sometimes experiences flooding, but it also occurs on terrestrial banks in both shaded and exposed areas (Reeb *et al.* 2018).

Figure 33. *Marchantia debilis* habitat on the riverbank in Madagascar. Photo courtesy of Catherine Reeb.

Figure 34. *Marchantia debilis* with *Riccia* on a riverbank in Madagascar. Photo courtesy of Catherine Reeb.

Hodgetts *et al.* (1999) similarly reported *Marchantia debilis* (Figure 28-Figure 32) from flushed rocks (Figure 35-Figure 36) in southern Africa. They are joined in this environment by the liverwort *Asterella bachmannii* (Figure 37), the mosses *Bryum alpinum* (Figure 38) and *Philonotis* spp. (Figure 39), and the hornworts *Anthoceros* spp. (Figure 40) and *Phaeoceros carolinianus* (Figure 41). *Marchantia debilis* also occurs on the soil and mud on river- and streambanks.

Figure 35. *Marchantia debilis* on rocks along riverbank in Madagascar. Photo courtesy of Catherine Reeb.

Leonard (1994) found that *Marchantia debilis* (Figure 28-Figure 32) occurred on the periodically flooded parts of sandstone cliffs near Yanonge, Zaire, typically with *Garckea flexuosa* (Figure 42).

Figure 42. *Garckea flexuosa*, an associate of *Marchantia debilis* in the flooded parts of sandstone cliffs in Zaire. Photo by Manju C. Nair, through Creative Commons.

Adaptations

The adaptations of *Marchantia debilis* (Figure 28-Figure 32) involve the same structures as in other species of *Marchantia*. They have large air pores bordered with 5-8 rings of cells, with half projecting above the epidermis and half below into the photosynthetic air space (Reeb *et al.* 2018). The ventral scales occur in four rows and do not cover more than 30-50% of the thallus. These are purple, at least in the median portion of the thallus.

The thalli can grow over mosses (Figure 43), providing them with a water-retaining sponge that keeps them moist longer than just soil.

Figure 43. *Marchantia debilis* in Madagascar, growing with mosses that can help to retain moisture. Photo courtesy of Catherine Reeb.

Reproduction

As is typical for species of *Marchantia*, *Marchantia debilis* (Figure 28-Figure 32) is **dioicous** (Reeb *et al.* 2018). I have not found information on stimuli needed to produce archegoniophores (Figure 44-Figure 45) or antheridiophores or what their seasonal behavior is. Gemmae (Figure 46) serve as effective means of asexual reproduction.

Figure 44. *Marchantia debilis* with an archegoniophore, in Madagascar. Photo courtesy of Catherine Reeb.

Figure 45. *Marchantia debilis* archegoniophore in Madagascar, showing large pores. Photo courtesy of Catherine Reeb.

Figure 46. *Marchantia debilis* with gemmae cups, in Madagascar. Photo courtesy of Catherine Reeb.

Biochemistry

Anchang *et al.* (2016) reported a new methanol extract, marchantinquinone-l'-methyl ether, from *Marchantia debilis* (Figure 28-Figure 32). In addition it had three known bis-bibenzyls. Asakawa (2021) noted that *Marchantia debilis* produces large quantities of marchantin-type bis-bibenzyls. Anchang and Simonsen (2019) reported that extracts from both wet and dry liverworts were able to inhibit the bacteria *Staphylococcus aureus* and *Dermatophilus congolensis*, and the fungus *Aspergillus flavus*. On the other hand, the bacteria *Pseudomonas aeruginosa* and *Bacillus* spp. were inhibited by extracts from dry, but not wet, *Marchantia debilis*. This suggests that at least one of the inhibitory substances must be produced in response to desiccation.

Yongabi *et al.* (2016) reported that petroleum extracts from *Marchantia debilis* (Figure 28-Figure 32) could be used to treat at least some of the bacteria responsible for diabetic bacterial foot infections. This product has been marketed as BryoCreamTM. It had a 90% cure rate in three weeks.

Marchantia emarginata (Figure 47-Figure 53)

(syn. = *Marchantia palmata*, *Marchantia sumatrana*)

The taxonomic relationships of *Marchantia emarginata* (Figure 47-Figure 53) have recently been evaluated in India (Singh & Singh 2013) and Japan (Zheng & Shimamura 2021, 2022a).

Figure 47. *Marchantia emarginata* with enlarged terminal buds. Photo by Taiwan Mosses, through Creative Commons.

Distribution

Marchantia emarginata (Figure 47-Figure 53) is widespread, occurring in the Northern Hemisphere in Asiatic and Oceanic regions (Bischler-Causse 1989). Its distribution includes Borneo, China, Guam, Hong Kong, India, Indonesia Japan, Korea, Malaysia, Marianas, New Britain, New Caledonia, New Guinea, Philippines, Solomon Island, Sri Lanka, and Thailand (Bischler-Causse 1989; Siregar *et al.* 2020). In Malesia, it occurs from sea level to 1500 m asl, and Lu and Huang (2017) reported that it occurs below 1800 m asl, adding Taiwan to its distribution. Singh and Singh (2013) reported it for the first time in the Indian Himalayas. It is threatened in Singapore (Ho 2013).

Aquatic and Wet Habitats

Marchantia emarginata (Figure 47-Figure 53) occurs on walls of bays, in side brooks, on a large block in pouring water, in waterfalls, and in thermal acidic spray in the tropics (Ruttner 1955). In Sumatra, Siregar *et al.* (2020) found it on soil (Figure 48) and rocks (moist, damp or wet, shaded, semi-exposed places, riversides, creeks; Figure 49-Figure 50). Lu and Huang (2017) reported similar habitats in Taiwan, including damp soils up to 1800 m asl. As seen in the images, it occurs on the sides of drainage ditches (Figure 51-Figure 52) as well.

Figure 48. *Marchantia emarginata* male on soil. Photo by Ellen8355, through Creative Commons.

Figure 49. *Marchantia emarginata* on rocks in and beside stream. Photo courtesy of Tian-Xiong Zheng (NICH).

Figure 50. *Marchantia emarginata* on rocks along stream. Photo courtesy of Tian-Xiong Zheng (NICH).

Figure 51. *Marchantia emarginata* on rocks and concrete along ditch. Photo courtesy of Tian-Xiong Zheng (NICH).

Figure 52. *Marchantia emarginata* on rocks along ditch. Photo courtesy of Tian-Xiong Zheng (NICH).

But it can also occur on soil banks (Figure 53) if there is enough moisture. In southern China, this species is found frequently with *Dumortiera hirsuta* (Figure 54) on soil banks beside roads (Figure 55) (Li Zhang, pers. comm. 12 August 2022).

Figure 53. *Marchantia emarginata* ssp. *cuneiloba* on soil bank beside road. Photo courtesy of Tian-Xiong Zheng (NICH).

Figure 55. *Marchantia emarginata* ssp. *tosana* with *Dumortiera hirsuta* (larger, hairy thalli). Photo courtesy of Li Zhang.

Tewari and Pant (1996) reported that *Marchantia emarginata* (Figure 47-Figure 53) grew along the borders of warm springs in hot spring areas of the Kumaon Himalaya, but was unable to grow in the hot, sulfurous springs.

Adaptations

This is not a truly aquatic bryophyte, but lives in habitats that can be wet part or most of the time, then experience drought when water levels recede. Hence we should expect adaptations that mediate these drier conditions.

Marchantia emarginata (Figure 47-Figure 53) has scales that are purple or pale-purple (see Figure 56) (Lu & Huang 2017). These contribute to water movement, absorption, and maintenance of hydration. One can only speculate about the advantages of the color. We have seen, in the chapter on light in Volume 1, that red pigments can be in higher concentrations in shade plants than in full sunlight (Melati *et al.* 2019). Furthermore, in the extreme shade of the rainforest, some forest floor tracheophytes have red or purple on the lower leaf surface, increasing the absorption of light at the upper end of the photosynthetic

action spectrum (Lee & Graham 1986). Hence, we can speculate that such a function might be operating in liverworts with purple scales. We need data to determine if the intensity of the color relates to the level of light in the habitat. I see no value to having this pigmentation on the ventral surface as a protection in high light. Do these scales somehow reflect light back to the photosynthetic tissue under low light conditions?

Figure 56. *Marchantia polymorpha* ssp. *ruderalis* scales showing purplish color of some *Marchantia* species. Photo by Des Callaghan, with permission.

Like other members of *Marchantia*, *M. emarginata* (Figure 47-Figure 53) has pores in the epidermis. These provide entry of CO₂ into the chamber beneath where photosynthetic filaments reside. And cuticular ridges around the pores are hydrophobic, preventing the entry of water that would greatly reduce the ability of CO₂ to enter the photosynthetic filaments.

Like many thallose liverworts, the thallus of *Marchantia emarginata* (Figure 47-Figure 53) often grows over mosses (Figure 57, Figure 61). These mosses provide a sponge-like base that helps to retain water longer than soil or pebbles alone, thus widening the habitat range of the liverwort.

Figure 57. *Marchantia emarginata* subsp. *tosana* growing on mosses. Photo from Taiwan Mosses, through Creative Commons.

Reproduction

Reproduction in *Marchantia emarginata* (Figure 47-Figure 53) follows that of other species in the genus. It is **dioicous** (Lu & Huang 2017). Cutting (1910) described the antheridial receptacles (Figure 58-Figure 59) of the species. A later description by Srinivasan (1939) suggests that it could actually be **protogynous** (female parts develop before male parts), with archegonial receptacles (Figure 60) developing first, then antheridial receptacles developing, a rather unusual order for bryophytes (see Vol. 1, Chapt. 3-2). Srinivasan describes the species as having receptacles that start as purely female, but soon one or more of the proliferations bear antheridia that grow out from the ventral surface. However, these proliferations once again become active lobes of the female receptacle. Srinivasan describes them as intermediate between an archegonium and an antheridium, later becoming typical antheridia. This observation leads him to the suggestion that the two reproductive structures are homologous. Nevertheless, the species is generally accepted as **dioicous**.

Figure 58. *Marchantia emarginata* males with antheridiophores. Photo by Ellen8355, through Creative Commons.

Figure 59. *Marchantia emarginata* males showing antheridial receptacles. Photo by Li Zhang, with permission.

Figure 60. *Marchantia emarginata* ssp. *tosana* females with archegonial heads. Photo courtesy of Li Zhang.

Asexual reproduction occurs by **gemmae** in cups (**cupules**) (Figure 61) (Ho 2013). In Singapore, these gemmae appear to be the primary means of reproduction, along with fragmentation and branching (see also Johnson 1958). On the other hand, Singh and Singh (2013) found no gemmae cups in the Himalayan material they studied, suggesting perhaps a climatic or photoperiod problem. We know that production of *Marchantia polymorpha* (Figure 2) gemmae are favored by short days (Carter & Romine 1969). If these conditions are coupled with the wrong temperatures, then the hormonal stimulus to produce gemmae might be absent.

Figure 61. *Marchantia emarginata* with gemmae. Photo by 楊玉鳳, through Creative Commons.

Kumra and Chopra (1989a,b) found that cytokinins (2iP, BAP, kinetin and zeatin) increased both growth and gemma cup formation in *Marchantia emarginata* (Figure 47-Figure 53) and were of decreasing effectiveness in that order. However, BAP is the most effective in increasing the number of gemmae. They also found (1989b) that vegetative growth and gemmae cup production were greatest in continuous light at 4500 lux, but were inhibited by applied auxins at most concentrations.

Li Zhang (pers. comm. 6 August 2022) sent me images of very unusual *Marchantia emarginata* ssp. *tosana* with

gemmae growing on the antheridiophore and archegoniophore (Figure 62-Figure 63). He concluded that the gemmae landed on these reproductive structures when the latter were young and the stalks had not yet elongated. These gemmae then were elevated as the antheridiophore and archegoniophore elongated. These two images represent two different populations in the same area. He considered that the high humidity in that location could make this unusual substrate possible. It also suggests that the inhibitor(s) to gemmae germination present in the thallus are absent in the archegoniophore and antheridiophore. But really, on the ends of the fingers of the antheridial head? It is interesting that the antheridial head does not have the typical shape seen in Figure 58.

Figure 63. *Marchantia emarginata* ssp. *tosana* with gemmaling on archegoniophore stalk, Guangdong, S. China. Photo courtesy of Li Zhang.

Fungal Interactions

Although I found little on fungal interactions for this species, Srinivasan (1939) reported fungal-forming **pycnidia** (flask-shaped fruiting body bearing conidiophores and conidia on interior and occurring in various imperfect fungi and Ascomycetes; Figure 64) in *Marchantia emarginata* (Figure 47-Figure 53). Srinivasan further suggested that the fungal attack might cause a change in the sex of the receptacle. This remains to be demonstrated experimentally, but with what we currently know about hormones from bacteria and fungi, and their influence on the development of bryophytes, this would be a worthwhile experiment.

Figure 64. *Phoma* (Coelomycetes) pycnidium. Some fungi have pycnidia that appear on *Marchantia emarginata*. Photo by Brawlings, through Creative Commons.

Iqbal *et al.* (1988) described vesicular-arbuscular mycorrhizal fungi from both rhizoids and the ventral thallus parenchyma of *Marchantia emarginata* (Figure 47-Figure 53).

Fatma (2018) determined an endophytic mold in *Marchantia emarginata* (Figure 47-Figure 53) to be *Daldinia eschscholtzii*. (Figure 65-Figure 66).

Biochemistry

Many biochemical studies have described the biochemical properties and potential uses of secondary compounds in the genus *Marchantia*. See Jantwal *et al.* (2019) for a review. The species *Marchantia emarginata* (Figure 47-Figure 53) may be less well known than the widespread *M. polymorpha* (Figure 67), but its biochemical studies are nevertheless numerous. Only a sampling will be presented here to suggest their ecological importance.

Figure 67. *Marchantia polymorpha* female with archegoniophores; this species is the typical example used for teaching about liverworts. Image copyright Stuart Dunlop <www.donegal-wildlife.blogspot.com>, with permission.

Yuan *et al.* (2021) demonstrated the presence of uridine diphosphate-dependent glycosyl transferases (UGTs) in *Marchantia emarginata* (Figure 47-Figure 53), noting the importance of flavonoid glycosides for their pharmaceutical activities. The value of pharmaceutical

compounds to the liverworts needs much experimental study. Are they merely a consequence of some other function or pathway, or do they defend the bryophytes against pathogens or herbivores?

Huang *et al.* (2010) isolated marchantin A, a bibenzyl ether, from *Marchantia emarginata* subsp. *tosana* (Figure 68). This secondary compound is able to induce **apoptosis** (death of cells which occurs as normal and controlled part of organism's growth or development) in human MCF-7 breast cancer cells. It furthermore has good anti-oxidant activity. Fatma (2018) likewise demonstrated anti-oxidant activity in this species. Antioxidants can be important in rehydration of bryophytes, countering the oxidative burst that often occurs (see for example Minibayeva & Beckett 2001).

Figure 68. *Marchantia emarginata* ssp. *tosana* females, a source of marchantin A. Photo from Taiwan Mosses, through Creative Commons.

Kumar *et al.* (2007) found that *Marchantia emarginata* could be used against tumors.

Wang *et al.* (2017) described the chemistry of the cuticle of *Marchantia emarginata* (Figure 47-Figure 53). They isolated the fatty ω -hydroxyacid/fatty alcohol hydroxycinnamoyl transferase (HFT) from the species and, based on a species of tobacco, suggested that its occurrence in the cells indicate that the **feruloylation** (subclass of carboxylic acid esterases that hydrolyze ester bonds between hydroxycinnamic acids and sugars present in plant cell walls) of the cutin monomers takes place in the cytoplasm. Bryophytes are often described as lacking cuticle, but **cutin** (insoluble polyester of C₁₆ and C₁₈ hydroxy fatty acids and main component of cuticle) is becoming well known in bryophytes. It appears that in bryophytes the cuticle is simply thinner than in tracheophytes.

Toyota *et al.* (2004) described the **sesquiterpene** alcohol 1,6-Humuladien-10-ol from *Marchantia emarginata* subsp. *tosana* (Figure 68). These **sesquiterpenes** are C₁₅-terpenoids comprised of three isoprene units. They are especially common in tracheophytes, but also are becoming well known in bryophytes (Awouafack *et al.* 2013). We know that sesquiterpenes can include essential oils and aromatic constituents; others are antimicrobial or provide protection against oxidative damage.

Alcoholic and acetonc extracts of *Marchantia emarginata* (Figure 47-Figure 53) indicated the presence of

carbohydrates, proteins, diterpenes, phytosterols, and anthocyanin, whereas flavonoids were present only in the alcoholic extract and phenol only in the acetonic extract (James *et al.* 2020). Alcohol extracts exhibited activity against the bacterium *Escherichia coli* (Figure 69) and both alcohol and acetone extracts against *Klebsiella pneumoniae* (Figure 70). However, neither alcohol nor acetone extracts exhibited activity against *Staphylococcus aureus* (Figure 71). This is unfortunate because this hospital scourge has become methicillin-resistant (Solberg 2000) and a new treatment is needed.

Spermine is a polyamine in all **eukaryotic** (having nucleus with nuclear membrane) cells and is involved in cellular metabolism. The amino acid ornithine is its precursor. It is an essential growth factor in some bacteria as well.

Culturing

Chopra and Dhingra-Babbar (1986) studied the effects of various amino acids, complex organic substances, and active charcoal on the growth and development of *Marchantia emarginata* (Figure 47-Figure 53). The amino acid response was dependent on the concentration, with lower concentrations enhancing growth and higher ones inhibiting it. Glutamic acid, histidine, and methionine stimulated callus growth, whereas tryptophan induced thallus differentiation. Activated charcoal delayed callus formation and growth was extremely reduced. Coconut milk stimulated callus growth at 15% (v/v) and inhibited it at 25%.

Marchantia inflexa (Figure 72-Figure 74)

Despite its somewhat narrow tropical distribution, *Marchantia inflexa* (Figure 72-Figure 74) has received considerable attention regarding its sexual expression and the role of the environment in this expression. Marks *et al.* (2019a,b) revealed that those genes on sex chromosomes are subject to greater diversifying selection than those on autosomal (non-sexual) and organellar genes. This diversification occurs mostly among male-specific genes, whereas divergence of other sex-linked genes differs little from that of autosomal genes.

Distribution

Marchantia inflexa (Figure 72-Figure 74) is restricted to the Neotropics and bordering regions, from Central America and the Caribbean and from northern Venezuela to the southern United States (Marks *et al.* 2019a).

Aquatic and Wet Habitats

Marchantia inflexa (Figure 72-Figure 74) occurs mostly on streambank rocks (Figure 75-Figure 76) and soil (Figure 77-Figure 78) (Marks *et al.* 2019a).

Physiology

water relations

Marks *et al.* (2019a,b) investigated dehydration tolerance, emphasizing differences between genetic lines, that allowed them to identify multiple dehydration-associated genes, two of which were sex-linked, suggesting that dehydration tolerance may be impacted by sex-specific genes. Identification of these genes permits the identification of gender when sexual expression is not present. Although the more common habitat for *Marchantia inflexa* (Figure 72-Figure 74) is on rock and soil surfaces along streambanks (Figure 79) in tropical forests, it can also colonize more exposed sites such as disturbed sites along roads.

Marks *et al.* (2019ab) explored the relationships to drought in five populations of *Marchantia inflexa* (Figure 72-Figure 74) in northern Trinidad and Tobago in the Republic of Trinidad. When grown in a common garden, the responses maintained the differences they had exhibited in their original habitats, indicating that they were genetically determined. They also found that males (Figure 86-Figure 87) had a lower desiccation tolerance than did females (Figure 88-Figure 89) in less exposed sites, but not in more exposed sites. The males furthermore exhibited more variation in morphology than did females, while females exhibited similar desiccation tolerance across the five sites.

Marks *et al.* (2021) identified stress responses to dehydration in *Marchantia inflexa* (Figure 72-Figure 74), including expression of LEA and ELIP genes and evidence of cell wall remodelling. They found, however, that there was little temporal synchronization of the responses across six genotypes. The researchers suggested that differences in timing of the transcriptional adjustments contribute to the variation seen among genotypes. Furthermore, developmental differences affect the relative tolerance of meristematic and differentiated tissues.

electrical responses

Measuring electrical responses in bryophytes is not a common activity, but such measures can be used to assess a plant's response to injury or environmental stimuli. Several studies have used *Marchantia inflexa* (Figure 72-Figure 74) as a subject. Cooper *et al.* (2022a) commented that the KCl-filled glass electrodes placed into plant tissues is subject to artifacts and is less reliable than the impedance method. Using the impedance method, one can detect plant injury and exposure to environmental compounds such as glutamate. This method was used successfully in *M. inflexa* by placing two impedance leads 2 cm apart into the thallus tissue, with a cut made to a third thallus between the two leads. Cooper *et al.* (2022b) found that the liverwort showed no electrical response to glutamate exposure, whereas *Arabidopsis thaliana* (Figure 80) and *Pisum sativum* (Figure 81) (both flowering plants) produced rapid depolarization upon exposure.

Adaptations

Among the common adaptations is their ability to form dense mats that help to maintain moisture in the soil (Figure 82-Figure 83). But this ability to form mats brings its own problems of self-competition.

Figure 82. *Marchantia inflexa* with overlapping thalli that can help to conserve soil moisture. Photo by Scott Zona, with permission.

Figure 83. *Marchantia inflexa* with gemmae cups, showing closely contacting and overlapping thalli. Photo by Jamie Newman, through Creative Commons.

Crowley *et al.* (2005a) described three mechanisms for competition for space (Figure 82-Figure 83): **expansion** (spreading to unoccupied habitat), **lottery** (replacing dead competitors), and **overgrowth** (encroaching on competitors along zones of contact). For *Marchantia inflexa* (Figure 72-Figure 74), a local stable coexistence of the sexes requires the avoidance of this self-competition. This stable coexistence of the sexes seems to be possible in a narrow range of disturbance intensities, explaining ambiguous results in simulation studies (McLetchie *et al.*, 2002). Crowley *et al.* noted the importance of **contact inhibition** in this species. They considered that the improbability that a disturbance regime could maintain death rates within the high and restricted range is consistent with stable coexistence and that it indicates that long-term coexistence of the two genders may be dependent on processes operating at the scale of the metapopulation (Garcia-Ramos *et al.* 2002, 2007). Garcia-Ramos *et al.* (2002, 2007) indicated that single-sex populations were common and that males were rare. In the tropics the two sexes often coexisted in a single patch; in the USA only all-male or all-female populations were known. The spores were able to colonize disturbed sites, and large disturbed areas permitted

the colonization and coexistence by both sexes, with fertilization typically occurring between patches.

Reproduction

For a species that has few publications describing habitats, *Marchantia inflexa* (Figure 72-Figure 74) has an abundance of published reproductive studies, particularly related to the environmental conditions. Like the genus, the species is **dioicous**. Prominent among the studies are those related to environmental effects on sex ratio.

McLetchie and Puterbaugh (2000) noted that unisexual populations and female- or male-biased populations were common in this **dioicous** liverwort. Garcia-Ramos *et al.* (2002) found that whereas both sexes could coexist in a single patch in the tropics, in the USA only all-male or all-female populations are known. McLetchie and Puterbaugh (2000) found that sex-ratio patterns could be related to growth rates, number of meristematic regions (Figure 72-Figure 73), and asexual reproduction in the riverside populations they studied in Trinidad. Of the 209 patches they observed, 83% contained no sex-expressing thalli. Only 9% contained thalli of both sexes. The remainder were either entirely female-expressing (4%) or male-expressing (4%). Small patches were less likely to be expressing sexual reproductive structures. Shade (less canopy openness) also correlated with lower sexual expression. In those populations with expression of both sexes, the ratios of male (Figure 86-Figure 87) to female (Figure 88-Figure 89) ranged 0.22-0.80.

But what causes this variation? McLetchie and Puterbaugh (2000) found that females (Figure 88-Figure 89) of *Marchantia inflexa* (Figure 72-Figure 74) grew faster, produced more meristematic tips (Figure 73), and had lower levels of asexual reproduction (Figure 83-Figure 85) than did males (Figure 86-Figure 87). Furthermore, the number of meristematic tips exhibited a negative correlation with both asexual reproduction and growth rate. Hence, these factors could lead to female sex bias in reproductive colonies. A further factor in shifting toward female dominance is that populations that reproduce better asexually (*i.e.* males) are less likely to succeed under stressful conditions. These relationships position the species to produce more spores under stressful conditions and thus have a means to arrive at a different location where the stress might not be present.

McLetchie *et al.* (2002) followed with a study on the local sex-ratio dynamics using *Marchantia inflexa* (Figure 72-Figure 74) from rock surfaces and bark in Trinidad. These populations differed widely in their population sex ratios at the study site in the rainforest. They followed seven life history stages. In some stages the thalli became more abundant and extend over the substrate and each other in their quest for space (Figure 84-Figure 85). The sex ratio within a patch was not stable: at low to moderate disturbance levels, females gradually eliminated males. At high disturbance levels, males (Figure 86-Figure 87) eliminated females (Figure 88-Figure 89). This pattern was not dependent on whether sexual propagules (spores) could germinate within the patch, but germination of gemmae (Figure 84-Figure 85) within the patch had an important role. Hence, sexual reproduction, while unimportant within patches, is critical in spatial landscapes (Garcia-Ramos *et al.* 2002).

Figure 84. *Marchantia inflexa* with gemmae. Photo by Jeff Garner, through Creative Commons.

Figure 85. *Marchantia inflexa* with gemmae cups. Photo by Jamie Newman, through Creative Commons.

However, spores may be the primary means for recolonizing patches eliminated by large-scale disturbances (McLetchie *et al.* 2002). Once a patch became fully occupied, the production of the wind-dispersed spores was maximized. Once the colony became re-established, spore production declined and the sex ratio became increasingly more biased toward one or the other sex. Such scenarios support the concept that the sex ratio is determined at the **metapopulation** (group of spatially separated populations of same species which interact at some level; regional group of connected populations of species) level.

One question that arises is how does a species maintain sexually dimorphic pre-adult traits (Fuselier & McLetchie 2002). Fuselier and McLetchie noted that sexual dimorphism can influence the distribution of the sexes, the population sex ratios, the maintenance of the sex in populations, and the evolutionary potential of the species. Hence, in species like *Marchantia inflexa* (Figure 72-Figure 74), where sexual dimorphism results in greater growth and reproduction in females, the population could develop a female-biased sex ratio. Fuselier and McLetchie found that the sexes overlapped in habitat use. Furthermore, different populations exhibited differences in growth, asexual reproductive rates (Figure 84-Figure 85), degrees of sexual dimorphism, and the strength of their

among-trait correlations. The investment in growth and in asexual reproduction differed in single-sex and mixed-sex populations, but the degree of sexual dimorphism did not. The researchers concluded that the local environment may exert more influence than does the presence of the opposite sex in maintaining sexual dimorphism. Furthermore, between-sex correlations were not significant in the greenhouse common garden, but were significant in the field. Garcia-Ramos *et al.* (2002) found that males were able to persist longer in local populations due to minor disturbances such as drought.

Females (Figure 88-Figure 89) exhibited a cost for plasticity, whereas males (Figure 86-Figure 87) did not (Fuselier & McLetchie 2002). Among females, early sex-expressing individuals produced fewer gemmae cups than did late-expressing plants, supporting the concept that there is a tradeoff between the two modes of reproduction. These observations suggest that events during the life of the plant can influence its success at the local population level. These events can differ among the years of its life, making the success of a given population a somewhat random process dependent upon the changing conditions in the environment.

Figure 86. *Marchantia inflexa* males. Photo by Jeff Garner, through Creative Commons.

Fuselier and McLetchie (2004) explored several environmental parameters to determine if the two sexes exhibited different preferences. Using two populations in Trinidad and ten in the USA, they found no differences in preference for substrate, humidity, wind speed, or exposure among or within populations. However, in the USA, male populations (Figure 86-Figure 87) tended to occur under

more open canopies and in a wider light range than did females (Figure 88-Figure 89).

Figure 87. *Marchantia inflexa* males. Photo by Scott Zona, with permission.

Figure 88. *Marchantia inflexa* females. Photo by Jeff Garner, through Creative Commons.

Figure 89. *Marchantia inflexa* females. Photo by Jeff Garner, through Creative Commons.

Crowley *et al.* (2005b) postulated that the long-term coexistence of the sexes in *Marchantia inflexa* (Figure 72-

Figure 74) might be only temporary. They found that fragmentation is important in overgrowth competition. Stanley (2019) hypothesized that females (Figure 88-Figure 89) in bryophytes would show a greater competitive ability, thus at least in part accounting for the frequent female (Figure 88-Figure 89) bias in bryophyte sex ratio. In their greenhouse cultures of *M. inflexa*, they found that both sexes averaged 41% more growth if accompanied by the opposite sex than that of single-sex cultures. Their model predicted coexistence between the sexes, but that males (Figure 86-Figure 87), not females, would be in greater numbers, with a ratio of 3.2 males to 1 female.

Groen *et al.* (2010a) were surprised to find that males (Figure 86-Figure 87) of *Marchantia inflexa* (Figure 72-Figure 74), the gender that occurs in more tree-canopy openness, have lower chlorophyll *a:b* ratios than do females. Generally, a low chlorophyll *a:b* ratio, caused by more chlorophyll *b*, is an adaptation to shade. But both sexes had lower edge pore density in greater canopy openness; males had a weak positive correlation between edge pore density and light intensity (Groen *et al.* 2010b). Thus it appears that light intensity and canopy openness have opposing effects on edge pore density in males (Figure 86-Figure 87). The researchers suggest that males might be more responsive to water stress than are females (Figure 88-Figure 89). Females, on the other hand, have more support tissue, providing greater storage, and providing the resources needed for the female plants to support their sexual role.

Garcia-Ramos *et al.* (2007) noted that as a patch of *Marchantia inflexa* (Figure 72-Figure 74) persists through time, it is more likely to lose males (Figure 86-Figure 87) than females (Figure 88-Figure 89). This is due, at least in part, to the faster tissue growth of females. On the other hand, both sexes generally persist in the metapopulation, but with females predominating. Males had the advantage during patch filling, with their more abundant gemmae (Figure 84-Figure 85) providing an effective colonization strategy. Since males kept colonizing these available patches, they were maintained in the metapopulation. Similar maintenance of both sexes, particularly in small, highly disturbed populations where life-history traits and mortality differ between sexes, is likely to be a widespread phenomenon, particularly among dioicous bryophytes.

Using methods described by Chang *et al.* (2006), Fuselier (2008) found that geographically separated populations were significantly different. Single-sex populations of *M. inflexa* (Figure 72-Figure 74) in Oklahoma and Florida, USA form a distinct phenotypic group and it would be worthwhile to study physiological and developmental differences as well. Plants from single-sex and both-sex populations differed in their life history strategies. Those in single-sex populations invested more in growth than in asexual (gemmae; Figure 84-Figure 85) reproduction. While they produced as many sexual structures, they produced fewer gametangia per gametophore than did plants from both-sex populations, suggesting a possible chemical interaction among the plants. Characters of female plants (Figure 88-Figure 89) were positively correlated with geographic, nearest-neighbor distance. Characters of male plants (Figure 86-Figure 87) showed no relationship to geographic distance.

Dispersal is a logical choice for differences in population genders. Male plants produce more gemmae (Figure 84-Figure 85) and therefore should propagate more new plants near the parent colony. Female plants (Figure 88-Figure 89) produce spores and can therefore colonize areas at greater distances. But the gemmae, mostly falling within 1 m of the parent, have a greater chance of landing on a suitable substrate with suitable environmental conditions. To further complicate the picture, gemmae from males (Figure 86-Figure 87) (producing more males) have lower survivability than female gemmae due to desiccation (Stieha *et al.* (2014).

Brzyski *et al.* (2014) collected male and female plants from two strikingly different habitats within the same region: along natural sites (rivers) and along novel human-modified sites (roadsides). They used a common garden to demonstrate a strong sex by habitat interaction: male (Figure 86-Figure 87) and female (Figure 88-Figure 89) responses differed significantly by their source habitat. Road-collected females had higher growth and asexual reproduction compared to females from riverside habitats. In males, the pattern was not significant, but tended to be opposite to that of the females. The researchers found significant genetic differentiation between plants of the two habitats and found no evidence of individual differences in growth plasticity. However, there was a genotype effect for gemmae production. Although males and females did not differ genetically, river-collected plants with lower sexual potential were more diverse than roadside-collected plants. Could this be due to founder events, or are there selection pressures yet to be discovered? Nevertheless, these populations show that individual variation in reproduction is controlled by the interaction of genetics and environment.

Moore *et al.* (2016) questioned the selection for gamete dispersal and capture in clump water-holding capacity. In *Marchantia inflexa* (Figure 72-Figure 74), a dense tomentum-like mass of scales surrounds the archegonia (Figure 88-Figure 89), presumably retaining sperm-laden water. The male receptacle (Figure 86-Figure 87), on the other hand, has no scales and may serve as a dispersal splash platform (Figure 86).

Stieha *et al.* (2014) observed the productivity and dispersal of gemmae in *Marchantia inflexa* (Figure 72-Figure 74). Male plants produce more gemmae and more quickly than do female plants, but male plants have lower desiccation tolerance, leading to lower gemmae survival rates. They found that gemmae in this species can move up to 20 cm per minute in a light rain, permitting them to reach locations unoccupied by their parents. Models demonstrated that long-distance dispersal of gemmae is possible and they are likely to be successful if they stay moist. They warned that measurements of different stages to dispersal can be misleading about the survival of the sexes. Nevertheless, the gemmae are critical to the maintenance of both sexes.

Stieha *et al.* (2017) summarized the known mechanisms for maintaining both sexes to be "semi-independent dynamics of populations within a metapopulation. These semi-independent dynamics are influenced by dispersal and recolonization rates, which are affected by the spatial arrangement of populations." Using a mathematical model, Stieha and coworkers demonstrated

that at intermediate distances between populations, metapopulations maintained both sexes, and the spatial arrangement of populations changed the threshold at which one sex was lost. However, when populations were close to one another, one sex was eliminated and the single-sex metapopulation persisted through dispersal of asexual propagules. When populations were far apart, one sex was eliminated, and the metapopulation either went extinct due to lack of recolonization by asexual propagules or persisted because clumped populations facilitated recolonization. Hence, spatial arrangements are important in the maintenance or elimination of sexes in clonal organisms. This helps to explain the persistence of geographic parthenogenesis and the continuance of asexual species such as founder populations of dioicous species.

With so much known about the sexual behavior of *Marchantia inflexa* (Figure 72-Figure 74) populations, Walter (2015) set out to detect genetic evidence of sexual reproduction in sexual and asexual populations. She predicted that genetic variation would be higher in sexually reproducing populations when compared to asexually reproducing populations. In these haploid organisms, there is rapid selection for advantageous traits and rapid removal of deleterious ones. Sexual reproduction permits recombinations among the genes on different chromosomes, creating variability among offspring. Asexual reproduction such as gemmae produces a carbon copy of the parent. The results, using *Marchantia inflexa* (Figure 72-Figure 74), are fascinating. Bisexual populations are becoming more female biased (Figure 88-Figure 89), suggesting some mechanism of competition. The all-female populations have a low level of genetic diversity, implying that they have arisen mostly from asexual reproduction.

Brzyski *et al.* (2018) noted that sexual reproduction requires close proximity to potential mates. Clonal growth can increase this distance by carrying the reproductive structures farther from a neighboring plant of the opposite sex, thus reducing the probability of mating. The researchers calculated the spatial distributions as the likelihood that pairs of individuals were the same sex or genotype of *Marchantia inflexa* (Figure 72-Figure 74) and determined how the likelihood was affected by habitat patch size. In this species, asexual reproduction dominates within patches but could also occur between populations. Males (Figure 86-Figure 87) were more likely to occur near other males than the likelihood of females (Figure 88-Figure 89) being near other females, presumably reflecting the greater gemma production by males in *M. inflexa*. In small patches the likelihood of both sexes being near members of the same sex was greater than in large patches. In the large habitat patches, male genotypes were nearly 15% more likely to be near their own clone mates than were female plants. This difference is most likely due to differential survival or colonization. Thus, male plants were more likely to be aggregated clones than were females, particularly in large patches.

Based on earlier studies on differences in light preference, Lay *et al.* (2022) experimented with the effects of light intensity and quality on phytochromes in germination of gemmae of *Marchantia inflexa* (Figure 72-Figure 74). The germination responses of both sexual (spores) and asexual (gemmae) offspring were consistent

with a phytochrome-mediated event. This contrasts with germination in *M. polymorpha* (Figure 90) wherein photosynthesis mediates the event.

Figure 90. *Marchantia polymorpha* with gemmae in cups. Photo by Brenda Dobbs, through Creative Commons.

Stanley (2019) likewise found that in single-sex cultures, males had more asexual structures (gemmae) than in the mixed-sex cultures, with the reverse relationship for growth rate. Such an increase of asexual structures in single-sex cultures would increase the probability of encountering females. The reduction in growth is a tradeoff in resource allocation. The same pattern did not occur in the females.

These differences in behavior of males (Figure 86-Figure 87) in single- vs mixed-sex cultures suggest an interaction, perhaps hormonal, based on density of plants and presence of females (Figure 88-Figure 89). Stanley (2019) suggested that in this case there could be a change in sex ratio before the plants allocate their resources to sexual reproduction; this could also be caused by environmental conditions.

Such changes in sex ratio due to environmental conditions have been known in monoecious seed plants for some time. Freeman *et al.* (1981) found that in xeric conditions the males (Figure 86-Figure 87) were more prominent, whereas female (Figure 88-Figure 89) functions were more abundant on mesic sites. Similar results were found by Dawson and Elheringer (1993) for *Acer negundo* (box elder, Figure 91) in the Intermountain West, USA. In drought-prone habitats, the male:female ratio is 1.62:1, whereas in moist-streamside habitats (Figure 76) it is female (Figure 88-Figure 89) biased (0.65 male:1 female). By reviewing many publications, Golenberg and West (2013) indicated that environmental conditions could affect ethylene concentrations, which in turn affected other hormones in flowering plants, ultimately affecting the expression of sexual structures.

Blake-Mahmud and Struwe (2020) even found that sexual expression as male in the sexually plastic *Acer pensylvanicum* (striped maple, Figure 92-Figure 93) could be completely suppressed by wounding, with increasing likelihood of the sex changing to female as the severity of damage increased. Understanding such responses of bryophytes to environmental stresses is important to our

understanding of the changes we might expect as the climate becomes more stressful, particularly as drought increases and more severe weather events occur.

Interactions

Like many, probably most, other bryophytes, *Marchantia inflexa* (Figure 72-Figure 74) consorts with bacteria. The bacterial communities associated with bryophytes contribute to nutrient cycling, community interactions, and cost-benefit relationships of the individual organisms involved (Marks *et al.* 2018). There is evidence of nitrogen fixation by these associated bacteria from the early invasion of bryophytes on land (Knack *et al.* 2015).

Marks *et al.* (2018) compared the bacterial community between males (Figure 86-Figure 87) and females (Figure 88-Figure 89) of *Marchantia inflexa* (Figure 72-Figure 74) across habitats. They found an abundant and diverse community, even when grown in a common garden. Differences were present among habitats as well as between sexes. Marks and coworkers suggested that differences in communities between males and females may contribute to "subtle differences in both physiology and form," possibly contributing to their acclimation to the local environment. Females differed from males in having higher abundances of the bacterial order **Rhizobiales**, (Figure 142-Figure 143) an order known to have species that are able to fix nitrogen. At the same time, females had a lower abundance of nitrogen-fixing **Cyanobacteria** (Figure 94) compared to males.

Figure 94. *CylandrospERMUM* sp., a nitrogen-fixing member of **Cyanobacteria**. Photo from CSIRO ScienceImage, through Creative Commons.

Graham *et al.* (2018) noted that some bacterial associations with *Marchantia inflexa* (Figure 72-Figure 74) growing on streambanks (Figure 75) appear to have methane oxidation capabilities. Since streams are known sources of methane, albeit heterogeneous within the stream (Crawford *et al.* 2017), the bryophytes might have an important role in reducing this greenhouse gas.

Marchantia miqueliana

(syn. = *Marchantia cataractarum*)

Distribution

Marchantia miqueliana appears to be endemic to Java. Because of this narrow distribution, little has been published about it. Siregar *et al.* (2013) were unable to relocate it in Sumatra, a location that had been reported by Bischler-Causse (1989). Instead they found what they

considered to be a new species on soil in a wet place around the Dwi Warna waterfall at 1100 m asl.

Aquatic and Wet Habitats

Marchantia miqueliana occurs on the walls of bays and in the spray of waterfalls in the tropics (Ruttner 1955). Campbell (1908) likewise reported it from near a waterfall in Java.

Adaptations

Biochemistry

Despite its rarity, Campbell *et al.* (1979) listed flavonoids from *Marchantia miqueliana*. These included apogenin and flavone.

Marchantia paleacea (Figure 97-Figure 99)

(syn. = *Marchantia nitida*, *Marchantia nepalensis*)

Bischler (1986) sank a number of species into this one, based on type material, but warned that other records of these species do not necessarily belong to *Marchantia paleacea* (Figure 98-Figure 100).

Marchantia paleacea (Figure 97-Figure 99) usually is considered to have two subspecies, ssp. *paleacea* and ssp. *diptera* (Figure 95-Figure 96) (Zheng & Shimamura 2019; Zheng *et al.* 2020b). In China and Japan, *Marchantia paleacea* subsp. *paleacea* tends to be distributed in higher altitudes and latitudes compared to subsp. *diptera* (Zheng & Shimamura 2019). Zheng and coworkers (2020b) found that the two subspecies overlap in western Japan and may be able to interbreed there.

Distribution

Marchantia paleacea (Figure 97-Figure 99) is a widely distributed tropical and subtropical species, ranging through the West Indies, Mexico, Guatemala, Asia, Europe, Azores, and Africa (Svihla 1940). Country records include Andaman Islands, China, India, Japan, New Guinea, Ryukyus, southeastern Asia, Sri Lanka, and Taiwan (Lu & Huang 2017; Bischler-Causse 1989). Borovichev and Bakalin (2014) added it to the known Russian flora, stating that it is poorly known there. It is considered vulnerable in Italy (Poponessi *et al.* 2020) and rare in southern Africa (Perold 1995). In the Americas, it is known from the southern states of the USA, Mexico, and Central America (Bischler 1988).

Aquatic and Wet Habitats

Marchantia paleacea (Figure 97-Figure 99) can occur submersed in small pools, on the walls of bays, and in waterfalls in the tropics (Ruttner 1955). Lu and Huang (2017) reported subspecies *paleacea* to occur on damp soil from 300 to 2500 m asl in Taiwan. It can occur on wet rocks beside rivers and streams (Figure 100). Des Callaghan photographed it on a rock wall at the edge of a subtropical laurel forest in Madeira (Figure 101). Zheng and Shimamura (2022b) described this subspecies in Japan as growing on boulders, soil, concrete, or limestone walls in wet or shaded places. They provided a similar but slightly different habitat description of *Marchantia paleacea* ssp. *diptera* (Figure 95-Figure 96) on stones or soil in shaded or semi-shaded areas, anthropogenic regions, or near streams.

Bischler (1986) reported that *Marchantia paleacea* (Figure 97-Figure 99) had a high environmental tolerance, *i.e.* a wide niche, for soil factors, but that its climate tolerance was narrower.

In Oklahoma, USA, *Marchantia paleacea* (Figure 97-Figure 99) occurs on constantly moist, shaded rock outcrops within a few feet of water, on travertine deposits along streams (Figure 102-Figure 106), and on moist, shaded bluffs (Figure 107) (Little 1936). Images provided by members of Bryonet indicate that in some parts of the world it can occur elsewhere on wet banks (Figure 108-Figure 109), on the sides of drainage ditches (Figure 109-Figure 110), and in the splash of spring water (Figure 111-Figure 112) used for drinking.

Physiology

Kaul *et al.* (1962) found that regenerating thalli of *Marchantia paleacea* (Figure 97-Figure 99) did not form protonemata, contrasting with regenerants of mosses. Liquid culture caused the production of more gemmae cups. Those gemmae germinated on solid media produced rhizoids, but those in liquid cultures did not, suggesting that these would not be able to attach if they germinated in water in nature. However, that might be remedied if the water level receded. Unlike observations for most *Marchantia*, gemmae frequently germinated within the cups.

Takio *et al.* (1988) demonstrated that *Marchantia paleacea* ssp. *diptera* (Figure 95-Figure 96) could synthesize chlorophyll in the dark as well as in the light in cell suspension culture. This ability continued for the one year of experiments. Doubling time (dry weight) required 1.2 days in the light, but 1.5 days in the dark. Could this behavior permit the species to survive and even grow while temporarily covered by litter or snow? Ngumi *et al.* (1990) further found that when the dark-grown cells were placed in the light, there was no lag phase before they were able to grow photoautotrophically. Their optimum light was 6 W m⁻² or higher in an atmosphere of 2.5% CO₂. Using *Marchantia paleacea* ssp. *diptera*, Taya *et al.* (1995) obtained "good growth" at 1% CO₂. They demonstrated both stimulatory and inhibitory light levels. At levels of 5.4-60 W m⁻² growth rate increased with light intensity; above 60 W m⁻² the rate decreased as the light intensity increased.

One has to ask what advantages a thallose liverwort has when it is able to grow heterotrophically in the dark. This would seem like a suitable trait for those in areas with snow, but this is a species (*Marchantia paleacea* ssp. *diptera*; Figure 95-Figure 96) that is mostly distributed in areas that do not see snow. Ngumi *et al.* (1990) grew it heterotrophically for two years, in the dark, then transferred it to light. The cells started to grow immediately, photoautotrophically, with no lag phase. Optimum growth occurred at 6 W m⁻² and above in an atmosphere of 25% (v/v) CO₂. The growth cycle exhibited high photosynthetic activity (7-88 mol O₂ per kg chlorophyll h⁻¹) with a high chlorophyll content of 17-25 g per kg dry weight. The cells once again returned to heterotrophic growth when placed in the dark.

Eguchi *et al.* (2002) investigated further and found that transfer of *Marchantia paleacea* var. *diptera* (Figure 95-Figure 96) to darkness resulted in a reversible repression in the gene coding for NADPH: protochloride oxidoreductase (EC 1.3.1.33). Further investigation suggested that the photosynthetic electron transport was involved in regulation of the stability of the por transcript involved in the reactions.

Nitrogen processing is also affected by light. Harada *et al.* (1993) found that when dark-grown cells were transferred to the light, the levels of activity of NaR and NiR activities decreased to about half those of cells remaining in the dark. When ammonium was the only nitrogen source supplied, activities of NiR, GS, and NADH-GOGAT were greatly reduced. Fd-GOGAT and GDH activities were not affected as greatly. But all this still begs the question how the dark production of chlorophyll is able to benefit the plant enough for the genes to remain in the population.

Many bryophytes are known for their ability to accumulate heavy metals. Concentrations of Pb, Cu, Ni, and Zn were higher in plant samples of *Marchantia paleacea* (Figure 97-Figure 99) from disturbed sites as compared to less disturbed sites in the Kumaon Hills, India (Sahu *et al.* 2014). Mn concentration, on the other hand, was higher in soil samples as compared to plant samples. Correlation analysis (r) was also performed to investigate the relationship between the soil samples and accumulation of metals in the plant. At the Bhowali taxi stand (Nainital),

Sahu and coworkers recorded significant accumulation ($P < 0.01$) of Pb, Cu, and Ni.

It appears that activation of enzymes might help to protect *Marchantia paleacea* ssp. *diptera* (Figure 95-Figure 96) from some heavy metals (Tanaka *et al.* 1995, 1996, 1998). The cytosolic Cu/Zn-superoxide dismutase is inactivated when the cells are copper deficient and reactivated when copper is added (Tanaka *et al.* 1995). The conversion from the active form to the inactive form of Cu/Zn-SOD by release of copper is the first step in the process of its degradation. Furthermore, a copper chelator causes transformation to the inactive form. Shiono *et al.* (2003) further found that the presence of copper decreases the accumulation of gene transcripts for Fe-SOD, but increases that for CuZn-SOD in a moss, whereas it produces little effect on the gene for Fe-SOD in the liverwort *Marchantia paleacea* ssp. *diptera*.

Shiono *et al.* (2003) found that whereas copper represses the expression of Fe-superoxide dismutase (Fe-SOD) in chloroplasts of the moss *Barbula unguiculata* (Figure 113), this is not the case in *Marchantia paleacea* ssp. *diptera* (Figure 95-Figure 96). Both are typical chloroplastic SODs, comparable to those in tracheophytes. The difference in *M. paleacea* var. *diptera* is that the copper has little effect on the gene for the Fe-SOD in the liverwort. Sakaguchi *et al.* (2004) found that instead the photosynthetic electron transport system differentially regulates the expression of the SOD genes in *M. paleacea* var. *diptera*.

Figure 113. *Barbula unguiculata*, a species in which copper represses the expression of Fe-superoxide dismutase (Fe-SOD) in chloroplasts. Photo by Michael Lüth, with permission.

Suzuki *et al.* (2001) explored the role of **phytochrome** (photoreceptor in plants; sensitive to light in red and far-red region of visible spectrum) and red/far-red reversibility in *Marchantia paleacea* ssp. *diptera* (Figure 95-Figure 96). Hata *et al.* (1997) found that the cell growth rate related so well to the light intensity that it could be used to calculate the light intensity. Chlorophyll content was inversely related to the light intensity.

Siregar *et al.* (2021) demonstrated strong antioxidant activity (LC50=25.25 µm mL⁻¹) for *Marchantia paleacea* (Figure 97-Figure 99). This is important during rehydration, when most bryophytes experience an oxidative

burst. It appears that the oxidative burst prevents bacteria from entering the cells, whereas the antioxidant prevents the high oxygen levels from harming the cells.

Marchantia paleacea (Figure 97-Figure 99) is one of the species that has been used as an indicator of heavy metals (Afroz & Srivastava 2009). Afroz and Srivastava found that it is a good accumulator, and therefore can be useful as an indicator species of heavy metals in the soil.

Sahu *et al.* (2014) similarly touted the use of *Marchantia paleacea* (Figure 97-Figure 99) as a bioindicator. Among their sites in the Kumaon Hills, they found that Pb, Cu, Ni, and Zn concentrations were higher from disturbed sites. Mn, on the other hand, was higher in soil samples than in the liverwort. Lead (Pb) exhibited a significantly higher concentration in the liverworts at a taxi stand.

Adaptations

Marchantia paleacea (Figure 97-Figure 99) requires a somewhat humid environment and can suffer from desiccation (Figure 114). Therefore, it survives with adaptations that permit it to live in places that are wet or sometimes submersed, but that also can become dry for days at a time.

Figure 114. *Marchantia paleacea* in a partially dry condition. Note that the terminal portions, where growth occurs, are still alive. Photo by Jan-Peter Frahm, with permission.

Marchantia paleacea (Figure 97-Figure 99), like other members of the genus, has pores (Figure 115) in the upper epidermis of the thallus, overlying air chambers that have photosynthetic filaments (Apostolakos *et al.* 1982). As noted earlier by Schönherr and Ziegler (1975), the cuticular ledges around the air pores prevent the entry of water into the thallus, thus permitting gas exchange without the interference of water within the thallus. The ledge has a surface of methyl and methylene groups and is covered by a layer of cutin. Schönherr and Ziegler considered these ridges to be "perfect" structures to protect against the entry of water.

Figure 115. *Marchantia paleacea* with gemmae cups, showing thallus pores. Photo by Efrain DeLuna, through Creative Commons.

Apostolakos and coworkers (Galatis *et al.* 1978b; Apostolakos *et al.* 1982; Apostolakos & Galatis 1985a,b,c) have provided us with a detailed study of the development of the air pores and air chambers in *Marchantia paleacea* (Figure 97-Figure 99).

Oil bodies can have multiple benefits to the liverwort plants. Oil bodies nearly fill the thallus cells they occupy in *Marchantia paleacea* (Figure 97-Figure 990) (Galatis *et al.* 1978c). The role of oil bodies was the subject of speculation for some time. Galatis *et al.* (1978a) provided an early assessment of the contents of oil bodies in *Marchantia paleacea*. They observed that the polysaccharidic material is first elaborated in the dictyosomes, then transferred into the oil bodies by their vesicles. Proteins appear to be absent in the oil bodies. However, phenolics and other aromatic compounds seem to be present, at least in the inner oil bodies. These observations suggest as the oil bodies serve as energy reserves and as sites of protective compounds such as phenolics.

One means of conserving water is to grow with overlapping thalli that reduce evaporation (Figure 116-Figure 118). Others grow on a mat of mosses (Figure 119). These mosses provide a sponge that keeps the water in proximity to the rhizoids and that further reduce evaporation from the soil.

Figure 119. *Marchantia paleacea* growing over mosses in India. Photo by Michael Lüth, with permission.

Zheng and Shimamura (2019) suggested that the inward bent receptacle (Figure 120) of *Marchantia paleacea* ssp. *diptera* might help it to withstand the high temperatures and desiccation it experiences in its southern Japan distribution.

Figure 120. Females of *Marchantia paleacea* ssp. *diptera* showing inward bent margins of the female receptacle. Photo courtesy of Tian-Xiong Zheng (NICH).

Reproduction

Marchantia paleacea (Figure 97-Figure 99) is considered to be **dioicous** (Bischler 1986; Perold 1995; Lu & Huang 2017). Like other *Marchantia* species it develops antheridiophores (Figure 121-Figure 122) and archegoniophores (Figure 123-Figure 129). Other than these reproductive branches, the two sexes look the same (Bischler 1986). The life cycle is typical for species of *Marchantia*.

Populations are usually small and do not increase in size rapidly (Bischler 1986). Growth seems to be limited by water availability. The lack of outcrossing may account for the limited variability of the species, the absence of ecotypes, and division into only two subspecies.

Male plants in nature are less frequent than female plants (Evans 1917; Bischler 1986). Near the borders of the range, males are almost completely absent (Bischler 1986).

Sporophytes can be found on the Azores islands and in the Caucasus mountains at fairly high elevations (Bischler 1986). Thus, male plants are present along with the females. Is it temperature that controls males, or do they have a dispersal limitation?

But even when both males and females are growing intermixed, only 25-42% of the females produce sporangia (Bischler 1986). Nevertheless, Bischler wondered why it was so high when both sperm and archegonia were elevated on stalked structures. But evidence presented in this chapter demonstrates that sperm, easily splashed, swim

directly to the archegoniophore and may even be carried upward by the same means that water moves upward.

With so few males, especially in some areas, *Marchantia paleacea* (Figure 97-Figure 99), relies to a great degree on gemmae (Figure 130-Figure 135) for local spread. As the gemmae age, the gemmae cups may disintegrate (Figure 136-Figure 138).

Interactions

Bacterial Interactions

Using cultures from gemmae of *Marchantia paleacea* (Figure 97-Figure 99), Alcaraz *et al.* (2018) isolated members of *Bryobacter*, *Lysobacter* (Figure 139),

Methylobacterium (Figure 140), *Paenibacillus* (Figure 141), *Pirellula*, *Rhizobium* (Figure 142-Figure 143), and *Steroidobacter* from the thalli. These bacteria are known to promote plant growth, degrade complex exudates, fix nitrogen, use and convert methylene, and suppress disease.

Figure 143. *Rhizobium* showing typical red color of nodules. Photo from CSIRO, through Creative Commons.

On the other hand, as in many liverworts, Pinfang *et al.* (2001) found that *Marchantia paleacea* (Figure 97-Figure 99) alcohol extracts were active against the Gram-positive bacterium *Bacillus subtilis* (Figure 144).

Figure 144. *Bacillus subtilis* stained with Nile Red, a species that is inhibited by alcohol extracts of *Marchantia paleacea*. Photo by EditorInTheRye, through Creative Commons.

In their study of 52 bryophyte species, Banerjee and Sen (1979) found that *Marchantia paleacea* (Figure 97-Figure 99) exhibited the broadest spectrum of antibiotic activity against the 12 microorganisms tested.

Fungal Interactions

Fungi have played a major role in the nutrition of land plants, and *Marchantia paleacea* (Figure 98-Figure 100) is no exception to these benefits. But they also contribute to this relationship. Rich *et al.* (2021) found that in the relationship between this species and its arbuscular mycorrhizal fungi, lipids are transferred from the liverwort to the fungus. Bouwmeester (2021) likewise found that liverwort lipids served to "entice" fungi into the mutualism and were essential to its establishment.

When gemmae (Figure 130-Figure 138) from this liverwort were cultured with tracheophyte roots, it took only 18 days for the liverwort to exhibit arbuscules, indicating fungal colonization (Kobae *et al.* 2019). These arbuscular mycorrhizal fungi entered through the rhizoids.

Field *et al.* (2019) identified the presence of both **Glomeromycotina** and **Mucoromycotina** fungal groups in *Marchantia paleacea* (Figure 97-Figure 99). They found that dual partnerships, hosting two different fungal species, provided complementarity both in greater nutrient pool use and greater allocation of photosynthate to the fungal partners. The partners seemed to provide different functions and the researchers argue for this complementarity as a reason for the success of multiple fungal partners in the plant kingdom. In this case, only the **Mucoromycotina** provided liverworts with substantial access to algal N, unrelated to atmospheric CO₂ concentration. Both fungal symbionts increased P uptake, but **Glomeromycotina** were often more effective.

Kodama *et al.* (2021) identified carotenoid-derived strigolactones in *Marchantia paleacea* (Figure 97-Figure 99). These compounds are known to both serve as hormones to regulate growth and development and to serve as rhizosphere-signalling molecules that induce a symbiotic relationship with arbuscular mycorrhizal fungi. However evidence suggests that in *Marchantia paleacea* the receptor needed for it to serve as a hormone is absent. It does, on the other hand, seem to serve as a mycorrhizal signalling device.

Other Interactions

It appears that *Marchantia paleacea* (Figure 97-Figure 99) might even have allelopathic effects on tracheophytes. Wang *et al.* (2013) found that secondary metabolites, in particular bibenzyls, from callus cultures of this species could inhibit seedling growth of the flowering plant *Arabidopsis thaliana* (Figure 80), with a dose-dependent response.

Biochemistry

Takio *et al.* (1998) found that expression of the cDNA that encodes the NADPH:protochlorophyllide oxidoreductase in *Marchantia paleacea* ssp. *diptera* (Figure 95-Figure 96) is light-dependent, whereas in most tracheophytes it is light-independent.

So *et al.* (2002) verified the presence of marchantin C, isoriccardin C, and the phenanthrene derivative, 2-hydroxy-3,7-dimethoxyphenanthrene in *Marchantia paleacea* (Figure 97-Figure 99). They also described the structures of two novel cyclic bis (bibenzyls), isoriccardinquinone A and B.

Yuan *et al.* (2021) characterized three genes for uridine diphosphate-dependent glycosyl transferases (DBRs) in this species. Wu *et al.* (2018) isolated and characterized two double bond reductases (DBRs). These enzymes are capable of catalyzing the NADPH-dependent reduction of the α,β -unsaturated double bond. The two reductases differed in their behavior and temperature optima. This was the first report of a microbial type of DBR in any plant. Both enzymes are important in protection against environmental stress in liverworts.

Mukhia *et al.* (2014) demonstrated that *Marchantia paleacea* (Figure 97-Figure 99) exhibited potential antioxidant activity and the existence of a variety of phytochemicals involved in scavenging activities.

Sakurai *et al.* (2016) identified the monocyclic monoterpene aldehyde, perillaldehyde, as the major component of volatiles, comprising about 50% of the volatiles in *Marchantia paleacea* subsp. *diptera* (Figure 95-Figure 96). This represents the first report of a perillaldehyde in a liverwort. Minor volatiles included α -selinene, β -selinene, β -caryophyllene, β -pinene, and limonene. But what do they do for the liverwort?

We have named a number of secondary compounds here, but in many cases their role for the liverwort is unclear. It is presumed that most of these serve in protection against pathogens and herbivores, but some might simply be intermediates in a pathway toward another needed compound. Others are apparently part of the ability to survive drought.

The antimicrobial properties (Xia *et al.* 2001) of many of these compounds may be of use to them. Examples include action against the Gram-positive bacterium *Bacillus subtilis* (Figure 144). Xia *et al.* (2001) isolated 2-hydroxy-3, 7-dimethoxyphenanthrene, marchantin C, and isoriccardin C from *Marchantia paleacea* (Figure 97-Figure 99).

Culturing

Awasthi *et al.* (2012) compared sterilization techniques in culturing *Marchantia paleacea* (Figure 97-Figure 99) and several other thallose liverworts. They found the best results with 1% sodium hypochlorite solution for 8-10 seconds. They used repeated sub-culturing to ultimately achieve aseptic cultures. All of these species grew well in half strength Knop's macronutrients + Nitsch's trace elements with 10 ppm freshly prepared ferric citrate under the continuous illumination of 4,500-5,000 lux at 20 \pm 2°C.

Marchantia pappeana (Figure 147)

Distribution

Marchantia pappeana (Figure 145) is widely distributed in tropical Africa. Bischler-Causse (1993) reported it from the Cape Verde Islands to Ethiopia and south to southern Africa, generally at an elevational range of 1000-2500 m. Its distribution in southern Africa

includes the Northern Province, Northern Transvaal, and Eastern Transvaal, Gauteng [PWV], Swaziland, KwaZulu-Natal, eastern [Orange] Free State, and Lesotho (Perold 1995). Müller (1995) recorded it for Zaire. Manyanga and Perold (2004) listed it for Zimbabwe. Enroth *et al.* (2019) recorded it from the Mwatate River in Kenya (see also Chuah-Petiot 2001). The World Flora Online (2022) simply describes the distribution as tropical Africa.

Figure 145. *Marchantia pappeana* along ditch in Ranomafana National Park, Madagascar. Photo courtesy of Catherine Reeb.

Aquatic and Wet Habitats

Marchantia pappeana (Figure 145) often grows in the same localities as *M. debilis* (Figure 28-Figure 36), including vertical soil banks of streams (Figure 146-Figure 148), at waterfalls, at sluice canals, rarely on rotting wood or on rocks, in open grassland, or in forests, sometimes in deep shade (Perold 1995; World Flora Online 2022).

Figure 146. *Marchantia pappeana* habitat on Zahamean riverbanks, Madagascar. Photo courtesy of Catherine Reeb.

Figure 147. *Marchantia pappeana* habitat on Zahamean riverbanks, Madagascar. Photo courtesy of Catherine Reeb.

Figure 148. *Marchantia pappeana* habitat on Zahamean riverbanks, Madagascar. Photo courtesy of Catherine Reeb.

Wigginton (2013) considered *Marchantia pappeana* (Figure 145) on Ascension Island to be a plant that grows mostly on rocks and soil (Figure 146-Figure 149), rarely on tree roots. Catherine Reeb (pers. comm. August 2022) has found it on the walls of ditches (Figure 149).

Figure 149. *Marchantia pappeana* along ditch in Ranomafana National Park, Madagascar. Photo courtesy of Catherine Reeb.

Reproduction

Marchantia pappeana (Figure 145) is **dioicous** (Perold 1995). Male plants produce antheridiophores; females produce archegoniophores (Figure 150). But sometimes male branches appear on the female receptacle (World Flora Online 2022).

Figure 150. *Marchantia pappeana* with archegoniophores along ditch in Ranomafana National Park, Madagascar. Photo courtesy of Catherine Reeb.

Sporangia are elevated on the archegoniophore (Figure 151). These disperse spores that are aided by wiggling elaters (Figure 152) as moisture changes occur.

Figure 152. *Marchantia pappeana* with mature sporangia dispersing spores, along ditch in Ranomafana National Park, Madagascar. Photo courtesy of Catherine Reeb.

Like other species of *Marchantia*, gemmae (Figure 153-Figure 154) are important means of asexual reproduction. Their hormone system curtails production of gemmae cups when sexual development begins. Of the 50 specimens Perold (1995) examined, 62% had cupules, 20% had antheridiophores, and 34% had archegoniophores; only 6% had both cupules and sexual structures.

Fungal Interactions

Strullu-Derrien *et al.* (2014) indicated that the fungal associations in *Horneophyton ligneri* from Rhynie Chert closely resemble the **Glomeromycota** symbionts in *Marchantia pappeana*. Field *et al.* (2015) found that the **Glomeromycota** found in *Marchantia pappeana* (Figure 155-Figure 156) were similar to the structures of the typical arbuscular mycorrhizae occurring in flowering plants. This species lacks studies on the benefits to *Marchantia pappeana* and its partner(s) in this association.

Figure 156. *Marchantia pappeana* colonized by **Glomeromycota** with detail of large vesicle. Modified from Strullu-Derrien *et al.* 2014, with permission from Jeff Duckett.

Biochemistry

Despite its somewhat narrow distribution, *Marchantia pappeana* (Figure 146) has experienced several biochemical studies. Linde *et al.* (2016) reported that sesquiterpene hydrocarbons are characteristic of this species (see also Combrinck *et al.* 2015). Linde *et al.* (2016) found that crude extracts of *M. pappeana* from South Africa (as well as *Pallavicinia lyellii*) had the highest level of antibacterial activity against *Escherichia coli* among the nine liverworts tested. Much remains for us to learn about the role of these sesquiterpenes for the liverwort.

Summary

The species of *Marchantia* covered in this subchapter are those of wet habitats. They may become

submersed occasionally during flooding events, but they do not normally live submersed. To survive in these habitats, they are protected by a thick thallus with air chambers to permit CO₂ entry. Oil bodies serve as a storage organ for polysaccharides and for secondary compounds that help prevent herbivory and protect the thallus from pathogens. A ridge of cutin around the pore prevents water entry. Scales on the lower surface help to move water to the thallus and to retain it in capillary spaces. Some rhizoids anchor the thallus while others help in directing water to the thallus on the lower surface.

They all have gemmae, which seem to be their primary means of reproduction. Yet some are able to colonize rapidly after a fire, suggesting that they are also dispersed by spores. The longevity of spores and gemmae has not been tested.

Secondary compounds, mostly sesquiterpenes and flavonoids, help to protect the plants from herbivory and pathogens.

Acknowledgments

Lars Söderström helped me with puzzling nomenclature. Masaki Shimamura alerted me to nomenclature problems in *Marchantia paleacea* vs. *M. polymorpha* in some important publications. Li Zhang sent me a variety of papers and reviewed my treatment of *Marchantia emarginata*. Catherine Reeb introduced me to *Marchantia debilis* and *M. pappeana* as species of wet habitats and provided me with many images and habitat information. Thank you to Tian-Xiong Zheng and for sending me much needed images. And thank you to the many photographers who have given me blanket permission to use their images or who have put them in Creative Commons.

CHAPTER 1-24

AQUATIC AND WET MARCHANTIOPHYTA, CLASS MARCHANTIOPSIDA: MARCHANTIACEAE, PART 2

Figure 1. *Marchantia polymorpha* in a typical waterside habitat. Photo by Michael Lüth, with permission.

Marchantiaceae, cont.

Marchantia polymorpha (Figure 1-Figure 12)

(syn. = *Marchantia alpestris*; *Marchantia aquatica*; *Marchantia coarctata*) – see Long (1995) for a discussion of the history of older naming of the species and subspecies.

Boisselier-Dubayle *et al.* (1995) elaborated on the genetic variability in the three subspecies of *Marchantia polymorpha* (Figure 1-Figure 12). The three subspecies [*montivagans* (Figure 2-Figure 4), *polymorpha* (Figure 5), *ruderalis* (Figure 6-Figure 8)] had high genetic similarity within each subspecies over a wide geographic area, but the similarity was low between subspecies. These differences indicate that speciation included adaptation to different ecological niches, followed by reproductive isolation.

Figure 2. *Marchantia polymorpha* ssp. *montivagans* with antheridiophores. Photo by Jan-Peter Frahm, with permission.

The variety *aquatica* (Figure 9) (Campbell 1968; Hollensen & Taylor 1981; Kitagawa 1987) is not recognized by Söderström *et al.* (2016). Instead, it is considered within the species *Marchantia polymorpha* as ssp. *polymorpha*. Nevertheless, it appears that those thalli that develop underwater can be distinguished by a black

midrib (Michael Lüth, pers. comm.). Recognition of this distinction can give us an ecological history of plants we find and deserves some experimental attention.

Figure 9. *Marchantia polymorpha* ssp. *polymorpha* with distinct black midribs, typical of aquatic forms, in Europe. Photo by Michael Lüth, with permission.

Google Scholar found 20,500 references in a search for *Marchantia polymorpha* (Figure 1-Figure 12). *Marchantia polymorpha* has been a subject of intensive study for nearly 200 years (Shimamura 2016). The species offers many benefits for research, including its short life cycle, ease of propagation and crossing, high frequency of transformation, haploidy, and small genome size (approximately 280 Mb).

Figure 10. *Marchantia polymorpha* with overlapping thalli. Photo by Sanja through Wikimedia Commons.

Berrie and Webster (1982) elaborated on the ultrastructure of the plastids and mitochondria of the *Marchantia polymorpha* gemmae (Figure 4). They found that division among plastids and maturing vegetative cells differed from that of developing oil body cells and rhizoid initials. Bopp and Vicktor (1988) developed methods for following protoplast development, determining that cell wall formation requires light.

Figure 11. *Marchantia polymorpha* thallus. Photo from Botany Website, UBC, with permission.

A Liverwort Model

genetics and sequencing

The species has served as a model organism in many biological studies (Chiyoda *et al.* 2008), including the discovery of sex in cryptogams and more recently the elucidation of the V chromosome (term for male chromosome in haploid organism), understanding the plant life cycle, and origins of polarity in development. The use of *Marchantia polymorpha* s.l. (Figure 1-Figure 12) as a plant model system continues (Durand 1908; Alam & Pandey 2016; Shimamura 2016), with its dominant haploid generation being a benefit for genetic studies and gene expression as well as details of evolutionary and developmental biology.

Marchantia polymorpha (Figure 1-Figure 12) has been used to demonstrate the presence of "X" and "Y" chromosomes in bryophytes, now referred to as U and V chromosomes, respectively (Renner *et al.* 2017). I shall continue this discussion using the designation of U for female and V for male. This early discovery of sex chromosomes was followed by the sequencing of the male and female genomes (Ohyama 2001). Ohyama found that some of the genes on the V chromosome were unique, whereas those on the U chromosome were also on somatic chromosomes or even on the V chromosome. Since these are haploid organisms, the males have a very small V chromosome with no U chromosome and females have one U chromosome with no second U or any V (Lorbeer 1934; Tanurdzic & Banks 2004). Sporophytes are UV.

Yamato *et al.* (2007) reported that these V chromosomes differ from other chromosomes in lacking recombination. They reported the gene organization of the V chromosome of *Marchantia polymorpha* (Figure 1-Figure 12) and identified 64 genes on the V chromosome. Of these, 14 are found only in the male genome and are expressed only in male reproductive organs. Another 40 are expressed in thalli and reproductive organs. Interestingly, at least 6 of these have U-linked counterparts that are expressed in both thalli and sex organs of females. Yamato and coworkers suggested that these sex chromosomes share ancestral autosomal genes, and they predict that essential genes on sex chromosomes of haploid organisms are more likely to persist than those in diploid organisms.

As in many other studies, *Marchantia polymorpha* (Figure 1-Figure 12) was the choice for studying the divergence of land plant chloroplast (Figure 12) genes (Morton 1994). Bischler (1986) analyzed the karyotype. In *Marchantia polymorpha* the genes with the highest codon adaptation index correspond to the ones that are expressed at the highest levels (Morton 1994). This relationship is weaker in *Nicotiana tabacum* (Figure 13).

Figure 12. *Marchantia polymorpha* thallus section through pore, showing location of photosynthetic filaments with chloroplasts. Photo from Botany Website, UBC, with permission.

Figure 13. *Nicotiana tabacum*, a species that demonstrates the conservation of *Marchantia* genes in flowering plants. Photo through Creative Commons

One interesting finding is that chloroplast ribosomal protein rpl 21 in *Marchantia polymorpha* (Figure 1-Figure 12) is encoded by the plastid gene, but in tobacco and rice this is a nuclear gene (Smooker *et al.* 1990). Sone *et al.* (1999) reported for the first time a co-localization of repeat rDNA in land plants. These researchers suggested that the structural re-organization of rDNAs occurred after the evolutionary divergence of bryophytes from other plants.

Marchantia polymorpha (Figure 1-Figure 12) appeared to be one of the first organisms to have its chloroplast and mitochondrial DNA sequenced (Ohya *et al.* 1986; Oda *et al.* 1992a; Kisiel *et al.* 2011; Lin *et al.* 2016). But unfortunately, the species used in early studies (Ohya *et al.* 1986; Oda *et al.* 1992a,b,c,d) was a misidentified *Marchantia paleacea* (Figure 14) (Kijak *et al.* 2013, 2016; Masaki Shimamura, pers. comm. 10 July 2022). Hence, this first sequencing cannot be attributed to *Marchantia polymorpha*.

Figure 14. *Marchantia paleacea* with archegoniophores. Photo by Jan-Peter Frahm, with permission.

Posno *et al.* (1986) showed that there was "substantial" conservation in the chloroplast genome sequences between *Marchantia polymorpha* (Figure 1-Figure 12) and those of the aquatic flowering plant *Landoltia punctata* (Figure 15). Umesono and Ozeki (1987) found that the chloroplast genome sequence of *Marchantia polymorpha* differs little in gene makeup and function from that of flowering plants, despite flowering plants one that is 25%.

Figure 15. *Landoltia punctata*, a species with considerable conservation of the chloroplast genome sequences found in *Marchantia polymorpha*. Photo from US Dept. Interior, through Creative Commons.

Kohchi *et al.* (1988) characterized parts of the chloroplast DNA in presumably *Marchantia paleacea* (Figure 14), under the name of *M. polymorpha*. Raubeson and Jansen (1992) further explored what these DNA sequences had in common with later plants.

Takemura *et al.* (1992) elaborated on ribosomal proteins that are coded in the mitochondrial genome of *Marchantia polymorpha* (possibly *M. paleacea*), and these differ substantially in size from their counterparts in the bacterium *Escherichia coli* (Figure 16). In the same year, Oda *et al.* (1992a,b,c) found that the mitochondrial DNA of *Marchantia paleacea* (Figure 14; misidentified as *M. polymorpha*) is a single circular form that exhibits no incorporation of chloroplast DNA. Whichever species was actually used, Ohyama *et al.* (1982, 1983, 1986, 1988a,b,c; Ozeki *et al.* 1987; Los & Semenenko 1991) showed that many (most?) chloroplast genes in such liverworts as *Marchantia* have been conserved in tobacco, *Nicotiana tabacum* (Figure 13).

Figure 16. *Escherichia coli*, a bacterium that exhibits very different ribosomal proteins from those of *Marchantia polymorpha/paleacea*. Photo from USDA, through public domain.

Takemura *et al.* (1992) elaborated on ribosomal proteins that are coded in the mitochondrial genome of *Marchantia polymorpha* (possibly *M. paleacea*), and these differ substantially in size from their counterparts in the bacterium *Escherichia coli* (Figure 16).

Downie *et al.* (1991) and Sibbald (1988) subsequently compared chloroplast DNA of dicotyledonous flowering plants with those attributed to *Marchantia polymorpha*. Comparisons between mosses and liverworts with hornworts indicated that the two former groups were more closely related to each other than either was to hornworts (Katoh *et al.* 1983).

The entire gene sequence was not known until 2017, using *Marchantia polymorpha* ssp. *ruderalis* (Figure 17-Figure 19) (Bowman *et al.* 2017). Since then, the subspecies have been sequenced and their evolutionary relationships elucidated (Linde *et al.* 2020). The results supported the hypothesis that *M. polymorpha* ssp. *ruderalis* is not a hybrid of the other two subspecies, as some researchers had thought.

Marchantia polymorpha (Figure 1-Figure 12) has likewise been used as a model organism in understanding development in thallose liverworts (Suzuki *et al.* 2020).

But the scientific study of this species, especially regarding development, has been occurring for at least 200 years (Shimamura 2016). Suzuki and coworkers described merophyte lineages and elaborated on the derivation of growth from stem cells in the apical notch (Figure 20).

Figure 20. *Marchantia polymorpha* showing apical notch with brown covering scale. Photo by Li Zhang, with permission.

Linde *et al.* (2021) compared rates of mutations among the major plant groups and found that the gymnosperms had the fewest synonymous mutations, flowering plants the most, and bryophytes were located between those two. In this regard, the silent site substitution rate (neutral evolution) is lower for the liverwort compared to flowering plants, but not as low as that of gymnosperms. They found the same selective constraints on the haploid-specific genes as those on the diploid-specific genes. However, in the haploid generation the new mutations experience immediate and direct selection, hence quickly being lost if they are maladaptive. The nonsynonymous to synonymous substitution rate ratio (dN/dS) represents selective evolution. This silent site substitution rate is lower for liverworts as compared to flowering plants, but again not as low as for gymnosperms. The selection pressure, measured as dN/dS, is not remarkably lower for bryophytes when compared to diploid dominant plants as we might expect based on the **masking hypothesis** (predicts more efficient selection in haploids than in diploids, because dominant alleles can mask deleterious effects of recessive alleles in diploids; however, gene expression breadth and noise can potentially counteract the effect of masking on the rate at which genes evolve), indicating that other factors are more important than ploidy.

Liu *et al.* (2019) noted that the dN/dS for nuclear genes was more than three times higher for bryophytes when compared to seed plants. However, the sets of genes compared were not the same genes in both groups. Linde and coworkers (2021) compared the same 42 genes in both groups and found that the dN/dS rates were much more similar. This raises the question of why bryophytes, given their long history, are less diverse and appear to have less morphological diversity than tracheophytes, especially flowering plants. But as I have argued elsewhere, they are confined to being small due to their lack of lignin. They furthermore, because of this small size, are at greater risk of disappearance due to herbivory and pathogens. If one

considers their biochemical diversity, affording them protection from herbivores and pathogens, are they really less diverse?

Fang *et al.* (2014) reported for the first time the presence of oleosin genes in liverworts, using *Marchantia polymorpha* (Figure 1-Figure 12). The liverworts tested exhibited only M-oleosins, whereas three types are known from various plant lineages. This seems to be a precursor to the other two oleosins, suggesting another piece of the evolutionary story.

With all of our knowledge about molecular similarities and differences, molecular/genetic studies have become the driving force in plant systematics. Using the **Marchantiales**, Boisselier-Dubayle *et al.* (1997) were among the early researchers to point out that there can be an incongruence between morphological characters and molecular data, complicating our systematic efforts.

Understanding the genome, coupled with the greater ease of working with haploid organisms, has contributed to the use of *Marchantia polymorpha* (Figure 1-Figure 12) in transferring genes to determine their functions.

teaching

The genus *Marchantia* is notable in the pre-Renaissance literature, with illustrations of *M. polymorpha* (Figure 1-Figure 12) appearing as early as the mid-15th Century (Bowman 2016). Notable early treatments are those of Schmidel (1762) and Hedwig (1783). It has been used for centuries in nearly every textbook and classroom that teaches about bryophytes or life cycles (Cutting 1910; Inoue & Asakawa 1966; Register & West 1971; Une 1998; Bowman 2016).

Marchantia polymorpha (Figure 1-Figure 12) has also been used as a pedagogical model to teach the bioindicator concept to seventh graders (Pedroza-Manrique & Arévalo 2009). This was part of a study on comparison of learning strategies. Results demonstrated that "learning must be related to the environment of the students and must also represent a challenge for them, this allowed for significant learning."

Durand (1908), in preparing material for teaching a course in embryology, selected *Marchantia polymorpha* (Figure 1-Figure 12) to represent development in liverworts. He wrote that he "naturally selected *Marchantia polymorpha*" because of its accessibility and ease of study. And it is illustrated in practically every textbook that treats liverworts.

Distribution

Marchantia polymorpha (Figure 1-Figure 12) has a worldwide distribution (Figure 21), especially in the Northern Hemisphere (Bischler-Causse 1989; Lu & Huang 2017). It is known from Afghanistan, Bhutan, China, India, Indonesia (Java, Sumatra), Iran, Iraq, Israel, Japan, Korea, Lebanon, Malaysia, Nepal, New Guinea, New Zealand, Pakistan, Philippines, Russia, Sri Lanka, Syria, Tadjikistan, Taiwan, Tasmania, Thailand, Turkey, USSR, Uzbekistan, and Vietnam (Bischler-Causse 1989; Söderström *et al.* 2010; Ginting & Batubara 2019). As seen in Figure 21, it is also extensively reported throughout North America. *Marchantia polymorpha* has three subspecies. In South Africa, *M. polymorpha* ssp. *ruderalis* (Figure 6-Figure 8, Figure 17-Figure 19) only occurs in

nurseries (Figure 22-Figure 23), indicating that it has been introduced (Ginting & Batubara 2019).

Aquatic and Wet Habitats

Boisselier-Dubayle and Bischler (1989) described the electrophoretic biochemistry of *Marchantia polymorpha* (Figure 1-Figure 12) as having a good correlation with the habitats. They identified two ecotypes: domestic with a spread over a wide geographic area (possibly corresponding with *M. polymorpha* ssp. *ruderalis* – Figure 6-Figure 8, Figure 17-Figure 19), and a wet-habitat-restricted ecotype that exhibited two biotypes [corresponding with *M. polymorpha* ssp. *polymorpha* (Figure 5) and possibly *M. polymorpha* ssp. *montivagans* (Figure 2-Figure 4)].

In their recent publication on *Marchantia* in Japan, Zheng and Shimamura (2022) described the habitat of *Marchantia polymorpha* ssp. *polymorpha* (Figure 5) as growing on wet soil in marshland or stone near streams, seldom on wet concrete. They described *Marchantia polymorpha* ssp. *ruderalis* (Figure 6-Figure 8, Figure 17-Figure 19) as often on soil, stone, gravel, or walls of drainage channels in anthropogenic regions, supporting the conclusions of Long (1995). But Zheng and Shimamura (2022) also found that when the latter subspecies grows in dripping wet habitats, "plants often have an erect and robust thallus with a distinct and continuous blackish median band on the thallus and are sometimes difficult to distinguish from ssp. *polymorpha* based on these characters." However, they consider that the discontinuous blackish median band and prostrate thallus of ssp. *polymorpha* will distinguish them. I would like to see common garden experiments on the effects of wet vs drier habitats on the expression of the black median band (midrib) in each of the subspecies.

Subspecies *montivagans* (Figure 2-Figure 4) in Britain and Ireland is a species occurring in springs, marshes, and flushes, in somewhat calcareous areas, and occurs mostly in subalpine or montane habitats (Long 1995). It can also be found on damp calcareous mossy banks and rocks beside streams and ravines. However, in their studies Boisselier-Dubayle and Bischler (1989) found it in some locations together with *M. polymorpha* ssp. *polymorpha* (Figure 5).

Frye (1928) found that *Marchantia polymorpha* (Figure 1-Figure 12) was sometimes submersed in winter. This, presumably, was ssp. *polymorpha* (Figure 5).

Darigo (2004) reported the aquatic form of *Marchantia polymorpha* (as *Marchantia aquatica*; now *M. polymorpha* ssp. *polymorpha*; Figure 5) as new to Missouri, USA, noting its distinctive black midrib. He found it in dense mats on shaded moist soil and limestone bedrock at the base of a small waterfall. It was associated with *Fissidens grandifrons* (Figure 24), *Rhizomnium punctatum* (Figure 25), and *Leptodictyum riparium* var. *laxirete* (Figure 26).

Marchantia polymorpha s.l. (Figure 1-Figure 12) occurs in wet places around lakes, especially in shade, and in bog water in Scotland (West 1910). In Denmark it can be found on terrestrial soil or submerged (Sørensen 1948). It is uncommon with the graminoid *Eleocharis quinqueflora* (Figure 27) and the moss *Paludella squarrosa* (Figure 28) Geissler & Selldorf 1986).

Marchantia polymorpha (Figure 1-Figure 12) occurs in shady areas with high humidity and exhibits a low tolerance to desiccation (Lagos-López 2008). In such areas it can develop extensive cover (Linares 1986; Churchill & Linares 1995; Uribe & Aguirre 1995; Lagos-López 2008). But perhaps one of the most extensive covers develops in burned over areas (Durand 1908; Janet Marr, pers. obs. 2022), usually not an aquatic habitat.

streams and rivers

Watson (1919) described the habitat of *Marchantia polymorpha* (Figure 1-Figure 12) as often on boulders in streams, on banks with frequent submergence and slow water. In the Western Carpathians it occurs in the rock community in streams near Lacko (Mamczarz 1970). It

occurs in streams in Greece (Papp 1998) and in streams in northeastern Finland (Heino & Virtanen 2006). It is among the most common species in the River Tweed, UK (Holmes & Whitton 1975) and is among the commonest species in English and Welsh rivers (Scarlett & O'Hare 2006).

It can also be common in rivers (Ferreira *et al.* 2008), such as the Iskur River, Bulgaria, and its main tributaries (Papp *et al.* 2006), as a hygrophyte in Bulgarian rivers (Gecheva *et al.* 2010, 2013), and in the Iregua River of Spain (Martínez-Abaigar & Ederra 1992).

It is often a mountain species, occurring in alpine streams in the Swiss Alps (Geissler 1976) and in mountain streams of northwest Portugal (Vieira *et al.* 2005) as well as mountainous streams on Madeira Island (Luis *et al.* 2015). Frye (1928) reported it from western Washington, USA, in burned sites, but also in submersed sites. It is interesting that several *Marchantia* species occur in both aquatic habitats and as pioneers after fire.

stream and river banks

Perhaps the most common wet habitat for *Marchantia polymorpha* (Figure 1-Figure 12) is the damp banks of streams and rivers (Figure 29-Figure 32). In the Haute Ardenne rivers in Belgium, it occurs on earthy and gravelly substrates of river banks (Leclercq 1977) and in the UK it occurs on the riverbank of the River Tees (Holmes & Whitton 1977a). It can be found throughout the River Swale, Yorkshire, UK (Holmes & Whitton 1977b), and mostly in the mid to lower River Tyne, UK (Holmes & Whitton 1981b). It is similarly associated with the River Wear in England (Birch *et al.* 1988). In Germany it occurs in the middle and lower reaches in the Harz Mountains (Bley 1987). Ginting and Batubara (2019) similarly describe it from rocks of a creek wall in exposed places (Figure 33), at 1500 m altitude in Indonesia. In western Canada, it is restricted to terrestrial habitats of montane streambanks (Vitt *et al.* 1986; Glime & Vitt 1987).

In Denmark *Marchantia polymorpha* (Figure 1-Figure 12) can be found in ditches at pH 6.2-8.5 and in neutro-alkaline lakes, peat pits of spring bogs (Figure 34) at pH 6.2-8.0, on terrestrial soil or submerged (Sørensen 1948; Clausen 1952). Alfasane *et al.* (2013) recorded environmental conditions in Lake Rainkhyongkain, where it grew in masses in the shallow littoral zone of the lake. These included mean values ($n = 4$) of dissolved oxygen

content ($7.93 \pm 0.78 \text{ mg L}^{-1}$), alkalinity ($1.70 \pm 0.12 \text{ meq L}^{-1}$), soluble reactive phosphorus ($17.25 \pm 0.62 \text{ } \mu\text{g L}^{-1}$), soluble reactive silicate ($10.44 \pm 0.72 \text{ mg L}^{-1}$), and $\text{NO}_3\text{-N}$ ($34.00 \pm 4.00 \text{ } \mu\text{g L}^{-1}$). The mean temperature on the sampling date was 33.5°C and pH was 7.39.

In the high moor transition areas of Denmark *Marchantia polymorpha* (Figure 1-Figure 12) can be found at pH 5.0-6.09 (Sørensen 1948). O'Toole and Synnott (1971) found that *Marchantia polymorpha*, along with *Funaria hygrometrica* (Figure 35), was an early indicator of increased calcium carbonate and phosphorus levels on blanket peat following fertilization of the peat. However, these two bryophytes are suited to other environmental conditions, with *M. polymorpha* preferring wet, unsheltered plots with no iron or copper, whereas *F. hygrometrica* prefers dry, sheltered locations with iron (Synnott 1987). Li Zhang (pers. comm. 4 August 2022) has found *Marchantia polymorpha* in peatlands (Figure 34) in China.

Figure 35. *Funaria hygrometrica*, an indicator, along with *Marchantia polymorpha*, of increased calcium carbonate and phosphorus levels in blanket peat. Photo by Bonnie Nickel, through Creative Commons.

In Taiwan, Lu and Huang (2017) found *Marchantia polymorpha* (Figure 1-Figure 12) on damp soils from 300-2500 m asl, a habitat similar to that on Mt. Edith Cavell in Canada (Figure 36).

In high moors in Denmark it occurs in the transition areas at pH 5.0-6.0 (Sørensen 1948). In the Caucasus it is in watery and swampy lands (Alijev & Babajev 1976).

Figure 36. *Marchantia polymorpha* with gemmae, on damp soil with mosses on the mountainside of Mt. Edith Cavell, Jasper, Canada. Photo by Janice Glime.

Other damp soil habitats are also suitable, including open areas (Figure 37), moist slopes (Figure 38), marshy areas (Figure 39), and other wetlands (Figure 40). Thatcher (1949) found it in an artificially illuminated cave.

Figure 37. *Marchantia polymorpha* on soil, with gemmae cups, in Europe. Photo by Michael Lüth, with permission.

Figure 39. *Marchantia polymorpha* in a marshy habitat near a stream. Photo by Michael Lüth, with permission.

One of the more interesting habitats for *Marchantia polymorpha* (Figure 1-Figure 12) is on a **desalinating wadden-polder** (tract of low land reclaimed from the sea; Figure 41) (Joenje & During 1977). Although it was able to colonize, it was unable to compete after 2-3 years. It was especially common on mussel banks. Joenje and During suggested that its small spores contribute to its rapid arrival on newly available substrata.

Figure 41. Gradual transition from recently deposited salt marshes and the Wadden sea on a desalinating wadden-polder. This stage is too salty, due to manipulation, and the only bryophyte able to live here is *Hennediella heimii*. Photo courtesy of Bart van Tooren.

Another unusual habitat where *Marchantia polymorpha* (Figure 1-Figure 12) can thrive is in geothermal areas (Figure 42). These can have some similarities to saline areas because of sulfur and other salts. In the Antarctic, they provide a warm haven for species from warmer climes, including *M. polymorpha* (Kennedy 1996). Takaki (1967) found it on an active volcano in Japan. Takaoki and Mitani (1986) used *Marchantia polymorpha* in experiments to develop a method for measuring the effects of SO₂ on photosynthesis in bryophytes and lichens. They found that illumination during the exposure to SO₂ caused the SO₂ to have greater inhibition of photosynthesis in *M. polymorpha* than did SO₂ alone. In this species, the photosynthetic system was more sensitive than the respiratory system. In concentrations less than 4 ppm, the thalli were able to partially recover.

Figure 42. Geothermal fissure with *Sphagnum*, Geyser, Iceland, a potential habitat for *Marchantia polymorpha*. Photo by Janice Glime.

Figure 43. Mt. Hood Riverside, Oregon, USA, post-fire, at a stage where *Marchantia polymorpha* can be a pioneer. Photo from U.S. Department of Agriculture, through public domain.

after fire

It is interesting that several species of *Marchantia* are post-fire colonizers (Figure 43). This is true for *Marchantia polymorpha* (Figure 1-Figure 12) (Benson & Blackwell 1926; Torrey 1932; Bradbury 2006). Frye (1928) and Hoffman (1966) both reported it on burned sites in Washington, USA, and Graff (1936) similarly found that the species invaded after forest fires. Adámek *et al.* (2016) studied post-fire vegetation in central Europe and again found that *Marchantia polymorpha* was among the first invaders, but it typically disappeared after a few years. Froment (1975) found it to be among the pioneer dominants in a Belgian high fen post-fire site. Heras-Ibáñez *et al.* (1991) recorded it in post burn sites in SE Spain, where it had diminished numbers after 6 years. They noted that some of the species, including *M. polymorpha*, were known to fix nitrogen (through bacterial partners) on such sites. Duckett *et al.* (2008) noted that *M. polymorpha* is common after fires in Canada and explored post-fire invasion at Thursley Common, UK. Once again, *M. polymorpha* was a common invader. In fact, they noted that thalli had abundant reproductive structures in the first year following the fire. They attributed the rapid colonization to the tiny (10-16 µm) spores. Subspecies. *ruderalis* and ssp. *polymorpha* were present side by side. The species formed patches reaching up to 12 m in diameter, with individual colonies of 5-20 cm diameter (Duckett & Pressel 2009). Rather than naming tracheophyte competition, they attributed the later decline to nutrient leaching (Duckett *et al.* 2008). Its presence is so common after fire that Rees and Juday (2002), when reporting it from Alaskan burned sites, considered it to be a fire specialist.

The succession of species following fire is a fairly constant one, as noted already by Skutch (1929). Typically, the pioneer stage with *M. polymorpha* (Figure 1-Figure 12) is succeeded by *Polytrichum* (Figure 44).

These habitats would seem to be quite different from the wet ones already discussed. But one thing they have in common is reduced competition, giving the liverworts time to become established.

Figure 44. *Polytrichum juniperinum*, a post-fire species that succeeds *Marchantia polymorpha*. Photo by James K. Lindsey, with permission.

Having said that, how then do we explain that in East Anglia *Marchantia polymorpha* (Figure 1-Figure 12) is more common in town than in the countryside (Stevenson & Hill 2008)? Is the subspecies *ruderalis* more tolerant of competition, or do the spores manage to find spots with limited competition?

Physiology

It is not surprising that the anatomy and physiology of this well known species were among the early bryological studies (Mirbel 1835). Since that time, a long period of mostly taxonomic activity ignored the physiology of most bryophytes. However, *Marchantia polymorpha* (Figure 1-Figure 12) was frequently the subject of those studies that did address bryophyte physiology.

hormones - IAA

Among the many studies on *Marchantia polymorpha* (Figure 1-Figure 12), it often served as the model organism for understanding physiology of thallose liverworts, or bryophytes in general. Maravolo and Voth (1966) reported the actions of various concentrations of indoleacetic acid (IAA), naphthalene acetic acid (NAA), and maleic hydrazide on development of sterile gemmae (Figure 45) of *Marchantia polymorpha*. They found that the two auxins

(IAA and NAA) promoted similar responses, often resembling those of tracheophytes. In *M. polymorpha*, rhizoids elongated on the dorsal surface; the growing region became dormant, and cells became strongly elongated. When apical growth (Figure 20, Figure 46) was inhibited, the thallus became winged. The maleic hydrazide likewise elicited responses similar to those in tracheophytes, including inactivation of meristematic regions, deterioration of chloroplasts, inhibition of rhizoid production, and **hyperplasia** (enlargement of organ or tissue caused by increased reproduction rate of its cells).

Figure 45. *Marchantia polymorpha* with gemmae in gemmae cups. Photo by Holger Casselmann, through Creative Commons.

But at that time, the production of IAA by bryophytes was still unknown. Schneider *et al.* (1967) reported for the first time that IAA (indoleacetic acid) occurs in bryophytes, using *Marchantia polymorpha* (Figure 1-Figure 12) as one of the test organisms. Furthermore, Sheldrake (1971) reported auxin in the substrata of bryophytes, so its effect on them is relevant. However, concentrations of the IAA in substrata with no bryophytes were the same in those that had them. Hence, it is questionable whether these substrate sources were of importance to the development of the bryophytes. Nevertheless, they could play a role in the induction of rhizoids as they do for roots. And they might have more effect on some bryophytes not included in the tests.

Following up on the possible functions, Otto and Halbsguth (1976) examined the effects of light and the auxin IAA on the formation of the primary rhizoids of gemmae in *Marchantia polymorpha* (Figure 1-Figure 12). They found that the number of rhizoid-forming gemmae depends on the wavelength of irradiation. Following a 1-hour exposure to 10^{-4} M IAA, rhizoids developed as they would if exposed to red irradiation for one hour. They concluded that this relationship suggests a role of the phytochrome system in membrane permeability for IAA.

Transport of the auxin 11C-indoleacetic acid occurs basipetally in the thallus, where it is localized in the midrib (Figure 46-Figure 47) (Maravolo 1976; Gaal *et al.* 1982).

Figure 46. *Marchantia polymorpha* with strong midrib on older thalli; this character is common in aquatic forms. In several branches you can see apical dominance where a single branch is dominant and the other is shorter or has an unbranched midrib (e.g. center left). Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 47. *Marchantia polymorpha* with only hints of midrib on young thallus tissue, probably ssp. *ruderalis*. Photo by Janice Glime.

Reynolds and Maravolo (1973) determined that extracts of *Marchantia polymorpha* (Figure 1-Figure 12) contain substances that in the lab can enhance or inhibit IAA oxidation. These extracts contained four unknown phenolic compounds. Two of these enhanced the oxidase activity and two inhibited it. Although the inhibitors were present throughout the thallus, they were slightly more concentrated in basal and apical areas. In other words, there was an **acropetal** (movement of dissolved substances outward toward shoot and basal apices) gradient of increase in this cofactor concentration. In this case IAA moves away from the growing tips.

Gaal *et al.* (1982) used tracer experiments to determine that ^{14}C IAA transport is localized in the cells of the midrib of the thallus (Figure 46). It occurs both acropetally and basipetally, with a far greater intensity basipetally. In anaerobic conditions, basipetal transport was reduced by 40-50%. Centrifugation also disrupted it, reducing basipetal transport by 30-40%. Hence, in the parameters measured, transport of IAA in *Marchantia polymorpha* (Figure 1-Figure 12) is essentially the same as that in seed plants.

Davidonis and Munroe (1972) described apical dominance (Figure 46) in *Marchantia polymorpha* (Figure 1-Figure 12), a function known from tracheophytes. The species dichotomous branching and its apical dominance is exhibited by one of those branch lobes having greater growth than the other (Figure 46). They demonstrated that if the lobes are separated by a cut, the dominance is lost. IAA is needed to maintain this dominance. If it is applied to the smaller lobe after the cut, that lobe is again inhibited. It also exhibits greater inhibition of the smaller lobe when applied to the intact plant. Interestingly, the dominant lobe is neither inhibited nor enhanced by application of IAA to it. They suggested that this behavior indicates that the two lobes have a different sensitivity to the auxin. This is somewhat reminiscent of apical dominance in plants like snapdragons. IAA produced in the apex of the plant migrates downward and inhibits the development of side branches. If the apex is removed, a lower branch becomes dominant.

Hormones can both activate and suppress pathways in *Marchantia polymorpha* (Figure 1-Figure 12). Binns and Maravolo (1972) found that cytokinin suppressed the normal germination of gemmae (Figure 45), instead stimulating nodular, callus-like growths. Responses were time-dependent on the cytokinin-enriched medium. Auxin, on the other hand, had no effect on the regeneration of normal thallus growth. Auxin could, however, reverse the suppression caused by inhibiting compounds such as transcinnamic acid. Auxin exhibited a basipetal gradient and this gradient is essential to normal growth and regeneration. These two hormones interact, with high levels of cytokinin destroying the polarity by increasing the auxin-synthesizing capacity. Maintaining the right balance permits the liverwort to maintain its apical dominance (Figure 20, Figure 46).

Flores-Sandoval *et al.* (2015) characterized the functions of the auxin transcriptional response in *Marchantia polymorpha* (Figure 1-Figure 12). It acts to facilitate branching, differentiation, and growth, but it does not determine specific tissues.

Eklund *et al.* (2015) found that the auxin IAA regulates the dormancy of gemmae (Figure 48) on the *Marchantia polymorpha* (Figure 1-Figure 12) thallus. Kato *et al.* (2015) found that auxin repression could cause severe defects in the development of *Marchantia polymorpha*, including gemmaling development, dorsiventrality, organogenesis, and tropic responses, noting the interactions of hormones. Billhardt (2021) further discussed the interactions, and using these was able to explain the long-known observation that gemmae typically do not germinate while still on the parent thallus (Figure 48). This dormancy mechanism is controlled by high levels of abscisic acid (ABA) in the cup (see also Tougan *et al.* 2010). But gemmae are not attached to the thallus while they reside in the cup. Therefore, it appears that the actual signal is a gas. Billhardt found that when the regulators of the ethylene signalling pathway were mutated, it affected the dormancy, suggesting that ethylene regulates dormancy through ABA. Müller (2021) notes that ABA and ethylene commonly act antagonistically, possibly explaining these observations.

Ishizaki *et al.* (2012) used transgenic plants to monitor the effects of auxin-mediated transcriptional activation in

plants. This demonstrated that IAA had a role in the transcription of some genes. These genes were demonstrated at the bottom of the gemmae cups. Additional activity occurred at the gametophyte-sporophyte junction and in the developing sporophyte.

Figure 48. Gemmae cups with loose dormant gemmae on thallus of *Marchantia polymorpha*, demonstrating their continued dormancy while associated with the parent tissue. Photo by Hermann Schachner, through Creative Commons.

hormones - gibberellins

Melstrom *et al.* (1974) found that *Marchantia polymorpha* (Figure 1-Figure 12) exhibits gibberellin activity and was responsive to photoperiod. When they increased the photoperiod from 12 to 18 hours of light the activity of the gibberellins increased and thallus elongation and **orthogeotropic** (directly in line with gravitational pull; Figure 49) growth increased.

Figure 49. *Marchantia polymorpha* ssp. *polymorpha* growing upright in water. Photo by Oleg Kosterin, through Creative Commons.

Maravolo (1980) applied both auxins (IAA) and gibberellin to bryophytes, including *Marchantia polymorpha* (Figure 1-Figure 12). In this case, the applied auxin stimulated rhizoid growth, cell proliferation, and elongation. Gibberellin, on the other hand, promotes cell enlargement, chloroplast development, and starch degradation. Under the right photoperiod, it also influences the geotropic curvature and causes ultrastructural changes in starch granules and thylakoids.

Loomis and Maravolo (1985) found that exogenous gibberellin increases the amylolytic activity of two protein fractions from *Marchantia polymorpha* (Figure 1-Figure 12).

hormones - ethylene

Little information has been available on ethylene presence and physiology in bryophytes. Ethylene is a gaseous hormone and therefore can be used to communicate between plants. Katayose *et al.* (2021) noted that genes for ethylene have been conserved from the algae, but that the function and biosynthesis of this hormone remain unknown in the bryophytes. They found that *Marchantia polymorpha* (Figure 1-Figure 12) synthesizes ethylene. However, treatment with the precursor ACC only slightly promoted the production of ethylene. On the other hand, ACC "remarkably" suppressed thallus growth and rhizoids, contrasting with the slight promotion of thallus growth when external ethylene was applied. These experiments indicate that ethylene functions independently of ACC and that ACC is not essential to its production in *Marchantia polymorpha*.

Li *et al.* (2020) similarly found that ACC (ethylene precursor) and ethylene can induce different responses in *Marchantia polymorpha* (Figure 1-Figure 12). Ethylene causes larger gemmae, induces more gemmae cups, and promotes the dormancy of the gemmae. ACC, on the other hand, inhibits gemma growth and development by suppressing cell division. This suggests that the pathway might be different from that tracheophytes.

In *Marchantia polymorpha* (Figure 1-Figure 12), more ethylene is produced in the light than after prolonged darkness (Fredericq *et al.* 1977; Rethy *et al.* 1977). Veroustraete *et al.* (1982) further elaborated on ethylene physiology in the species. They found involvement of the low energy red:far-red reversible type of phytochrome action for both the light-induced ethylene production and the control of **epinasty** (nastic movement in which plant part such as flower petal or thallus branch is bent outward and often downward; Figure 50) in the species. They found that CO₂ had no effect on the production of ethylene when the thallus was irradiated with terminal far-red light, but in controls without the light treatment, there was a clear CO₂ dependency. This behavior suggests the involvement of phytochrome. De Greef *et al.* (1979) studied environmental effects on ethylene production in *M. polymorpha* and concluded that ethylene production requires energy and depends on either cyclic photophorylation or oxidative phosphorylation.

Figure 50. *Marchantia polymorpha* showing an unusual margin formation that exhibits **epinasty**. Photo by Steve Trynoski, with permission.

hormones - cytokinins

Binns and Maravolo (1972) found that cytokinin suppressed germination of gemmae (Figure 45) in *Marchantia polymorpha* (Figure 1-Figure 12). Externally applied auxins had no effect on regeneration from thallus discs.

Aki *et al.* (2019a,b) noted that cytokinins regulate a variety of physiological events in plants. They found that the cytokinin signalling pathway in *Marchantia polymorpha* (Figure 1-Figure 12) controls the formation of both gemmae cups (Figure 45, Figure 48) and rhizoids (Figure 53-Figure 54) during the development of the thallus. It is further implicated in the distribution of air pores (Figure 51) and the shape of the thallus margin (compare Figure 49 and Figure 50), suggesting that cytokinins regulate cell division or differentiation of precursor cells, thereby coordinating development.

Figure 51. *Marchantia polymorpha* epidermis with air pores, showing green layer beneath. Photo by Walter Obermayer, with permission.

hormones – ABA and lunularic acid

In 1979, Weiler used a radioimmunoassay in an attempt identify the presence of ABA in *Marchantia polymorpha* (Figure 1-Figure 12). At that time, using that sensitive technique, ABA appeared to be absent. Fortunately, that result was not accepted by everyone. Li *et al.* (1994) announced, for the first time, the presence of abscisic acid (ABA) in liverworts, using *Marchantia polymorpha* as the model organism. In fact, the concentrations were similar to those of tracheophytes.

Akter *et al.* (2014) found that pretreatment with ABA and sucrose increases the survival rate after both freezing and desiccation of gemmalings in *Marchantia polymorpha* (Figure 1-Figure 12). ABA also increases the accumulation of soluble sugars. Furthermore, ABA induces the accumulation of transcripts for proteins that are similar to late embryogenesis abundant (LEA) proteins, proteins that accumulate in maturing seeds as they acquire desiccation tolerance. ABA also causes the vacuoles to fragment, causing an increase in the cytosolic volume and increasing the volume and density of chloroplast distribution.

Eklund *et al.* (2018) also found that ABA delays the germination of gemmae (Figure 48) in *Marchantia polymorpha* (Figure 1-Figure 12).

Ghosh *et al.* (2016) was the first to report on the regulation of ABA in the liverwort *Marchantia polymorpha* (Figure 1-Figure 12). Previously, a hormone with similar functions, **lunularic acid**, was known from some liverworts. Ghosh and co-workers found that the expression of ABA-induced β -glucuronidase (GUS) reporter gene was less in older, mature thalli than in young gemmalings of this species. This change corresponded with reduction in the sensitivity to exogenous ABA. Lunularic acid, on the other hand, had no effect on GUS expression.

Nevertheless, it appears that *Marchantia polymorpha* (Figure 1-Figure 12) has **lunularic acid** (Gorham 1977; Abe & Ohta 1983), a hormone with functions similar to those of ABA. However, it appears that in *M. polymorpha*, the prelunularic acid greatly exceeds the lunularic acid (Abe & Ohta 1984). Gorham found it in all parts of *M. polymorpha*. In continuous light, both lunularic acid and fresh weight increased relative to that in interrupted light periods. It appears that the lunularic acid either was not inhibited by continuous light or that the photosynthetic products overrode the inhibition.

Imoto and Ohta (1985) found that lunularic acid compounds were equally distributed in vacuoles and cytoplasm, but they were absent in plastids, mitochondria, and peroxisomes.

hormones - brassinosteroids

Brassinosteroids occur in a wide range of organisms, including early land plants (Bajguz & Hayat 2009). These steroidal plant hormones affect the promotion of plant growth and development. Metabolism of these steroids is altered when plants respond to abiotic stresses as well as bacterial, fungal, and viral pathogens. Ko *et al.* (1995) characterized five 4-demethylsterols that seem to be potent biosynthetic precursors of brassinosteroids in suspension cell cultures of *Marchantia polymorpha* (Figure 1-Figure 12).

cell growth

Fries (1964) explored the effects of growth inhibitors on growth and elongation in *Marchantia polymorpha* (Figure 1-Figure 12).

Matsui *et al.* (1991) detected the activity of lipoxygenase in *Marchantia polymorpha* (Figure 1-Figure 12) in culture. Most of this activity occurred in the **cytosol** (aqueous component of cytoplasm of cell). The activity increases rapidly during the lag phase of cell growth (Matsui *et al.* 1996). This activity decreased in the logarithmic phase, then increased again in the stationary phase. This series of changes in lipogenase activity is caused by *de novo* synthesis and degradation of the same lipoxygenase. They also found enzyme activity that degrades fatty acid hydroperoxides – products of lipoxygenase.

circadian rhythm

Lagercrantz *et al.* (2020) examined the circadian clock in *Marchantia polymorpha* (Figure 1-Figure 12). They found that this clock coordinates the **nyctinastic** (periodic movement plant parts, especially flowers or leaves, caused by nightly changes in light intensity or temperature) thallus movement of the species and suggested it is controlled by auxin (IAA). The thalli "wave" up and down on a 24-hour cycle in 12 hours light: 12 hours dark. These movements

in gemmalings are maintained in continuous light. The auxin, produced in the apical region (Figure 20), travels basipetally through the midrib region, creating a gradient. The circadian rhythm regulates the IAA levels. At low doses (10-100 nM) the angle of growth is reduced, creating a more flattened thallus. These experiments support the observations of Went and Thimann (1937) that the response to auxin depends on the time of day.

Marchantia polymorpha (Figure 1-Figure 12) has often been a model for evolution in land plants. Linde *et al.* (2017) found homologues of core clock genes in *Arabidopsis* (Figure 52), bryophytes, and charophytes, with fewer copies in the latter. The data supported the hypothesis that adaptation to terrestrial life occurred earlier than that supposed by current theory, particularly occurring in the charophytes. The bryophytes exhibit not only duplication and acquisition of new genes, but also loss of genes in development of their circadian clock.

Figure 52. *Arabidopsis thaliana*, in a genus that has homolog genes with early land plants and is frequently used for evolutionary comparisons. Photo by Roepers, through Creative Commons.

Cuitun-Coronado *et al.* (2022) noted that photosynthesis is a circadian process in some flowering plants and Cyanobacteria. They reported the first record of circadian regulation of the photosynthetic pathway in a liverwort, *Marchantia polymorpha* (Figure 1-Figure 12). They determined that the light:dark cycle synchronized the 14-hour photosynthetic cycle, but that the phases of different thalli desynchronize under free-running

conditions. They suggested that chloroplast translation might be necessary for the clock to control the light-harvesting process in this plant.

Lagercrantz *et al.* (2021) used sequencing to identify the genes involved in circadian rhythms in *Marchantia polymorpha* (Figure 1-Figure 12). They identified a homolog of the *Arabidopsis* (Figure 52) gene *DE-ETIOLATE1* as having a high amplitude and morning phase. The circadian rhythm resulting from *MpDE1* expression is disrupted when core clock genes lose their function in mutants. In knock-down experiments with this gene, the circadian rhythm of nyctinastic thallus movement is altered. But the researchers were unable to detect any effect in response to light, leaving us with no explanation of the function of the *MpDE1* gene in *M. polymorpha*.

water relations

Ghosh *et al.* (2021) explored the drought tolerance in this model organism. They desiccated gemmae in various desiccating solutions and found that these led to extreme growth inhibition, disruption of membrane stability, and reduction in chlorophyll content. At the same time, the accumulation of hydrogen peroxide and malondialdehyde increased and electrolyte leaked from the gemmalings, creating oxidative stress. Activities of antioxidant enzymes, including superoxide dismutase, catalase, ascorbate peroxidase, dehydroascorbate reductase, and glutathione S-transferase increased, while total antioxidant activity also increased in response to increased oxidative stress. When they applied exogenous ABA, it reduced drought-induced tissue damage and improved the activities of antioxidant enzymes and accumulation of proline.

Godinez-Vidal *et al.* (2020) noted that both water deficit and ABA cause osmotic adjustment in *Marchantia polymorpha* (Figure 1-Figure 12). This species increases its ABA levels under water deficit. Like Ghosh and coworkers, they found decreased growth and morphological changes in response to water deficits. Cell organelles changed locations, largely due to the volume change of the central vacuole, a consequence of the change in osmotic potential.

Hatanaka and Sugawara (2010) found that after exposure to drying below $0.1 \text{ g H}_2\text{O g}^{-1}$ dry weight the desiccation tolerance level of *Marchantia polymorpha* (Figure 1-Figure 12) was very low, with a survival rate of less than 10%. When cells were pretreated in 0.5 M sucrose, the survival rate rose to 87%, even at lower water levels. This treatment caused cell alteration and the accumulation of a large amount of sucrose and newly made proteins.

Duckett and Ligrone (2003) found that rhizoids (Figure 53) in the bryophytes, particularly the **Marchantiales**, contribute to their water movement. They also contribute to movement of food. The smooth rhizoids (Figure 53-Figure 54) are living cells and often contain fungal hyphae. The pegged rhizoids (Figure 53-Figure 54) are dead, but they nevertheless contribute to the movement of water in the grooves of the archegoniophores. They also help to prevent the collapse when the thalli dry out and they facilitate recovery upon rehydration.

Figure 53. *Marchantia polymorpha* ventral surface of thallus showing pattern of horizontal pegged rhizoids that are close to the thallus and that facilitate water movement and uptake. The pinkish rhizoids toward the base are the perpendicular smooth rhizoids that adhere to the thallus. Photo by Larry Jensen, with permission.

Marchantia polymorpha ssp. *ruderalis* (Figure 6-Figure 8, Figure 17-Figure 19, Figure 56) was among the first plants to use extracellular ice formation (Figure 55) as a dehydrating agent, a mechanism to provide freezing avoidance (Schott *et al.* 2021). During exposure to freezing temperatures, ice crystals formed in the air chambers and grew out the pores. These hygroscopic crystals, along with other ice on the outside of the thallus, drew ice out of the cells and caused their dehydration. This ice removal can prevent the formation of crystals within the cells, where the crystals can cause membrane and structural damage. The thallose liverwort *Conocephalum salebrosum* (Figure 57) proved to be more resistant to frost than did *Marchantia polymorpha* ssp. *ruderalis* (Figure 56).

translocation

Rota and Maravolo (1975) traced the translocation of ^{14}C sucrose in *Marchantia polymorpha* (Figure 1-Figure 12). They found that during regeneration, higher levels of ^{14}C -sucrose moved to the apical region than during normal growth. The auxin IAA inhibited the transport and thallus regeneration.

desiccation

Pence (1998) found that for successful cryopreservation, *Marchantia polymorpha* (Figure 1-Figure 12) required both ABA and encapsulation in alginate beads, differing from *Riccia fluitans* (Figure 58) and *Helicodontium capillare* (Figure 59) that only required one of these. Without ABA and encapsulation, *M. polymorpha* was killed upon drying in liquid nitrogen. I found that interesting because *R. fluitans* is more aquatic than is *M. polymorpha*, but perhaps it is because it is structurally smaller.

nutrients

Voth and Hamner (1940) described some of the symptoms of nutrient deficiency as expressed in *Marchantia polymorpha* (Figure 1-Figure 12). They found that cultures that lacked Ca ions but contained ions of K and Mg were able to regenerate new thalli, primarily from adventitious buds that arose from ventral cells in the midrib region. When NO₃ and PO₄ were absent, the ventral layers of cells developed a red-violet color in the walls, reminiscent of the phosphate deficiency in seed plants. Nevertheless, phosphate was needed in very small quantities in *Marchantia polymorpha*. Increasing levels of nitrate increased growth, provided all essential nutrients were present.

Rico-Reséndiz *et al.* (2020a) unravelled the responses to low phosphate in *Marchantia polymorpha* (Figure 1-Figure 12). They found that phosphate starvation elicited the induction of phosphatase activity, acidification of the media, reduction of the internal phosphate concentration, and developmental changes in the rhizoids. Lipid turnover enzymes led to the synthesis of **auronidins** (see below). Up-regulation of certain genes led to changes in organic acid biosynthesis and transport, favoring citric acid exudation. The genes involved in the synthesis of cytokinin are repressed and those involved in auxin and ethylene signalling are upregulated (Rico-Reséndiz *et al.* 2020b). Genes involved in jasmonate synthesis were highly upregulated, but those involved in jasmonate signalling did not change their expression. It appears that auxin and ethylene act as positive regulators in rhizoid development when phosphate is limited, possibly increasing surface area for potential phosphate absorption. Cytokinin, on the other hand, may act as a negative regulator. These observations revealed diverse strategies that contribute to the ability to cope with low phosphate levels.

Voth (1941, 1943) compared various nutrient solutions on *Marchantia polymorpha* (Figure 1-Figure 12) growth. It is interesting that vegetative growth was favored by different concentrations than were gemmae cups. Furthermore, gemmae cups are in greater number on male plants compared to female plants, with a ratio of 1.44 to 1.0. High salt concentrations caused the growing tips to die and the thalli to become translucent. In low salt concentrations, "anthocyanin" (probably auronidin; see Albert *et al.* 2018; Kubo *et al.* 2018) was produced, along with numerous rhizoids and a sturdy plant body with thicker cell walls. Presumably the assumption of anthocyanin was due to a red coloration.

Absence of K (potassium) in the medium causes development of tan-colored bases on the plants and narrower tips (Voth 1941). Absence of Ca causes nearly immediate death of the growing tips. Both nitrate and phosphate deficiency cause reddening of the scales (Figure 60-Figure 61), rhizoids, and lower epidermis.

Miller *et al.* (1962a) developed methods to obtain nutritionally deficient mutants of *Marchantia polymorpha* (Figure 1-Figure 12). At that time, even few mutants of tracheophytes had been created for that purpose. Nevertheless, little has been published on nutrient deficiency symptoms in bryophytes.

Takio (1987) reported nitrate reductase activities in extracts from cultured cells of *Marchantia polymorpha*

(Figure 1-Figure 12) growing in a medium with only nitrate as a nitrogen source. They found that the liverworts differed from the mosses in using NADPH as the electron donor, whereas the mosses used NADH. The coenzyme requirement also differed from that known for the other green plants.

Figure 60. *Marchantia polymorpha* ssp. *ruderalis* scales showing purplish color that could develop as a deficiency symptom or possibly help to reflect the green light back to the chloroplasts. Photo by Des Callaghan, with permission.

Figure 61. *Marchantia polymorpha* ventral scale and epidermis showing reddening that is typical of phosphate or nitrate deficiency. Photo by Masaki Shimamura, with permission.

Not all nutrients are inorganic compounds. Some of these are organic. Dunham and Bryan (1968) found that *Marchantia polymorpha* (Figure 1-Figure 12) is able to use a number of different nitrogenous compounds. They tested 24 compounds and found that nine of these had any effect on normal development. Among these, l-isoleucine, l-leucine, l-methionine, and l-threonine caused a disruption of the apical regions at concentrations of 10⁻³ M. At even lower concentrations, l-arginine, l-histidine, l-hydroxyproline, l-lysine, and l-tryptophan each caused morphological irregularities that were highly specific to the

amino acid. The modifications ranged from lack of development of the air chambers to complete thallus disorganization. The effects were dependent on the concentrations of the amino acids. This negative interaction raises questions about the role of compounds released by the decomposition of leaf litter in the environment in interfering with the growth of at least some bryophytes.

Effects of nutrients can differ between males and females of *Marchantia polymorpha* (Figure 1-Figure 12). Males with abundant nitrates produce many gemmae cups, narrower thalli, and incurved margins. Female plants in these conditions produce fewer cups, have broader thalli, and plant surfaces remain flat.

Bryophytes grow in strange places and on strange substrata. Walkinshaw *et al.* (1970) tested *Marchantia polymorpha* (Figure 1-Figure 12) among the plants used to see the effects of lunar rocks on plant growth. They found that this liverwort grew several times larger than normal and had enhanced pigmentation when grown on media enriched with lunar rocks. Hoffman (1974) tested the effects of finely ground ilmenite basalt and loam-textured C-horizon substrate that was rich in volcanic ash, mixtures that closely resemble lunar samples from the Apollo 11 mission, on the growth of *Marchantia polymorpha*. The moon rock was already known to stimulate the growth of *M. polymorpha*. Analyses of the two Earth volcanic soil types suggested that the growth stimulus resulted from additional nutrients present in the basalt or volcanic ash.

heavy metals and pollution

For most nutrients, high concentrations become lethal. This is particularly true for heavy metals (Wu & Bradshaw 1972; Ares *et al.* 2018). These are often needed in small quantities in enzymes, but soon become toxic at higher quantities.

For this reason, bryophytes, including *Marchantia polymorpha* (Figure 1-Figure 12, Figure 23), are suitable organisms to indicate heavy metal pollution (Maschke 1981). Coombes and Lepp (1974) examined the effects of zinc and copper on gemmalings of *Marchantia polymorpha*. Copper proved to be more toxic than zinc, inhibiting gemmaling growth at levels above 8 ppm. Zinc actually had little effect on the gemmalings.

Ares *et al.* (2018) examined the physiological responses of *Marchantia polymorpha* (Figure 1-Figure 12) to Cd, Cu, Pb, and Zn. Under high concentrations, there was a significant enrichment and translocation of Cu, Zn, and especially Cd, achieving a concentration of $1800 \mu\text{g g}^{-1}$ in three weeks. On the other hand, Pb achieved the lowest concentration ($50 \mu\text{g g}^{-1}$), with 90% of the total concentration in the rhizoids. Ozkem *et al.* (2019) further found that when *Marchantia polymorpha* was exposed to elevated levels of CuCl_2 , ZnCl_2 , and $\text{Pb}(\text{NO}_3)_2$ it experienced a significant reduction in chlorophyll content.

Both zinc and copper are toxic to the gemmalings of *Marchantia polymorpha* (Figure 1-Figure 12), with copper being more effective (Coombes & Lepp 1974). At levels of copper above 8 ppm *M. polymorpha* gemmalings exhibited greatly reduced growth. Other morphological changes also occurred.

Lepp and Roberts (1977) found that cadmium at levels above 5 ppm had negative impacts on gemmaling growth

of *M. polymorpha* (Figure 1-Figure 12). Furthermore, respiration rates diminished with increasing Cd levels. Gekeler *et al.* (1989) found that *M. polymorpha* produces two phytochelatin when exposed to cadmium.

Samecka-Cymerman *et al.* (1997) summarized previous studies on heavy metals, noting that the concentrations of elements in the liverworts they studied, including *Marchantia polymorpha* (Figure 1-Figure 12), correlate positively with the concentrations of elements in the soil. Some, such as cobalt, surpass the background values found in most bryophytes, indicating the ability of the bryophytes to accumulate them. Some elements, such as Fe, Co, Pb, and Cu, caused an ionic imbalance in this liverwort and others.

Iron is sometimes considered a micronutrient and sometimes a macro nutrient. *Marchantia polymorpha* (Figure 1-Figure 12) uses reduction-based iron acquisition. Under deficiency conditions, growth of this species is reduced. Activity of ferric chelate reductase is increased and proton ATPase becomes active (Lo *et al.* 2016).

Manganese is needed in photosynthesis where it catalyzes the water-splitting reaction, but excess Mn creates metal stress. In *Marchantia polymorpha* (Figure 1-Figure 12) excess Mn causes a strong accumulation of N-methylalanine, a response differing from that of tracheophytes (Messant *et al.* 2022). When the concentrations of Mn were not optimal, the ratio of photosystem I to PSII changed and the organization of the thylakoid membranes was altered. This is important in photoprotection. The deficiency of Mn favors cyclic electron flow around PSI, thus protecting PSII against photoinhibition.

As demonstrated by the **bryometer** (air bags holding bryophytes), pollutants such as SO_2 , oxidants, NO, and NO_2 can cause severe toxicity to *Marchantia polymorpha* (Figure 1-Figure 12) on the leeward side of a pollution source, resulting in the lowest growth rate in the area (78%) (Yokobori 1978; Yokobori & Taoda 1980).

responses to abiotic stress

Fujita *et al.* (2006) pointed out that much of the research on molecular mechanisms that cope with stress in plants have been carried out independently. Hence, our understanding of the evolutionary relationships and convergence points between biotic and abiotic stress signaling pathways remains very incomplete. More recently, evidence is emerging that suggests that hormone signaling pathways regulated by abscisic acid, ethylene, jasmonic acid, and salicylic acid, in addition to ROS-signaling pathways, play important roles in the crosstalk between biotic and abiotic stress signaling.

Marchantia polymorpha (Figure 1-Figure 12) has a large repertoire of responses to environmental changes (Spinedi *et al.* 2021). In response to anthracene, they found an increase in the activity of main ROS-detoxifying enzymes of 34.09% of peroxidase and 692% of ascorbate peroxidase, supported at transcriptional level with the up-regulation of ROS-related detoxifying responses. The net result was the activation of antioxidant mechanisms and the accumulation of the anthracene pollutant within the plant tissues.

Hirata *et al.* (2000) used bornyl acetate as a chemical stressor of *Marchantia polymorpha* (Figure 1-Figure 12).

In response, the liverwort produced peroxidase. This is a glycoprotein that is stable at temperatures as high as 50°C for up to one hour, suggesting that the liverwort might have protection against the increasing temperatures of climate change. Its optimum pH is 6.5, which does not bode well for the dangers of acid rain. The peroxidase appears to be unlike any of those known from tracheophytes.

Hydrogen peroxide (H₂O₂) often has a protective role in plants. It forms in *Marchantia polymorpha* (Figure 1-Figure 12) in the presence of MnCl₂. Its production is also stimulated by phenols such as 2,4-dichlorophenol (a 2,4-D precursor) or *p*-coumarate, both processes similar to the last step in lignification, suggesting that while bryophytes apparently lack lignin, they already had a large part of the process required for its production. Phenols are important substances in antiherbivory in bryophytes.

Bryophytes are often resistant to stresses that can kill tracheophytes. Merwin (2003) found that herbicides designed for long-term use on tracheophytes actually promoted the growth of *Marchantia polymorpha* (Figure 1-Figure 12). They furthermore were resistant to the human traffic in the orchard.

Measurements of impedance can be a tool to determine health of small plants like *Marchantia polymorpha* (Figure 1-Figure 12). Bulanda (1980) Researchers have used this species to develop and test the efficacy of a method for measuring the resistance and capacity of the thallus, based on previous methods for measuring these in cell suspensions (Bulanda 1980; Paszewski *et al.* 1982).

radiation damage

A need to understand radiation damage arose as we began to explore space and to use radiation for energy. Typically, the effects on the nucleus were used to assess such damage (Miller & Sparrow 1964). One generalization that arose indicated that cells with smaller nuclei had more resistance to the radiation than did those with large nuclei. Using *Marchantia polymorpha* (Figure 1-Figure 12) Miller and Sparrow found that a more accurate indicator was the nuclear volume (at interphase) divided by the chromosome number. Miller *et al.* (1965) found that larger nuclei in gemmae exhibited inhibition at lower levels of radiation than did smaller nuclei.

Sarosiek and Wozakowska-Natkaniec (1967) demonstrated that chronic gamma radiation caused inhibition of the development of sex organs in *Marchantia polymorpha* (Figure 1-Figure 12).

One of the tools used in assessing effects of such things as X-rays is to use mutants (Miller *et al.* 1962a, b). Bryophytes, particularly *Marchantia polymorpha* (Figure 1-Figure 12), are particularly suitable for this because of their haploid condition. Miller and coworkers used the method to obtain nutritionally deficient mutants, a condition that could affect the response to radiation.

CO₂

The current atmosphere has a CO₂ concentration of about 0.0415% (415 ppm) (Climate.gov, accessed 21 September 2022). But it seems that most of the studies on CO₂ effects on the physiology of *Marchantia polymorpha* have been done at much higher levels.

Katoh *et al.* (1979) found that in 1% CO₂ *Marchantia polymorpha* (Figure 1-Figure 12) had a dry-weight doubling time of 1.76 days. The increase rate of chlorophyll was 1.6 times that of the growth rate. In the exponential phase of growth, the photosynthetic activity was at least 60 μmol mg⁻¹ chl h⁻¹. The highest chlorophyll content they recorded was 24 mg g⁻¹ dry weight.

Bockers *et al.* (1997) compared responses of *Marchantia polymorpha* (Figure 1-Figure 12) to two levels of CO₂. At the higher concentration (2.0%), the chloroplast shape seemed modified and there were 70% more chloroplasts per cell than at 0.4%. However, the chlorophyll content per cell indicated a reduction in chlorophyll per chloroplast. Furthermore, the cell size was about 37% lower in the higher CO₂ concentration. The net result was that the photosynthetic oxygen evolution was about the same under both conditions.

Marchantia polymorpha (Figure 1-Figure 12) has a C₃ pathway (Hanson *et al.* 2002), as do all bryophytes. Its growth form is a thallus, similar to that of hornworts. Its CO₂ compensation point (CO₂ concentration at which photosynthetic rate = respiration rate) was 64 ppm (Hanson *et al.* 2002), whereas the hornwort *Megaceros* (Figure 62), a genus lacking pyrenoids (Villarreal & Renner 2012), had a compensation point of 31 ppm (Hanson *et al.* 2002). On the other hand, *Notothylas* (Figure 63) and *Phaeoceros* (Figure 64), both with pyrenoids, had compensation points of 11-13 ppm CO₂. Those species lacking pyrenoids had more RuBisCo content, permitting them to increase their carboxylation catalytic rate (*Marchantia*, 2.6 s⁻¹; *Megaceros*, 3.3 s⁻¹; *Phaeoceros*, 4.2 s⁻¹; *Notothylas* 4.3 s⁻¹). *Marchantia polymorpha* had the highest percentage of RuBisCo per soluble protein (8%), *Megaceros* followed (4%), and the pyrenoid-containing species had only 3%.

photosynthesis

Kato (1983a) grew a cell line of *Marchantia polymorpha* (Figure 1-Figure 12) in suspension culture, using 1% CO₂. He found a growth rate in the exponential phase of 0.171 and a doubling time of 1.76 days. The rate of chlorophyll increase was 1.6 times higher than the growth rate. The cells reached their highest chlorophyll content at 24 mg g⁻¹ dry weight in their exponential phase, with at least 60 μmol mg⁻¹ chlorophyll h⁻¹.

Kato (1983b) considered the inability of cells of *Marchantia polymorpha* (Figure 1-Figure 12) in suspension culture to grow in the dark to be the result of low respiration. In the light, the respiration increased to four times that in the dark. The compensation ratio

(photosynthetic rate/respiration rate) was less than 1.0 during the growth period. Furthermore, these cells are unable to grow anaerobically in light in the absence of CO₂. Addition of 1% CO₂ permitted the liverwort to sustain growth. They found that at least one-third of the cellular carbon came from atmospheric CO₂.

light

Fredericq (1964) tested the influence of far-red light on thallus development in *Marchantia polymorpha* (Figure 1-Figure 12). Rethy *et al.* (1976) explored the effects of different light treatments on chlorophyll content in *Marchantia polymorpha*.

Courtoy (1965-1966) experimented with light regimes on the germination and development of gemmae of *Marchantia polymorpha* (Figure 1-Figure 12). In artificial light of 4000 lux and 16-hour photoperiod, there were two distinct phases of growth. In the **juvenile phase**, requiring at least 15 days, light quality was unimportant. Adding sucrose in the juvenile phase reduces the phase to 5 days. In the **inductive phase**, when primordia appear, incandescent light permits development, suggesting the importance of red wavelengths.

Mache and Loiseaux (1973) found that the maximum growth rate of *Marchantia polymorpha* (Figure 1-Figure 12) in low light was at 2-3 x 10³ lux, its saturation level. In optimal conditions, photosynthetic rates reach as high as 35 μM CO₂ h⁻¹ mg⁻¹. High light inhibited the photosynthetic rate, with small grana in the chloroplasts and fret membranes being replaced by continuous grana.

Carter and Nickell (1967) experimented with the effects of wavelengths of light on both thallus growth and gemmae cup production. Using 16-hr light:8 hr dark at 21°C day:13°C night, they incubated 4 gemmae per Petri dish. After 11 weeks the controls with no colored acetate had produced a mean of 32.7 cm² of thalli and 83.3 gemmae cups per dish. Dishes with single-wrapped red acetate produced only 16.11 cm² of thalli (Figure 65) and 19.83 gemmae cups per dish (Figure 66). On the other hand, double-wrapped red dishes produced 17.5 cm² of thalli and 8.25 gemmae cups, suggesting that the lower light inhibited production of gemmae cups, putting more of the available resources into thalli. Those in single-layered green dishes produced 14.8 cm² of thalli and 8.16 gemmae cups per dish, a response consistent with the greater activity of photosynthesis in the red range. The double green, single blue, and double blue produced a mean of 10.5, 11.5, and 1.2 cm² of thalli respectively, but produced no gemmae cups, again supporting the importance of red light.

Aro (1982) used *Marchantia polymorpha* (Figure 1-Figure 12) to show that bryophytes had more chlorophyll associated with their light-harvesting protein complexes and less with reaction center complexes than did tracheophytes. Furthermore, the tracheophytes had a chlorophyll *a:b* ratio of 3, whereas it was only 2 in the bryophytes. These figures indicate that the bryophytes are shade plants, having proportionally more chlorophyll *b* when compared to that of tracheophyte sun plants.

Figure 65. *Marchantia polymorpha* growth in long and short photoperiods. Image modified from Carter & Romine 1969.

Figure 66. *Marchantia polymorpha* gemmae cups per week in long and short days. Modified from Carter & Romine 1969.

In further studies, Aro *et al.* (1981) determined that the plastid ultrastructure of the sun species *Ceratodon purpureus* (Figure 67) was characteristic of a sun plant, whereas in *Marchantia polymorpha* (Figure 1-Figure 12) it was characteristic of a shade plant. Nevertheless, both species exhibited photosynthetic kinetics typical of shade plants.

Figure 67. *Ceratodon purpureus* with young sporophytes, a sun species with plastid ultrastructure of a sun plant, but with photosynthetic kinetics of a shade plant. Photo by Claire Halpin, with permission.

Shinmen *et al.* (1991) determined that *Marchantia polymorpha* (Figure 1-Figure 12) produced arachidonic acid (ARA) and eicosapentaenoic acid (EPA) in cell culture. During high growth rate conditions the cells produced high quantities of both acids, with 98 mg L⁻¹ of arachidonic acid and 48 mg L⁻¹ of eicosapentaenoic acid. Kajikawa *et al.* (2004) isolated and characterized the genes behind the production of these acids in *Marchantia polymorpha*. The role of arachidonic acids in cold weather has already been discussed. Eicosapentaenoic acids are known for their antifungal effects against plant pathogens (Bajpai *et al.* 2008). Both of these compounds seem to be essential in the wounding response forming volatiles in *Marchantia polymorpha* (Kihara *et al.* 2014). Eight-carbon volatiles form rapidly (within 40 minutes) of wounding.

Kajikawa *et al.* (2008) reported that *Marchantia polymorpha* (Figure 1-Figure 12) synthesizes arachidonic acid and eicosapentaenoic acid. By causing the overexpression of the involved genes, they produced 3-fold and 2-fold accumulation of these two acids, respectively. They were able to transplant these genes to tobacco and soybean, a feat that suggests that *M. polymorpha* can provide genes for transplantation to tracheophytes and provide them with desirable traits.

Later, Takemura *et al.* (2011) elucidated some of the physiological mechanisms involved in the observed effects of light quality and intensity on these acids. They noted that *Marchantia polymorpha* (Figure 1-Figure 12) synthesized both arachidonic acid (AA) and eicosapentaenoic acid (EPA), polyunsaturated fatty acids that are not known in tracheophytes. They found that the relative content of EPA to total fatty acid was highest under blue light, but that of AA did not vary. EPA content also increased under higher intensity white light. They found that 80 photon flux density $\mu\text{mol m}^{-2} \text{s}^{-1}$ was the optimum intensity for both AA and EPA accumulation.

Harrer (2003) demonstrated that *Marchantia polymorpha* (Figure 1-Figure 12) has the same structure of the PS II-light-harvesting assembly as that of seed plants. They provided the first 3-d structure for such a large assembly by using this liverwort.

Marchantia polymorpha (Figure 1-Figure 12) was used in a study to describe the polyphasic rise of chlorophyll fluorescence at the onset of strong continuous light. Neubauer and Schreiber (1987) described the saturation characteristics and partial control by photosystem II.

In low light, bryophytes can exhibit etiolation. Ninnemann and Halbsguth (1965) elucidated the role of phytochrome in etiolation of ***Marchantia polymorpha*** (Figure 1-Figure 12). Ninnemann (1967) then described the growth substances, phytochrome, nucleic acid, and protein synthesis involved in the etiolation of the gemmae of ***Marchantia polymorpha***.

Rao *et al.* (1979) described the Hill reaction rates of three members of the Marchantiales, including ***Marchantia polymorpha*** (Figure 1-Figure 12). Using three different measures of the Hill reaction activity, they determined that the rate was lower in the three liverworts than in the seed plants tested. Furthermore, they also found lower total chlorophyll content and chlorophyll *a:b* ratio, all supporting the shade adaptation of these plants. They found that the greatest labelled ^{14}C occurred in the amino acids aspartate and alanine. ***Marchantia polymorpha*** exhibited higher photosynthetic rates than the other species in the test.

Maximum polyunsaturated fatty acids (PUFA) productivity is attained in ***Marchantia polymorpha*** (Figure 1-Figure 12) under low light intensity, with a photon flux density ca. $20 \mu\text{mol m}^{-2} \text{s}^{-1}$ (Chiou *et al.* 2001). Optimal inoculum size and glucose concentration for PUFA production are 8-12% and 2030 g L^{-1} , respectively. Ferrous ions, necessary components of many enzymes, promote PUFA productivity by increasing the intracellular lipid content. The highest productivities measured for PUFA were 35.0 ± 2.1 , for arachidonic acid 6.7 ± 0.4 , and for eicosapentaenoic acid $6.6 \pm 0.4 \text{ mg L}^{-1} \text{ day}^{-1}$.

High light has different effects on ***Marchantia polymorpha*** (Figure 1-Figure 12) from those of low light (Volchenkova *et al.* 2001). It affects the area occupied by the lipid molecule. The digalactosyl diacylglycerol and phosphatidyl glycerol fractions increase significantly after high light stress, increasing from 0.50 to 0.80 nm^2 and from 0.47 to 0.63 nm^2 respectively.

red/far-red

Fredericq and de Greef (1966) examined the red:far-red control on growth and chlorophyll content in thalli of ***Marchantia polymorpha*** (Figure 1-Figure 12) grown in the light. Fredericq and de Greef (1968) followed up on these experiments by subjecting the plants to daily far-red (FR)-irradiations at the end of photoperiods of white fluorescent light. Following the first sequence, at the end of the night, the chlorophyll content of the tips of the thalli was significantly lower than that of the controls lacking the far-red treatment. Instead, upward growth (Figure 68) was beginning.

By the end of the night following the first FR-exposure, the chlorophyll content of the tips was already significantly lower than that of the controls, and there was a beginning of upward growth (Fredericq & de Greef 1968). After 8 hours in white light, those effects had become much more pronounced. After one week, a 5-minute far-red treatment at the end of the photoperiod cause a 20-30%

lower chlorophyll content in the tips after the 8-hour photoperiod in white light. Following a 16-hour photoperiod, the chlorophyll was decreased by $\pm 10\%$. Morphogenic effects also were less pronounced after 16 hours compared to 8 hours of white light. Basal parts of the thalli were less affected than the tips. On the other hand, a 1-hour photoperiod following far-red treatment caused much greater effects on the basal portions than on the tips. If the daily light period was diminished to 5 minutes, it caused drastic bleaching of 60-70% chlorophyll *a* loss compared to controls. Of relevance to the aquatic habitat, de Greef and Fredericq (1969) found that when the incandescent light was filtered through water for 10 minutes, it caused a somewhat weak effect. These responses are similar to those of tracheophytes and indicate that high levels of the PFR form of phytochrome are needed to maintain the horizontal growth and optimal chlorophyll content in these thalli.

Figure 68. ***Marchantia polymorpha*** exhibiting upward growth as it would occur under far-red light at the end of a period of white light. Photo by Vladimir Bryukhov, through Creative Commons.

Among the photoreceptors in ***Marchantia polymorpha*** (Figure 1-Figure 12) and other bryophytes are the phytochromes (Inoue *et al.* 2019). Phytochromes are the only known receptors for red light and far-red light and are therefore important in controlling various developmental processes. The phytochrome Mpphy regulates the formation of gametangioophores, similar to the far-red response of flowering plants. Inoue and coworkers identified the genes responsible for this regulation and demonstrated that the production of Mpphy increases when the gene is multiplied, while disappearing when the gene is deleted.

Another effect of far-red light is to accelerate senescence in ***Marchantia polymorpha*** (Figure 1-Figure 12) (de Greef & Fredericq 1972). Once again, the reversibility indicates the involvement of phytochrome. A daily exposure of only 5 minutes of red light will prevent this aging; photosynthesis plays no direct part in this response.

UV light

When photosynthetic organisms first invaded land, one of the new problems they had to deal with was their introduction to UV light (Jordan *et al.* 2016; Sancha 2017). The levels of UV reaching the Earth's surface at that time were higher than now due to the less-well developed ozone

layer. Therefore, it stands to reason that the surviving bryophytes, previously as early invaders of land, should have mechanisms to protect them from UV radiation. In seed plants, flavonoids are important in this role.

Khetwal (1985) demonstrated the presence of the flavonoid glucuronides apigenin, apigenin-7-O-glucuronide, luteolin, and luteolin-7-O-glucuronide in *Marchantia polymorpha* (Figure 1-Figure 12).

There has been much activity in recent years to determine the effects of increased UV light on bryophytes. Markham *et al.* (1998) found that as they increased UV-B levels, the growth rate of *Marchantia polymorpha* (Figure 1-Figure 12) decreased, the production of gemmae cups (Figure 69) decreased, and the proportion of dead thallus increased. Total flavonoid levels had no statistically significant change, but the ratio of luteolin to apigenin glycosides did increase (Figure 69-Figure 71). The researchers did not consider this to be a means of filtering and protecting the plants from the UV-B, but instead they experienced an improved level of antioxidant defense.

Figure 71. *Marchantia polymorpha* with red archegoniophores, from Laxarbakki, Myvatn, Iceland, 26 July 1987. Photo by Janice Glime.

Clayton (2017) looked specifically at flavonoids in *Marchantia polymorpha* (Figure 1-Figure 12) exposed to UV-B radiation and determined that the flavonoids increased when UV-B radiation was enhanced. Flavones were the most predominant, with apigenin-based flavones in highest amounts and luteolin-based flavones second. The ratio shifted toward luteolin-based flavones at the higher UV-B levels. At these UV-B levels, reactive oxygen species (ROS) are produced, and the liverwort may require the luteolin flavones to scavenge these. Under low UV-B exposure, the flavone compounds accumulated in high concentrations in the epidermal layers, suggesting that they might participate in screening the UV-B. When flavone concentrations were lower, greater damage to the thallus occurred. Higher levels of flavones corresponded with greater protection and reduced thallus damage. When flavones were suppressed completely the plants became severely stunted under the UV-B treatment.

Sancha (2017) noted that bryophytes have "remarkable tolerance to UV radiation." Sancha subjected various bryophytes to enhanced UV radiation and found that all, including *Marchantia polymorpha* (Figure 1-Figure 12), showed increased levels of CARUVs (UV-radiation-absorbing compounds), with all being significant except for *Anthoceros agrestis* (Figure 72).

Figure 72. *Anthoceros agrestis*, a hornwort species with increasing, but not significant, UV-radiation-absorbing compounds with increasing of UV intensities. Photo by Hermann Schachner, through Creative Commons.

Soriano *et al.* (2019a) further examined UV damage in *Marchantia polymorpha* ssp. *ruderalis* (Figure 56, Figure 60, Figure 73). They found that liverworts subjected to low photosynthetically active radiation (PAR), low PAR+ UV-A, low PAR + UV-B, low PAR + UV-A + UV-B, and high PAR exhibited no significant difference in the maximum quantum yield of PSII after 35 days. There were no changes in the chl *a/b* ratio and only slight changes in growth. But both chlorophylls and carotenoids decreased in content in the UV radiation treatments and even more strongly in the high-PAR treatment. The xanthophyll index (antheraxanthin + zeaxanthin) / (violaxanthin + antheraxanthin + zeaxanthin) increased only in the high-PAR (Figure 73). On the other hand, the **sclerophylly index** (ratio between thallus dry mass and surface area) increased in the UV-B-exposed treatments, suggesting a UV-induced structural protection. Only the UV-B treated liverworts exhibited DNA damage.

Figure 73. *Marchantia polymorpha* ssp. *ruderalis* showing red bases, perhaps in response to high UV levels. Photo by Malcolm Storey <www.DiscoverLife.com>, with online permission.

In further studies, Soriano *et al.* (2021) found that the developmental stage was important in determining the accumulation of UV-absorbing compounds in *Marchantia polymorpha* ssp. *ruderalis* (Figure 56, Figure 60, Figure 73). They compared gemmae (Figure 69), one-month thalli, and two-month thalli after 38 days of exposure or non-exposure to UV radiation. They found that the UV responsiveness decreased with thallus age, with gemmae being the most responsive. Older thalli became progressively tougher in UV due to decreasing water content, possibly providing structural protection. Most phenolic compounds decreased with thallus age, but diglucuronide derivatives were highest in the 1-month thalli.

Close and McArthur (2002) contend that phenolics have the primary function of protecting plants from photodamage, not from herbivores as originally thought.

Kondou *et al.* (2019) reported that MpUVR8 provides physiological benefits in UV-B resistance in *Marchantia polymorpha* (Figure 1-Figure 12). It is highly expressed in

the apical notch (Figure 20) of the thalli and gametangiophores, including the antheridial and archegonial heads. In this species, citrine-fused MpUVR8 was translocated from the cytosol into the nucleus when exposed to increased UV-B radiation.

Ultraviolet light was a major stress to be overcome when plants first invaded land (Clayton *et al.* 2018). The *Marchantia polymorpha* (Figure 1-Figure 12) UVB response included many components already known from *Arabidopsis* (Figure 52), including production of UVB-absorbing flavonoids, the central activator role of ELONGATED HYPOCOTYL5 (HY5), and negative feedback regulation by REPRESSOR OF UV-B PHOTOMORPHOGENESIS1 (RUP1). Important differences included a greater importance for CHALCONE ISOMERASE-LIKE (CHIL). Mutants that disrupted the response pathway or flavonoid production were more easily damaged by UV-B than normal plants, whereas mutants that increased the flavonoid content exhibited increased UV-B tolerance.

Kondou *et al.* (2019) determined that UV-B resistance and the translocation of the UVR8 from the cytosol to the nucleus was operational in *Marchantia polymorpha* (Figure 1-Figure 12) in response to UV-B radiation. This series of events is highly expressed in the apical notch of the thalli and in the gametangiophores and receptacles.

fluorescence

It is widely known that chlorophyll fluoresces. The degree of fluorescence is a measure of the health of the plant. Shi *et al.* (1992) described two categories of fluorescence emission from bryophytes. *Marchantia polymorpha* (Figure 1-Figure 12) exhibits maximum emission around 725 nm. The fluorescence kinetics of primitive bryophyte photosynthesis, including *M. polymorpha*, exhibited lower PS II activity, lower efficiency of primary photoconversion in PS II, and lower photosynthetic C assimilation and efficiency than did the advanced bryophyte species.

photoperiod

Photoperiod is known to control various events in the life of a plant. Differences in response to photoperiod can keep closely related species from interbreeding by bringing reproductive parts to maturity at different times (see Reproduction section below), while taking advantage of the climatic conditions at the optimum time for the event.

Marchantia polymorpha (Figure 1-Figure 12) grown in a long photoperiod (18 hours daylight) are larger and have greater dry weight than those grown in a short photoperiod (9 hours daylight) (Voth & Hamner 1940; Carter & Romine 1969). Short photoperiods favor production of gemmae (Figure 69, Figure 153-Figure 170), whereas long photoperiods favor the production of gametangiophores.

Benson-Evans (1961) found that photoperiod influences the number of gametophores, and like Carter and Romine, found that longer days (16 hrs light) result in greater thallus size and fewer gemmae cups, but a faster production of the cups.

tropisms

A little-studied area of bryophyte physiology is tropisms. Yet the ability to grow in response to the

direction of light and gravity is of considerable adaptive importance to most bryophytes.

There is a long history of studies on rhizoid tropisms in *Marchantia polymorpha* (Figure 1-Figure 12). Haberlandt (1889) noted **positive gravitropism** (originally known as geotropism; growing toward the gravitational pull) in the apical rhizoids of *Marchantia polymorpha*. Weinert (1909) investigated rhizoid tropisms and growth in liverworts, including *Marchantia*. Rawitscher (1932) reviewed the tropisms in this species. Douin (1936) reported that the thallus exhibited photogravitropism. But Miller and Voth (1962) experimented with various orientations of the thalli and found that the rhizoids would securely anchor the thalli no matter what position the plant held, contrasting with the view held by Haberlandt (1889). Perhaps this is explained by the behavior I observed in *Fontinalis*. The rhizoids initially grow away from the plant and use a spiral growth pattern. However, once a rhizoid contacts a substrate, it branches and secures the plant to the substrate. I am not aware that this behavior has been observed in *Marchantia polymorpha*, but such behavior has not been disproved either.

So what does a gemma cup do when its parent plant is attached to a vertical surface? Miller and Voth (1962) observed that initially the cup exhibits no tropism, growing in a perpendicular alignment with its thallus. But when it develops the achlorophyllous scale-like rim of the cup, this is negatively gravitropic, permitting the cup to become upright with respect to gravity.

Rethy *et al.* (1990) described the role of far-red illumination in tropisms of *Marchantia polymorpha* (Figure 1-Figure 12). It causes greater cell elongation on the ventral side of the thallus just below the apical notch, causing upward growth, whereas red light reverses the reaction.

Komatsu *et al.* (2019) demonstrated that under low light both sporelings and thalli of *Marchantia polymorpha* (Figure 1-Figure 12) develop narrow shapes and their apices grow toward the light source. These responses are blue-light dependent and respond to **phototropin** (photoreceptor protein; flavoproteins).

temperature

Somehow, this fleshy liverwort manages to survive winter, even when covered by snow (Figure 74). Exact responses to temperature at the cellular level have been a puzzle. *Marchantia polymorpha* (Figure 1-Figure 12) serves as a model system to unravel these responses (Hirano *et al.* 2022). Chloroplasts respond to cold by changing positions, optimizing photosynthesis. This response is triggered by the blue-light photoreceptor phototropin, the cold-sensing molecule. This sensor is present in the plasma membrane, cytosol, Golgi apparatus, and periphery of the chloroplast. By using genetic variants, Hirano and coworkers demonstrated that the cold response originates with the phototropin in the plasma membrane, at least in this liverwort.

Antropova (1974) included *Marchantia* in studies on temperature adaptations in bryophytes. He incubated the bryophytes at 10 and 20°C for 72 hours. But this period of time does not influence either thermostability or cold resistance. A treatment of 3 hours at superoptimal temperatures does cause an increase in thermostability, but

no change in cold resistance. The behavior of the bryophytes was similar to that of flowering plants but differed from the temperature acclimation of algae.

Figure 74. *Marchantia polymorpha* in snow; note how dry the thallus appears, a condition that reduces damage from interior ice crystals. Photo by Vladimir Teplouhov, through Creative Commons.

But experiments by Weis *et al.* (1986) differed. Using *Marchantia polymorpha* (Figure 1-Figure 12) and other thallose liverworts, they found that high temperature treatment elicited a reversible depression of photosynthesis. The time required to achieve complete recovery depended on the extent of the heat damage. With severe heat treatment, PS II was damaged and inactivation of photosynthesis was irreversible. Unlike Antropova, Weis and coworkers found that exposure of these thallose liverworts to high sublethal temperatures did not result in the significant increase in heat stability of the photosynthetic apparatus as had been seen in seed plants. They interpreted this to mean that the heat hardening capacity of water-loving liverworts was extremely low.

Fletcher (1982) found no frost damage to *Marchantia polymorpha* (Figure 1-Figure 12) in cultivation in New Zealand populations. Some of the other species of thallose liverworts became severely bleached or blackened in greenhouse cultivation down to -5.5°C. The *M. polymorpha*, on the other hand, remained a healthy green all winter.

Response to heat appears to be more complicated. It involves several subcellular compartments as well as multi-level regulatory networks (Marchetti *et al.* 2021). Studies on *Marchantia polymorpha* (Figure 1-Figure 12) indicate that the core components of the response are conserved from bryophytes to flowering plants.

Temperature affects the relative production of fatty acids in *Marchantia polymorpha* (Figure 1-Figure 12) (Saruwatari *et al.* 1999). At 25°C this liverwort contained approximately 18% linolenic acid (18:3ω3), 11% arachidonic acid (20:4ω6) and 3% eicosapentaenoic acid (20:5ω3) as percentages of total fatty acids. At 15°C, the ratios of linolenic acid and arachidonic acid increased greatly, with less effect on the other acids. Arachidonic acid and eicosapentaenoic acid increased in the chloroplast but not elsewhere in the cell. Linolenic acid increased in

both fractions. Various galactolipids were present in one or the other or both compartments, but only monogalactosyldiacylglycerol and chloroplastic phosphatidylcholine increased in low temperatures. Gellerman *et al.* (1972) found that *Marchantia polymorpha* had arachidonic acid in all tissues, ranging 10-30% of the total fatty acids.

Takemura *et al.* (2012) likewise reported the production of arachidonic acid and eicosapentaenoic acid in *Marchantia polymorpha* (Figure 1-Figure 12), noting that neither is produced in tracheophytes. The accumulation of ω -3 polyunsaturated fatty acids increased significantly as the temperature decreased. At 5°C the concentration was approximately 3x that at 15°C. ω -6 polyunsaturated fatty acids, on the other hand, decreased at low temperatures.

Akter *et al.* (2011) acknowledged the role of ABA in both desiccation tolerance and freezing. This dual role is not surprising since one of the dangers of freezing is desiccation as ice crystals draw water out of the cell or make the water unavailable as ice. Akter and coworkers found that isolated gemmae (Figure 153-Figure 170) of *Marchantia polymorpha* (Figure 1-Figure 12) responded to increased ABA by increasing the sucrose concentration. These treated gemmae survived freezing, whereas most of the controls did not. The best survival occurred with 5% sucrose and 19 μ M ABA.

Takeuchi *et al.* (1980) even found a successful method for freezing *Marchantia polymorpha* (Figure 1-Figure 12) for cryopreservation.

The movement of organelles in response to stress is seldom discussed. In response to a cold treatment, *Marchantia polymorpha* (Figure 1-Figure 12) sporelings and gemmalings nuclei and peroxisomes relocated from the **periclinal cell wall** (wall parallel to surface of meristem or surface of organ; Figure 75) to the **anticlinal cell wall** (wall arranged perpendicular to surface of plant body; anticlinal division results in formation of anticlinal walls between daughter cells, enabling tissue to increase circumference, thus keeping pace with any increase in girth of organ; Figure 75) (Ogasawara *et al.* 2013). Mitochondria, on the other hand, did not relocate.

senescence

Sometimes it seems like bryophytes never die. They just keep growing at the top while lower portions remain and may even decay. But **senescence** (process of aging) does indeed occur. Stanislaus and Maravolo (1994) examined cell factors that influenced senescence. They found light-induced senescence in young, middle-aged, and old tissues of *Marchantia polymorpha* (Figure 1-Figure 12) all exhibited suppressed senescence in treatments with spermine, spermidine, and putrescine. Not surprisingly, ethylene induced senescence in these tissue ages, an effect that could be retarded by putrescine, a compound they tentatively identified in *M. polymorpha* extracts.

LaBelle *et al.* (1997) identified two isophosphatases in senescing *Marchantia polymorpha* (Figure 1-Figure 12) thalli. They found that spermine reduced total phosphatase activity by 135-175%. Ethylene, on the other hand, reduced it by 133-155%. When ethylene and spermine were added together, they decreased the activity by 120-163% compared to the levels with the ethylene treatment alone. LaBelle and coworkers interpreted these findings to indicate that phosphatase and ethylene are associated with senescence. Spermine, on the other hand, functions in preventing senescence.

It may seem inconceivable to a bryologist, but *Marchantia polymorpha* (Figure 1-Figure 12) is not always a welcome visitor in a garden (Figure 76). Altland *et al.* (2008) found that quinclamine can serve as both a PRE and POST activity herbicide at 4-6 mg L⁻¹. It could inhibit PRE germination in gemmae (Figure 153-Figure 170), but its ability to stay on the substrate made it increase the efficacy of other kinds of treatments.

Aging brings a variety of responses in plants. Maravolo (1976) found that transport, a function especially of the midrib, was inhibited by aging, cinnamic acid, and ethylene in *Marchantia polymorpha* (Figure 1-Figure 12).

Seaman *et al.* (2005) examined the role of spermine in programmed cell death of *Marchantia polymorpha* (Figure 1-Figure 12). They found that PKC (protein kinase C) concentrations in untreated young thalli were higher than those of older tissues. PKC refers to a family of protein kinase enzymes involved in a variety of signal transduction pathways (Blumberg 1991). PKC enzymes play important roles in several signal transduction cascades. When Seaman and coworkers treated older tissues with spermine, they also had higher cytosolic putative PKC concentrations than even the young untreated thalli. The spermine also resulted in higher total protein levels than untreated tissues. Hence, it appears that the spermine causes both qualitative and quantitative decreases in senescence.

One of the consequences of spermine is to reduce DNA fragmentation, as demonstrated in *Marchantia polymorpha* (Figure 1-Figure 12) (Pagoria & Maravolo 2005). The fragmentation is localized near the lower epidermis of the apical meristem. From there it progresses into the mesophyll cells. However, when these plants were treated with 100 μ M spermine, they exhibited significantly lower ($p < 0.001$) levels of DNA fragmentation in aged (2-5 cm) tissues.

Figure 76. *Marchantia polymorpha* females in garden in Houghton, Michigan, USA. So far we have been unable to find any males. This illustrates the density it can reach. Fortunately, the owners find these plants fascinating, permitting their invasion. The yellow patches are *Brachythecium* cf. *salebrosum*. Photo courtesy of Craig Waddell.

genetics

Marchantia polymorpha (Figure 1-Figure 12) is typically considered a model for the early terrestrial colonizing plants. With this in mind, Bowman *et al.* (2017) characterized the genome of this species as having low genetic redundancy in most of its regulatory pathways. This species differs from its purported charophycean ancestors by encoding novel biochemical pathways, new phytohormone signalling pathways (especially auxin), expanded repertoires of signalling pathways, and increased diversity of transcription factor families. It sheds light on the evolution of haploid sex chromosomes as they occur in a dioicous plant. The haploid condition makes gene transfer and subsequent study easier than in the diploid tracheophytes (Chiyoda *et al.* 2008).

Ikeuchi and Inoue (1988) used a computer-assisted homology search to identify the D1-D2-cytochrome b-559 complex protein region in the chloroplast genome of *Marchantia polymorpha* (Figure 1-Figure 12).

Takenaka *et al.* (2000) found that *Marchantia polymorpha* (Figure 1-Figure 12) had at least 1-4 copies of the hpt gene, an example of gene redundancy in early land plants.

Chung *et al.* (2006a) compared two bryophytes and *Arabidopsis thaliana* (Figure 52) to determine the number of genes in common. They found 79% of the genes expressed by *Marchantia polymorpha* (Figure 1-Figure

12) were also expressed in the moss *Physcomitrium patens* (Figure 77). They found 763 genes expressed not only in both bryophytes, but also in *Arabidopsis thaliana*. Another 363 genes were found in the bryophytes, but not in *Arabidopsis*.

Figure 77. *Physcomitrium patens*, a species that expresses 79% of the same genes as in *Marchantia polymorpha*. Photo through public domain.

Chung *et al.* (2006b) contrasted gene expression in *Marchantia polymorpha* (Figure 1-Figure 12) with that of *Arabidopsis thaliana* (Figure 52). In the latter tracheophyte species, ~50% of the expressed genes exhibited cell-type-specific expression patterns. On the other hand, in *M. polymorpha* the expression in cultured cells did not differ from those of the thalli. Instead, 110 genes were expressed in cultured cells of *M. polymorpha*, but not in those of *A. thaliana*, whereas in the 10 *A. thaliana* genes checked, they were expressed in whole plants of both species, but not in cultured cells of *A. thaliana*. Thus, *Marchantia polymorpha* with transplanted genes can be used more easily to determine the expression of tracheophyte genes.

Lin and Bowman (2018) identified micro RNAs in *Marchantia polymorpha* (Figure 1-Figure 12). Tsuboyama *et al.* (2018) elaborated on methods of using the model liverwort *Marchantia polymorpha* in AgarTrap transformation for studying genetic transformation, achieving a 97% transformation efficiency.

Schmid *et al.* (2018) found that methylation pattern of DNA changes in cytosines varies significantly during the life cycle. These coincide with four major epigenetic states, corresponding to the states of vegetative gametophytes, antherozoids, archegonia, and sporophytes. They concluded that epigenetic reprogramming occurs in at least two events during the life cycle, once in each generation. These events occur in parallel with the differences in the gene expression involved in DNA methylation.

Ishizaki *et al.* (2008) used *Agrobacterium* (Figure 20)-mediated transformations on immature thalli of *Marchantia polymorpha* (Figure 1-Figure 12) that had developed from spores. Plants grown from gemmae (Figure 153-Figure 170) of these plants all expressed the introduced gene GUS. Because of the haploid state of the

thallus, these plants offer a very useful system for such transformations.

Marchantia polymorpha (Figure 1-Figure 12) has become a model organism for using promoters in overexpression studies to determine gene functions (Althoff *et al.* 2014). The protocol developed has the potential to screen large numbers of transgenic plants, including the use of knock-down mutants.

These studies have shown the usefulness of *Marchantia polymorpha* to test the function of genes.

One of the applications of our genetic knowledge of this species is to determine its susceptibility to radiation damage. Using Co⁶⁰ gamma rays, Miller and Sparrow (1965) determined that the ability of the two apical cells to reproduce was inhibited at doses less than the lethality dosage. The thallus exhibits different radiosensitivity from that of the gemmae (Figure 153-Figure 170) when based on energy absorption; the thallus is 4.3 times as sensitive as the gemmae.

Adaptations

Halbsoth (1953) explored the development of dorsiventrality in *Marchantia polymorpha* (Figure 1-Figure 12). We can assume that this body form has advantages, particularly in habitats that can at times be very wet and at other times can dry out. The overlapping thalli of the colony help to retain water in the soil (Figure 78). This same advantage can be accomplished by growing with mosses (Figure 79).

Figure 78. *Marchantia polymorpha* in Houghton, Michigan, showing overlapping thalli. Photo by Matt Tianen, with permission.

Bischler and Jovet-Ast (1981) commented that members of the **Marchantiales** seem to have some characters that are not essential for survival, reproduction, or dispersal. Others seem to be disadvantageous, but they have not prevented the continued existence of these traits. Instead, they concluded, the adaptations to their niches are linked primarily to biochemical and biophysical properties of the cell content rather than to morphological expressions.

Since wet habitat species typically experience dry seasons, among the most common adaptations are those that conserve water. McConaha (1941) described the

ventral structures that affect water uptake and conservation. In the Marchantiales, these include smooth and tuberculate rhizoids (Figure 80-Figure 84) and ventral scales (Figure 83-Figure 86). Using several members of the order, including *Marchantia polymorpha* (Figure 1-Figure 12), McConaha reported that the **smooth rhizoids** (Figure 80) emerge from the scales and can make contact with the substrate (Figure 81-Figure 82). **Tuberculate (pegged) rhizoids** (Figure 53, Figure 83) serve a different purpose. They originate beneath the scales, forming numerous connected capillary strands that lie parallel to the thallus (Figure 53, Figure 83). This arrangement provides a rapid capillary distribution of water to all the absorptive areas of the thallus. The efficiency in water balance depends on the form and imbrication of the scales (Figure 84-Figure 86), as well as with the length and number of these rhizoids.

Figure 86. *Marchantia polymorpha* section showing scale and rhizoids on ventral surface. Photo from Botany Website, UBC, with permission.

Cao *et al.* (2014) further described the rhizoids (Figure 80-Figure 84) in *Marchantia polymorpha* (Figure 1-Figure 12). These researchers noted that the tuberculate (pegged) rhizoids converge toward the midrib (Figure 83-Figure 84). The smooth rhizoids occur in clusters in the free portions near the midrib at the thallus posterior (Figure 80, Figure 82). Unlike the tuberculate rhizoids, these lie perpendicular to the thallus, always growing toward the moist soil (Figure 81-Figure 82).

Many botany textbooks still claim that bryophytes lack cuticles. But we now know that this is not the case, at least for many bryophytes. Many species develop a thin cuticle that is not easily noticed. Brockington *et al.* (2013) and Xu *et al.* (2021) noted that even in flowering plants we lack understanding of the cuticle genetics and the role of the cuticle in evolution. Hence, these researchers have provided a detailed description of the cuticle and its genetic origins in *Marchantia polymorpha* (Figure 1-Figure 12). The cuticle is hydrophobic and is generally considered to be a barrier between the plant and the atmosphere wherein it helps to maintain internal moisture levels and to prevent entry of potentially pathogenic organisms. It is also a filter of UV radiation and barrier against mechanical damage. Because of these important roles in the terrestrial environment, it has been considered to be one of the key innovations needed for colonization of land (Corner 1964).

Xu *et al.* (2021) analyzed the role of the cuticle in preventing water loss in *M. polymorpha* (Figure 1-Figure 12). Using mutant plants, they found no change in morphology of the thallus for plants without a cuticle. However, they found more effects of desiccation in mutant plants with no cuticle. These plants frequently exhibited brownish tissues at the flank and tip of the thallus after five days with no cover and no added water. Most significantly, water content declined to about 70%, compared to 90% in non-mutant plants (Figure 87), the latter being only a 5% decrease in water content following the drying regime. Wu and coworkers were unable to detect any waxes in the cuticle of the lab-grown *M. polymorpha*. Rather, the cuticle of *M. polymorpha* in these experiments consisted only of cutin, except for the waxy cuticle surrounding the pores (Figure 88). We know that environmental conditions affect the manufacture of cuticle waxes in flowering plants and could have been a cause for suppression of these waxes in the lab populations of *M. polymorpha*.

While the plants with the addition of cuticles solved the problem of water loss, they had created another problem. An epidermis with a cuticle also interferes with gas exchange, impeding photosynthesis by the underlying photosynthetic tissue. In a thallose liverwort like *Marchantia polymorpha* (Figure 1-Figure 12) chloroplasts are buried (Figure 89, Figure 91-Figure 92) below the epidermis where light is reduced and it would be difficult to exchange CO₂ and O₂ if they did not have air pores (Figure 89-Figure 90). These openings permit the entry of air into the chambers (Figure 89, Figure 91-Figure 92) beneath them and the escape of the photosynthetic O₂. But these air pores present another problem. When the thallus becomes submersed or even when raindrops land in the pores, there is the danger that the water could enter the thallus and prevent the gas exchange. *Marchantia polymorpha* protects itself from this internal drowning by having cuticular ridges (Figure 90-Figure 94) around the

opening of the pores (Schönherr & Ziegler 1975). The hydrophobic waxes, helped by the cohesive properties of water, repel the water and prevent its entry. Schönherr and Ziegler considered them to be "perfect structures."

The adaptive value of oil bodies puzzled bryologists for a long time. Galatis and Apostolakis (1976) described the association of the microbodies with the cytoplasmic tubules of oil body cells in *Marchantia*. They found that the tubules increase in number at the stage when the cells are actively synthesizing oil.

One of the protections exhibited by liverworts is the ability to store sesquiterpenes and bisbibenzyls in oil bodies (Figure 95). Suire *et al.* (2000) isolated a number of isoprenoid biosynthetic enzymes from oil bodies (Figure 95-Figure 96) in *Marchantia polymorpha* (Figure 1-Figure 12). In *Marchantia polymorpha* these oil bodies are localized in oil body cells (Tanaka *et al.* 2016). Tanaka *et al.* (2016) reported that oil bodies served as sites of accumulation of sesquiterpenoids and marchantin A. They also observed that the number of oil body cells increased in thalli grown in low-mineral conditions.

Figure 95. *Marchantia polymorpha* section showing scales and oil bodies. Photo from Botany Website, UBC, with permission.

Figure 96. *Marchantia polymorpha* oil body in oil cell. Photo by Masaki Shimamura, with permission.

He *et al.* (2013) described the liverwort oil bodies (Figure 95-Figure 96) as "intracellular organelles bounded by a single unit membrane containing lipophilic globules suspended in a proteinaceous matrix." Oil bodies are unique to liverworts. In *Marchantia polymorpha* (Figure 1-Figure 12), we know that they contain protein complex that is immunologically related to the plastid and cytosolic enzymes of the isoprenoid synthesis. They are known as sites of essential oil accumulation and sequestration. Although they are known to contain compounds useful for medical purposes, their full function in liverworts remains unknown. What are the advantages of size and morphology – characters that differ sufficiently among species to be of taxonomic value?

By suppressing the genes controlling this sesquiterpenoid production, Romani *et al.* (2020) found that the terpenoid-rich oil bodies (Figure 95-Figure 96) are responsible for protecting *Marchantia polymorpha* (Figure 1-Figure 12) from arthropod herbivores, but that unlike those in tracheophytes, these oil bodies seem to have no

role in abiotic stress response, including desiccation. Takizawa *et al.* (2021) found that when *Marchantia polymorpha* was exposed to non-axenic conditions the number of oil bodies increased, as did the amounts of sesquiterpenes. They likewise demonstrated that the bacterium *Escherichia coli* (Figure 16) elicited the same response.

Kihara *et al.* (2014) found that *Marchantia polymorpha* (Figure 1-Figure 12) emitted C8 volatiles following mechanical wounding. Induction of these emissions occurred within 40 minutes of the wounding. When transgenic plants lacking arachidonic acid and eicosapentaenoic acid were wounded, only minimal C8 volatiles were detectable. Octan-3-one was produced only minimally when thalli were completely disrupted, but was the most abundant product in only partially disrupted thalli.

Yoshikawa *et al.* (2018) traced the wounding response in *Marchantia polymorpha* (Figure 1-Figure 12). Wounding of the thallus resulted in the synthesis of phenylpropanoids, including luteolin, apigenin, and isoriccardin C.

Watson (1919) suggests that reduced pores in *Marchantia* species might be an advantage in a wet habitat. Due to cohesion of the water molecules, water is unable to enter the smaller openings.

Among the advantages that bryophytes have are their plasticity and adaptability. Plasticity is exhibited by the various biochemical responses to different pathogens and environmental conditions. Adaptability is enhanced by the haploid condition. Selection on gametophyte plants is more rapid than in tracheophytes because there is only one set of chromosomes, permitting rapid removal of non-adapted genes in the population. This mechanism is evident in adaptations to heavy metals. Briggs (1972) demonstrated this in the response of *Marchantia polymorpha* (Figure 1-Figure 12) to lead contamination. When Briggs compared plants from areas with high levels of lead in the soil to those from an area with low levels of lead pollution, those from highly contaminated soil were highly tolerant of lead, whereas those from areas with less lead contamination are more sensitive. Krupinska (1976) found that lead tetraethyl causes distorted growth patterns in *Marchantia polymorpha*. The thalli become "profusely" branched, a reversible phenomenon. The chloroplasts degenerate and growth of the spores and gemmae is inhibited.

Reproduction

sexual

Marchantia polymorpha has been used in a number of studies on sexual expression in plants, particularly to demonstrate that expression in early plants. Nagai *et al.* (1999) generated 970 expressed sequence tag (EST) clones from an immature female sexual organ (Figure 112-Figure 128) of the liverwort *Marchantia polymorpha* (Figure 1-Figure 12). In 376 ESTs they found 123 redundant groups, reducing the unique sequences to 717.

Marchantia polymorpha (Figure 1-Figure 12) is a **dioicous** species with easily recognizable differences between **antheridiophores** (Figure 98-Figure 110) and **archegoniophores** (Figure 110-Figure 128). Durand (1908) described these as well as the sporangium. The

stages of the sexual life cycle can be seen in Figure 98-Figure 146.

As noted earlier, sex in *Marchantia* is determined by a **small V chromosome** in males and no U chromosome, whereas the female has a **single U chromosome** and no V chromosome (Lorbeer 1934). But the designation of the gender is not perfectly genetic. Naidu (1973) reported abnormal receptacles that bore both archegonia and antheridia, based on specimens from a population in India. The V chromosome (Figure 97) has several chromosome-specific sequence elements (Okada *et al.* 2001; Ishizaki *et al.* 2002). Okada *et al.* (2000) identified 70 male-specific PAC clones and verified that the V chromosome exhibits unique sequences that are not present on the U chromosome or any non-sex chromosomes. These repeat sequences contribute 2-3 Mb on the V chromosome. Okada and coworkers introduced us to the first active V chromosome-specific gene known in plants. Fujisawa *et al.* (2001) isolated two female-specific and six male-specific DNA fragments that originated from these U and V chromosomes. Okada *et al.* (2000) suggested that this liverwort was a suitable model for identifying roles of sex genes in sexual differentiation. Bisang *et al.* (2010) noted that molecular sex markers have thus far only been described for a few bryophytes, one of which is *Marchantia polymorpha*.

Figure 97. *Marchantia polymorpha* male chromosomes, with tiny V chromosome indicated by arrow. Photo from Okada *et al.* 2001, through Creative Commons.

Wann (1925) determined that photoperiod was important in initiating sexual branches in *Marchantia polymorpha* (Figure 1-Figure 12). In long days, males produce mature antheridiophores in 3-4 weeks. Females seem to respond to the same stimulus, but require 6-8 weeks for archegoniophores to reach maturity. The role of temperature remained unknown. High humidity hastens the sexual branches, but low humidity retards them and

may completely inhibit their production, particularly for archegoniophores. And as in some of the algae, low nitrogen relative to carbohydrate may initiate sexual branches. These nutrient relationships in algae signal the end of the growing season and the beginning of the unfavorable conditions of winter. The same could be likely for the bryophytes as the tracheophytes use up the nitrogen during the growing season. Hence, forming a sexual reproductive structure that can remain dormant until favorable conditions return is adaptive.

Lloyd and Steinmetz (1937) found that high temperatures (above 30°C) at least temporarily suppress development of archegoniophores and antheridiophores in *Marchantia polymorpha* (Figure 1-Figure 12). Low temperatures, on the other hand, promote development of these reproductive structures during short days. But during late autumn, plants moved to a warm greenhouse from the cool outdoors would also produce more archegoniophores and antheridiophores compared to plants that had remained in the greenhouse continuously. Furthermore, plants brought to the greenhouse in late autumn developed these sexual structures more quickly than those brought into the greenhouse earlier in the autumn. Greenhouse-grown plants could be induced to develop archegoniophores and antheridiophores during short days if they were exposed to natural autumn conditions found at Orono, Maine, USA. Nevertheless, a long photoperiod is important in inducing this sexual response.

Benson-Evans (1964) found that *Marchantia polymorpha* (Figure 1-Figure 12) produced gametangia at 21°C in long days (18 hours), but lowering the temperature to 10°C or the photoperiod to 6 hours resulted in no gametangia production.

Yamaoka *et al.* (2021) summarized that initiation of the development of gametangia depends on environmental factors such as light, but they considered that these factors are still elusive. They recognized recent studies that considered their development to use conserved regulatory modules that are involved in light signalling.

Maravolo *et al.* (1967) explored activity of 12 enzyme systems in various parts of *Marchantia polymorpha* (Figure 1-Figure 12). Of these, only phosphatases, esterases, and peroxidases were found in extracts of uninduced thalli, induced thalli, stalks, and antheridiophore and archegoniophore disks. They found an amplification of esterases in the antheridia (Figure 105-Figure 109). These esterases can hydrolyze particular esters into acids and alcohols or phenols. Gorska-Bryllass (1970) reported increased esterase activity in the early stages of spermatogenesis in *Marchantia polymorpha*, an activity that declines near the end of that cellular division. Could these be important in protecting the antheridia against stresses, especially desiccation?

Markham and Porter (1978) isolated an aurone (known for making flowers yellow) from *Marchantia polymorpha* (Figure 1-Figure 12) during its sexual phase. The aurone aureusidin 6-O-glucuronide is present only in the antheridiophores (Figure 98-Figure 110).

Figure 106. *Marchantia polymorpha* antheridial receptacle section showing arrangement of antheridia. Photo by Janice Glime.

Figure 107. *Marchantia polymorpha* antheridium section with developing sperm cells. Photo by Janice Glime.

Michelot-Gernez (1984) described the nuclear condensation during spermatogenesis in *Marchantia polymorpha* (Figure 1-Figure 12). Reynolds and Wolfe (1984) identified protamines in plant sperm, using *Marchantia polymorpha* as one of the representative organisms. These are small, arginine-rich proteins that replace histones near the end of the haploid phase of spermatogenesis; they are considered essential for sperm head condensation and DNA stabilization.

Carothers and Kreitner (1968) described the blepharoplast of the **spermatid** (developing spermatozoid) of *Marchantia polymorpha* (Figure 1-Figure 12). Bajon *et al.* (1995) described the nucleus of the **spermatozoid** (male gamete; sperm). They found that RNAs remain scattered in the spermatozoid throughout differentiation. They are closely associated with chromatin strands that fuse in the mature gamete. They found that mRNAs associated with the mature spermatozoid genome are stored mRNAs. They permit the transfer of paternal information to the zygote during fertilization. Using a high-speed video technique, Inouye and Hori (1991) described the movement of the sperm (spermatozoid) of *Marchantia polymorpha* as a breast stroke. Miyamura *et al.* (2002) further described the flagellar movement of the sperm, using high-speed video.

Figure 110. *Marchantia polymorpha* antheridiophores and archegoniophores, occurring on separate thalli. Photo by Robert Klips, with permission.

Une (1984) observed that female plants produce sexual branches more frequently than do male plants (Figure 111). Archegoniophores, in particular, may be inhibited by low humidity (Wann 1925). As in many algae, a low nitrogen:high carbohydrate ratio can stimulate the formation of sexual branches. This nutrient relationship often serves as a signal that growing conditions are declining and the formation of spores provides a mechanism for surviving until favorable conditions return or the spores land in a suitable habitat.

Figure 111. *Marchantia polymorpha* females in July 1982, in Rydhave, Denmark, showing how dense the population can become.

The archegoniophores (Figure 112-Figure 121) arise from a separate thallus from that of the antheridiophores. The archegoniophores are formed by an infolding and rolling of the thallus, trapping rhizoids and scales inside the stalk that is thus formed (Figure 118-Figure 121). The rhizoids, in particular, aid in the movement of water to the receptacle head at the top of the stalk.

The archegonial head, at maturity, is filled with scales that protrude from the fingers of the structure (Figure 118-Figure 122). These scales help to conserve water in the head and offer protection to the developing sporophyte.

The archegonia form on the fingers with the oldest near the stalk (Figure 123-Figure 129). Maintenance of dormancy by the egg (Figure 124-Figure 125, Figure 130) can prolong the period of time in which fertilization is possible. In *Marchantia polymorpha* (Figure 1-Figure 12), MpRKD regulates gametophyte development and keeps the egg cell dormant until fertilization occurs (Rövekamp *et al.* 2016). By doing this, it also prevents **parthenogenesis** (development of a zygote without fertilization).

In 1974, Zinsmeister and Carothers (1974) elucidated details of the fine structure changes involved in egg (Figure 124-Figure 125, Figure 130) formation. An amorphous substance surrounds the egg, perhaps preventing desiccation and protecting the egg.

Strasburger (1869, in Parihar 1961) described the splashing of **sperm** (=male gamete, antherozoid, or spermatozoid; Figure 131-Figure 132) from the surface of the antheridial receptacle to the surface of the archegonial receptacle at a time when the antheridiophore was taller than the archegoniophore, thus permitting the water droplets to travel downward to the archegonial receptacles. He considered the splashing to extend to about 65 cm. By this time archegonia would have developed on the lower surface and the water would flow over the edge of the archegonial receptacle to reach them.

Figure 129. *Marchantia polymorpha* archegoniophores in a female clone on 6 July 2018 in Houghton, Michigan, USA; males were nearby in a separate clone. Photo by Janice Glime.

Part of this curiosity was to understand how the sperm could reach the egg in these dioicous plants. Kitagawa (1985) noted that due to the dioicous nature of *Marchantia polymorpha* (Figure 1-Figure 12), the male and female must be near each other (Figure 110) for fertilization to occur (Figure 130). But just how near is near?

Figure 131. *Marchantia polymorpha* sperm. Photo from Botany Website, UBC, with permission.

Figure 132. *Marchantia polymorpha* sperm. Photo by Masaki Shimamura, with permission.

One of the puzzles in fertilization of plants is how the sperm find the eggs, or at least the archegonium. Lidforss (1904) was among the early researchers on this question. Again using *Marchantia polymorpha* (Figure 1-Figure 12), Lidforss found the proteins albumin, hemoglobin, and diastase could each attract the sperm into the capillary tube that held them.

Åkerman (1910) experimented with various salts as attractants or repellants of sperm (Figure 131-Figure 132) in *Marchantia*, possibly *M. polymorpha* (Figure 1-Figure 12). Some salts had positive effects on chemotaxis, whereas others, especially heavy metals, had negative effects.

Furuichi and Matsuura (2016) found time-dependent changes in sperm motility (Figure 131-Figure 132) from high to low motility states in *Marchantia polymorpha* (Figure 1-Figure 12). Based on the average lifetime of the high motility state and the speed of movement, they estimated that these sperm would travel less than 3 cm. Hence, they concluded that other factors were needed to explain apparent travel distances greater than this, and that the motility of the sperm itself most likely only was important in the final fertilization step.

Alvarez (2017) described the movement of the sperm (Figure 131-Figure 132) in *Marchantia polymorpha* (Figure 1-Figure 12), based on the publication of Myamura *et al.* (2002). The movement caused by these biflagellated sperm is waveform and differs between the two flagella. This permits the sperm to adjust both steering and propulsion. The beat of the posterior flagellum is more 3-d than that of the anterior flagellum. When the sperm collides with an obstacle, it does not exhibit backward swimming.

Shimamura (2016) reported that water droplets could splash sperm cells (Figure 131-Figure 132) 30 cm or farther from the male plants of *Marchantia polymorpha* (Figure 1-Figure 12), as previously demonstrated experimentally (Burgeff 1943; Brodie 1951; Duckett & Pressel 2009). Drops of dye-containing water dropped onto the antheridia did limited splashing and most of the dye (>90%) was absorbed by the ventral side of the antheridial receptacles. But the dye also quickly moved to the ground level and managed to spread throughout the entire colony within an hour. This was facilitated by the bundles of rhizoids in the archegoniophore. When encountering a female plant, the dye moved up the archegoniophore stalk to the archegonial receptacle through the bundles of rhizoids enclosed by the stalk. This movement upward required 30-60 minutes. Furthermore, Duckett and Pressel (2009) observed that the youngest sporophytes are located near the stalk and the older ones are located near the periphery, indicating that fertilization continues after stalk elongation.

But Pressel and Duckett (2019) also measured the distances travelled by the sperm (Figure 131-Figure 132) of *Marchantia polymorpha* (Figure 1-Figure 12) to achieve fertilization. They followed more than 80,000 males and females for two years after a major fire and recorded the number of sporophytes. While these numbers seem high, they found the astounding number of more than 200,000 sperm in individual antheridia of *Marchantia polymorpha* (Figure 1-Figure 12). This is a greater number than in most bryophytes, but it is coupled with very effective sperm dispersal. They found that distances could exceed 20 m and that dispersal resulted in 100% fertilization of the female plants. The dehiscing antheridia release lipids that help to move the sperm in the surface water films both along the antheridiophores and across the surface water films to the archegoniophores. In a single flooding event, a male thallus with 10-12 antheridiophores can release more than 50 million sperm. This high fertilization success, coupled with the numerous tiny spores, can account for the ease with which the species seems to arrive after disturbances such as fire.

sporangia

Fertilization occurs in the archegonia, making possible a number of sporangia on the same archegonial head. The embryos (Figure 133-Figure 134) remain in the arms of the archegonial head where they are protected by many scales. The maturing embryo forms a foot, seta, and capsule inside the archegonium (Figure 135-Figure 136). The scales protrude more as the embryo matures (Figure 137-Figure 146), thus helping to maintain moisture.

Wann (1925) found that sporophytes (Figure 139-Figure 145) became mature in 10-12 weeks. This rate can be increased by high humidity and retarded by relatively low humidity.

Dörken (2012) described the sporophytes (Figure 139-Figure 145) of *Marchantia polymorpha* as short-lived, dying back after releasing the spores (Figure 146). A capsule typically contains several hundred thousand spores of similar size and shape, helping to account for the ability of this species to colonize newly disturbed areas such as those after fire.

spores

O'Hanlon (1926) reported that in the Midwest of the USA, spores of *Marchantia polymorpha* (Figure 1-12) were "available" from early July to the middle of September. The sporophyte (Figure 147) produces an elater to spore (Figure 148-Figure 149) ratio of 1:128. A single capsule (Figure 141-Figure 142) of *Marchantia polymorpha* holds about 300,000 spores. Based on the typical number of capsules per archegonial head (~24), this would yield >7,000,000 spores per receptacle. But under favorable conditions, ~100 sporophytes are produced on one receptacle during a single growing season, suggesting that the total number of spores per individual archegonial receptacle is probably much greater (Duckett & Pressel 2009). The spores can be available for dispersal from early July to mid September, depending on latitude and altitude (O'Hanlon 1926). The spores remain viable for about one year.

Young and Kläy (1971) found *Marchantia polymorpha* (Figure 1-Figure 12) on the crater of a volcano on Deception Island, Antarctica, following the 1969 eruption. This rapid colonization of newly exposed substrata is itself remarkable, but the closest known source of propagules is 1,000 km away in South America! They assumed that numerous propagules must have arrived on just a small area to produce the colony pattern observed. Hence, the dispersal potential of this species is great, a factor that relates to the small size of its spores.

O'Hanlon (1925) detailed the germination of spores (Figure 150) and the early gametophyte stages in *Marchantia polymorpha* (Figure 1-Figure 12). Inoue (1960) studied the spore germination and early gametophyte development in the Marchantiales. Bischler (1984) examined spore morphology and germination in *Marchantia*.

Figure 150. *Marchantia polymorpha* spore germination stages to a 3-celled protonema. Photo by Masaki Shimamura, with permission.

When the spore germinates (Figure 150), it typically produces a single primary rhizoid (Figure 151) after the spore has expanded and produced chlorophyll (O'Hanlon 1926). The spore first produces a very short filament. This is followed by division in a second cell, resulting in the thalloid structure that describes the mature protonema. Branching of the young thallus is common and can begin at an early stage. Rather than having a single apical cell dividing, it produces a marginal row of meristematic cells that continue to produce the mature thallus. At a stage of 30-40 cells, a notch develops in the apical region (Figure 151). Rhizoids develop behind this notch, anchoring the thallus and establishing its dorsiventrality. Mucilage cells arise on the lower side of the apex. In early stages, diminished light seems favorable, but by this stage 13-15 hours of light per day is optimum, with an optimum temperature of 18-22°C. However, the optimum for "fruiting" is lower at 10-15°C. They also germinate and grow better on a solid substrate than in a liquid medium.

Figure 151. *Marchantia polymorpha* protonema development. Apical notch is shown at arrow on right. Photo by Masaki Shimamura, with permission.

Nakazato *et al.* (1999) were able to induce spore germination in *Marchantia polymorpha* (Figure 1-Figure 12) with intermittent irradiation with 15-min red light pulses given every 1 or 2 h for 24 h. Germination could also be induced by the addition of glucose to spores in total darkness. Their experiments indicate that photosynthesis is involved in the photoinduction of spore germination in this species, supporting the conclusion of Inoue (1960).

In the right conditions, the spores swell and gain chlorophyll (Figure 150) (Shimamura 2016). Once swollen they shed the primary spore walls and germinate within a few days. This germination is light-dependent (Heald 1898), suggesting a need for additional energy resources. The light requirement is 10 hours or longer (Nakazato *et al.* 1999). It seems to require a brighter light for protonema and thallus development than that required by other liverworts (Inoue 1960).

Red and far-red light affect both cell division and elongation in *Marchantia polymorpha* (Figure 1-Figure 12) sporelings (Figure 150) (Nishihama *et al.* 2015). Thus, it is likely that phytochromes are involved in development of sporelings.

Gemmrich (1976) found that both Fe and $\text{Ca}(\text{NO}_3)_2$ induce germination of the spores (Figure 150) of *Marchantia polymorpha* (Figure 1-Figure 12). Optimal germination also requires KNO_3 and MgSO_4 . Gibberellic acid had no effect on induction of spore germination in dark cultures.

Initial spore germination (Figure 150) is dependent on light (Hartmann & Weber 1990). As shown in *Marchantia*

polymorpha (Figure 1-Figure 12), following the initial series of reactions that ultimately result in the swelling of the spore, polarity develops (Figure 150). This becomes obvious when the protonema protrudes from the spore as a filamentous germ tube (Figure 150).

Spore germination (Figure 150) of **Marchantia polymorpha** (Figure 1-Figure 12) requires 10 hours or longer (Nakazato *et al.* 1999). The entire light spectrum is effective for germination, but red light is the most effective. The effect of red light is not reversed by subsequent far-red light.

Shibaya *et al.* (2005) demonstrated that AGPs (arabinogalactan proteins) differed before and after protonema development, suggesting that they are involved in differentiation and development. Furthermore, binding of the AGPs inhibits protonema development in **Marchantia polymorpha** (Figure 1-Figure 12), causing disturbances at the cell surface and inhibiting cell-wall synthesis.

Upon germination, one primary rhizoid appears (Figure 150) following the growth of the spore and chlorophyll development (O'Hanlon 1926). At a stage of about 30-40 cells a notch appears in the apical region of the young gametophyte (Figure 151-Figure 152). Although germination seems to benefit from more moderate light, growth is best at 12-15 hours of "good intensity light," with the best temperatures in the range of 18°-22°C. However optimum temperatures for sporophyte development are 10°-15°C. It is interesting that chlorophyll can form in the spores as they imbibe water in the dark. Furthermore, with glucose in the medium spore germination can occur in the dark, further supporting the conclusion that photosynthesis, hence the production of sugar, is necessary for germination.

gemmae (Figure 153-Figure 170)

Hallier (1966) experimented with germination of gemmae in **Marchantia polymorpha** (Figure 1-Figure 12).

He examined the effect of 2,4-mononitrophenol on respiration and induction of germination.

Terui (1981) reported that archegoniophore production in **Marchantia polymorpha** (Figure 1-Figure 12) occurs under long-day conditions, conditions that at the same time suppress the formation of gemmae cups. The gemmae cup suppression occurs about 20 days before the archegoniophore protrudes. High sucrose, on the other hand, induces gemmae cup development. When low light was provided for a prolonged time, it stimulated gemmae cup formation.

Une (1984) confirmed the negative correlation between gemmae cup (Figure 153-Figure 170) production and initiation of sexual structures. The gemmae cups occur more frequently on the margins of the colony, decreasing in number as sexual branches arise toward the inner part of that colony. This seems to relate to the age of the thalli and consequent change in the nutrient condition of the soil beneath the colony, with younger thalli occurring at the margins. Une also found that female plants produce sexual structures more frequently than do males.

Benson-Evans (1964) cultured **Marchantia polymorpha** (Figure 1-Figure 12) that produced gemmae (Figure 153-Figure 170) at 10°C in short days (6 hrs), the opposite conditions of those that resulted in archegoniophore production. On the other hand, Hedger *et al.* (1972) found that long days were needed to maintain the development of gemmalings of this species on an inorganic medium. Carbon additions did not affect the growth rate under long-day or short-day photoperiods.

Figure 166. *Marchantia polymorpha* females showing gemmae cups on younger thalli and mature archegoniophores on older parts. Photo courtesy of Craig Waddell.

Tarén (1958) described the gemmae (Figure 165) as growing on stalks in the cup (Figure 160, Figure 167),

where they are surrounded by hairs that excrete slime (Figure 161). They have two growing regions and branches develop from both.

Figure 167. *Marchantia polymorpha* gemmae with arrows indicating stalks. Photo by Masaki Shimamura, with permission.

Hiwatashi *et al.* (2019) and Yasui *et al.* (2019) explored the genetic encoding for the genes that are involved in the regulation and formation of gemmae (Figure 153-Figure 165).

Gemmae cups (Figure 153-Figure 164) need nutrients to develop. Plants lacking nitrate become light green and have few gemmae cups and infrequent forking (Voth 1941). By contrast, those lacking phosphate become dark green and produce gemmae cups. They also have frequent dichotomies that cause the plants to form rosettes.

The mechanism of dispersal of the gemmae (Figure 153-Figure 165) has been a favorite example for textbooks. In fact, Laplaud *et al.* (2022) even presented their work at a meeting of the American Physical Society.

The splash cup (Figure 168) a dispersal mechanism served as the topic for an entire book (Brodie 1951). Brodie noted that splash cups commonly form 60-70° angles with their horizontal surface. These cups have a broad basal attachment and the propagules are **lenticular** (lens-shaped). He suggested that such cups could facilitate splashing of their contents for about 60 cm in *Marchantia polymorpha* (Figure 1-Figure 12). Equihua (1987) conducted further experiments, finding that raindrops could splash the gemmae up to 120 cm from the parent cup.

Figure 168. *Marchantia polymorpha* with gemmae cups. Note the bird's nest fungus (*Nidularia*) beside the thallus, a larger splash cup. Photo by Martin Hutten, with permission.

The ease of dispersal of the gemmae (Figure 153-Figure 165) has been a point of consternation for nursery growers, inspiring research on the mechanism. England and Jeger (2005) experimented with an overhead sprinkler system to determine various nozzle differences and their effects on dispersal. They demonstrated the effectiveness of the dispersal by using red dye in the cups in place of gemmae. At extreme water pressures of 1.5 and 3 bars, fewer gemmae were dispersed at all nozzle sizes. When the flow rate was adjusted to 160 L h⁻¹ dispersal number increased with height of the nozzle. At the other flow rates tested the nozzle height lacked any clear effect on number dispersed. The maximum distance travelled was 1.6 m.

The gemmae cup (Figure 153-Figure 164) has a decorated border and is cone-shaped (Figure 169). The cup-shaped container permits a raindrop to splash the gemmae to some distance from the cups (Laplaud *et al.* 2022). When a raindrop is non-centered when it lands, it creates a jet of water splash that carries a few gemmae with it. Laplaud and coworkers found that this propulsion can carry gemmae up to a meter from the cup. They are continuing their research to determine the effects of cone angle and the presence of decorations on its border (Figure 169).

Figure 169. *Marchantia polymorpha* gemma cup showing decorated border. Photo by John Forlonge through Flickr.

The climatic conditions can be right for germination, but the gemmae (Figure 153-Figure 164) could be in the wrong place. To determine if a substrate surface is present, ethylene is the most likely hormone to carry out this function. Because it is a gas, it is able to accumulate between a gemma and its substrate. Duarte (2020) used constant ethylene-signalling mutants to search for such a response. She found that the hormone ethylene could be part of the process of dormancy establishment, maintenance, and release of gemmae (Figure 153-Figure 165) in *Marchantia polymorpha* (Figure 1-Figure 12).

But experiments by Thullen (1965) suggest that the substrate is not important in the orientation of the rhizoids (Figure 82-Figure 54) of *Marchantia polymorpha* (Figure 1-Figure 12) gemmae (Figure 153-Figure 165). When the light source is above, surface gemmae produced 92% of their rhizoids on the side away from the light; those gemmae submersed in the agar produced only 85% on the side away from light. When the light source is beneath the gemmae, only 50 and 45% of the rhizoids, respectively,

appeared on the side opposite the light. When light was provided from beneath the gemmae it changed the percentage of rhizoids arising from the upper surface, but did not change the total number of rhizoids. Gemmae grown in total darkness produced rhizoids only on the lower side. Thullen concluded that both gravity and direction of light are important in rhizoid production. Light intensities seemed to have no effect. Temperature appears to be an important determinant in gemma germination of *Marchantia polymorpha* gemmae. Thullen found a sharp decrease in the number of rhizoids produced by gemmae at temperatures of 26°C and above.

Otto (1976) also demonstrated that the orientation of the gemma (Figure 153-Figure 165) determines where rhizoids form, with the gravitational force assuring their development on the lower side of the gemma. If that side is in contact with the substrate, more rhizoids are produced than if that surface is exposed to air. In the dark, only ~20% of the gemmae produce rhizoids. If the gravitational direction is alternated and no illumination is provided, no rhizoids form. The direction of light source influences the location of rhizoids only when the gravitational direction is not constant, with more rhizoids formed on the darker side.

As already noted, Otto and Halbsguth (1976) found that 350 nm light was the most effective wavelength to induce rhizoids in the gemmae of *Marchantia polymorpha* (Figure 1-Figure 12). Wavelengths below 550 or above 670 nm failed to stimulate rhizoid formation. The responses exhibited red far-red reversibility, suggesting that phytochrome was involved. IAA at 10^{-4} M causes the same effect as 1 hour of red radiation. They suggested that the wavelength of light might affect the influence of the phytochrome system on permeability of the membrane to IAA.

Rousseau (1952, 1953, 1954a) explored the influence of heteroauxins (IAA) on the growth of gemmae cups (Figure 169) in *Marchantia polymorpha* (Figure 1-Figure 12). Rousseau (1954b) further showed that coumarin inhibited the growth of the gemmae.

Prior and Brown (1970) attempted to identify the hormone(s) involved in initiation of rhizoids. They found no influence on germination or initial intercalary growth of gemmae (Figure 153-Figure 165) by 2,4-D, maleic acid hydrazide, gibberellic acid, or 2-furanacrylic acid (β -2-furylacrylic acid) in a range of concentrations. Gibberellic acid delayed development. But none of them caused a difference in number of rhizoids. They did, however, find that apical cell activity and cell elongation were suppressed. Both 2,4-D and maleic hydrazide suppressed internal differentiation. They did find that increasing age of the thallus caused greater sensitivity to both type and concentration of the regulator.

Dunham and Bryan (1968) explored the effects of amino acids on the development of the gemmalings in *Marchantia polymorpha* (Figure 1-Figure 12). At concentrations of 10^{-3} , l-isoleucine, l-leucine, l-methionine, or l-threonine resulted in a disruption of the apical regions. At lower concentrations, l-arginine, l-histidine, l-hydroxyproline, l-lysine, or l-tryptophan caused morphological irregularities. The irregularities were amino acid specific.

Gemmalings can reach reproductive maturity relatively quickly. Miller and Colaiaice (1969) found that within 3-6

weeks the gemmalings of *Marchantia polymorpha* (Figure 1-Figure 12) responded to a 1% agar medium in a 24-hour photoperiod at 23°C by producing antheridiophores and archegoniophores.

During (2001) hypothesized that the tradeoff between dispersability and longevity in soil diaspore banks could result in the scarcity of weedy species such as *Marchantia polymorpha* (Figure 1-Figure 12) in the soil bank. But in fact, the opposite appears to be the case. Species with large spores (i.e. limited dispersal distances) tend to be more persistent in the soil diaspore bank. Presumably, this larger diaspore would include the large gemmae of *M. polymorpha*. This is also in sharp contrast to seeds, wherein small seeds predominate in the diaspore bank. During suggests that there is more predation on larger seeds. Furthermore, bryophytes have much more representation of asexual diaspores than do seed plants. Such asexual diaspores as gemmae are generally produced through a greater part of the growing season than the very seasonal seeds or most kinds of bryophyte spores. The spores of *M. polymorpha* might be an exception to that spore seasonality, however. And certainly, its spores greatly exceed gemmae in number.

Miller and Alvarez (1965) emphasized that in gemmae both notches with apical cells are capable of growing. In their experiments with ^{60}Co they found that both cells had to be damaged to eliminate the survival of the gemma.

Miller (1966) described the gemmae of *Marchantia polymorpha* (Figure 1-Figure 12) as discoidal with two apical notches 180° from each other. Each notch has two apical cells. These apical cells, however, are not the only locations where growth, as cell proliferation, can occur. In irradiated gemmae, the nuclear volume is important in the cell survival, with larger nuclei having greater survival.

Nehira (1973, 1977) explored the development of the rhizoids of the gemmae of *Marchantia polymorpha* (Figure 1-Figure 12) and the adsorption of Ca on the rhizoids of the gemmae and its role in their differentiation.

One surprising effect on germination of the gemmae is that of nickel (Ni). Lepp and Hockenhull (1983) found that NiSO_4 served as a significant growth stimulus at 0.15 ppm Ni, but at concentrations above 0.25 ppm the gemmalings exhibited a toxic response. On the other hand, NiCl_2 stimulated growth of the gemmalings at 0.25 ppm Ni, and they could tolerate $\text{Ni}(\text{NO}_3)_2$ up to 0.5 ppm. Furthermore, they observed different toxicity depending on the environment of the gemmalings, with those from an urban area being more tolerant than those grown in the glasshouse.

regeneration and growth

Perhaps the earliest form of reproduction is **regeneration**. This ability to grow new plants from fragments is known from the *Cyanobacteria* and algae and permits them to survive from parts when most of the whole has died. It is particularly useful in aquatic organisms that can be moved rather easily to new locations by the water.

Vöchting (1885) noted the regeneration capability of the *Marchantiales* and in 1887 (Vöchting 1887) reported that that every living cell in *Marchantia polymorpha* (Figure 1-Figure 12) was capable of regenerating an entire plant. Frye (1928) determined the age of a population of *Marchantia polymorpha* in western Washington, USA, to

be four years old. Only three of these yearly growth segments was alive. The growth habit of *Marchantia polymorpha* to die at the postical end while growing at the bifurcating apical end permits the population to expand.

Giles (1971) discussed the mechanism that governed the stability of differentiation in *Marchantia*. These included a possible mechanism intrinsic to the cell, presumably in more highly differentiated species. However, in other bryophytes this control might be more affected by factors in the environment. But the factors affecting cellular dedifferentiation of an isolated fragment remained unknown. Giles suggested that these factors must be biochemical, probably involving RNA metabolism, and should be investigated.

Barner (1990) found that only the rhizoids from subcultured explants were able to regenerate thalli. The cultures required a directional light source.

Light is critical in regeneration of bryophytes (Nishihama *et al.* 2015). These researchers demonstrated that *Marchantia polymorpha* (Figure 1-Figure 12) has a single phytochrome gene and that phytochrome regulates re-entry into the cell cycle and control of cell shape in newly regenerating tissues. Nevertheless, light is not essential for regeneration, but it exhibits considerable control over the process. But, sugar can cause normal regeneration in the dark, suggesting the importance of photosynthesis to supply the energy.

Li (1990) described the difficulties of culturing gemmae and gametophytes of *Marchantia polymorpha* (Figure 1-Figure 12). They found that in their cultures it required dedifferentiation and redifferentiation, with rather specific cultural conditions and media. They used 2,4D and 3% sucrose to encourage the tissue development. This process could require as long as 10 months. Nevertheless, they found the process to be easier than in tracheophytes.

Bryophytes are known for their "extraordinary competency of regeneration" (Nishihama *et al.* 2015). This is possible due to their high level of developmental plasticity, permitting them to regenerate from cells, tissue fragments, branches, and even reproductive organs. Gardeners in Japan and elsewhere take advantage of this ability to propagate many plants from just a few by drying and fragmenting them (see Horticulture chapter in Volume 5).

Yoshikawa *et al.* (2018) found that the stress caused by wounding (Figure 170) induces phenylalanine ammonia lyases. These lyases initiate the accumulation of phenylpropanoids in *Marchantia polymorpha* (Figure 1-Figure 12). Wounding induces the biosynthesis of luteolin, apigenin, and isoriccardin C, all of which are biosynthesized through the phenylpropanoid pathway.

Ishida *et al.* (2022) found that diminished auxin signalling triggers the cellular reprogramming needed for regeneration in *Marchantia polymorpha* (Figure 1-Figure 12). Auxin is produced in apical cells, and removal of the apex enhances regeneration. Addition of auxin inhibits regeneration. They were able to identify the gene responsible for the cell proliferation needed for regeneration.

Mechanisms that control regeneration are also at play in controlling apical dominance (Figure 20) in *Marchantia polymorpha* (Figure 1-Figure 12). Davidonis and Munroe (1972) found that the larger lobe in this dichotomously

branching plant is always the one closest to the midrib. If these two lobes are separated by a cut while still in an early stage of lobe growth, the smaller lobe is no longer inhibited and is able to grow to equal size. Adding the auxin IAA to the smaller lobe after cutting will re-establish the dominance of the other lobe. The researchers suggested "that the type of neighbor lobe dominance in *Marchantia* resulting in its typical fan-shaped growth habit is maintained by auxin through a differential sensitivity of the two neighbors to auxin inhibition."

Figure 170. *Marchantia polymorpha* gemmae cups and antheridiophores in Europe; note the dead thalli and the red gemmae cups that indicate stress. At the same time, the apical portions continue to grow. Photo by Michael Lüth, with permission.

Maravolo *et al.* (1975) traced the transport of labelled IAA in the thallus of *Marchantia polymorpha* (Figure 1-Figure 12). There was a marked dominance of the hormone in the primary lobe. Movement to the secondary lobe could be enhanced by disruption of the conductive tissue or by removing the primary apex. Gibberellin and cytokinin also increased the activity of the IAA in the subdominant lobe, indicating that gradients of these three hormones might serve as growth regulators and these could be established independently at each apex.

Bhargava and Chauhan (1978) reported a dichotomously branched vegetative thallus at the tip of a gametophore stalk. I have to wonder if this is a germinated gemma, such as that observed by Li Zhang for *Marchantia emarginata* (Figure 171) rather than a branch.

Figure 171. *Marchantia emarginata* ssp. *tosana*, in Guangdong, S. China, with germinated gemmae and young thalli with gemmae cups growing on male receptacle arms. Photo courtesy of Li Zhang.

Kubota *et al.* (2013) were successful in achieving *Agrobacterium*-mediated (Figure 172) transformation in regenerating thalli of *Marchantia polymorpha* (Figure 1-Figure 12). Developmental timing is important to the success of this transformation. Previously, efficient *Agrobacterium*-mediated transformation had only been accomplished with sporelings. Iwakawa *et al.* (2021) further described a protocol useful for using this method in *M. polymorpha*. GUS (β -glucuronidase) activity was detected 2 days after infection and became saturated after 3 days.

Figure 172. SEM of *Agrobacterium tumefaciens*; the genus *Agrobacterium* is used for genetic transformation and has been developed as a tool in *Marchantia polymorpha*. Photo from CDC, through public domain.

Shibaya and Sugawara (2007) found that the protoplasts of *Marchantia polymorpha* (Figure 1-Figure 12) could regenerate new cell walls in the initial culture, but the survival rate then decreased rapidly. β -glucosyl Yariv reagent (β glcY) could suppress this reduction in the survival rate. This substance binds to arabinogalactan proteins (AGPs) and does not increase survival except when added during the incipient cell wall regeneration. The researchers suggested that AGPs were involved in cell wall regeneration. Adding activated charcoal to the medium also permitted the cells to divide vigorously. It appears that AGPs and β -1,3-glucan are important in the survival and subsequent cell division of regenerated cells of *M. polymorpha* protoplast cultures.

Harashima and Ono (1991) tested the long-term culturing of *Marchantia polymorpha* (Figure 1-Figure 12). They found that after years of suspended culture they regained regeneration potential. The loss of morphogenetic potential in some was correlated with chromosome aberrations. They were able to maintain gemmae cultures for 213 months and spore cultures for 64 months.

Takenaka *et al.* (2000) used *Marchantia polymorpha* (Figure 1-Figure 12) for direct particle bombardment with

plasmid pMT. They produced hygromycin-resistant cell masses that developed into hygromycin-resistant thalli. These modified thalli transmitted the genetic modification to their gemmae for three generations. Hence, this could be a valuable tool for molecular analysis of this species and others.

Role

The role of aquatic bryophytes in accumulating pollutants is well known. Even *Marchantia polymorpha* (Figure 1-Figure 12) has been tested for its ability to purify water (Baltazar Pereda & Rebaza 2021). The researchers were concerned that there is no treatment for the wastewater for a sewage system in La Libertad. The water is used to irrigate stem crops, but it causes bad odors and endangers the health of those living around the canal. Both the water hyacinth (*Eichhornia crassipes* – Figure 173) and duckweed (*Lemna minor* – Figure 174) showed an excellent removal efficiency, improving oxygen and diminishing coliforms. However, the *Marchantia polymorpha* failed to make significant changes in water quality.

Figure 173. *Eichhornia crassipes* (water hyacinth), a species that is much more efficient at removing pollutants than is *Marchantia polymorpha*. Photo by Wouter Hagens, through public domain.

Figure 174. *Lemna minor* (duckweed), a species that is much more efficient at removing pollutants than is *Marchantia polymorpha*. Photo by Barbarossa, through Creative Commons.

Briggs (1972) reported that this species contains higher levels of lead than bryophytes that had been used in previous studies. Large quantities of plants could be grown quickly from gemmae, then exposed in a lead-polluted atmosphere to determine levels in the plants, and by extrapolation, the environment.

Accumulation of heavy metals characterizes many bryophytes (Cahuana & Aduvire 2019). Sharma (2007) placed *Marchantia polymorpha* (Figure 1-Figure 12) in moss bags to monitor pollution in several areas to compare pollutants. Plants accumulated the highest levels (2276 $\mu\text{g g}^{-1}$ dry weight) of lead in summer. But *Marchantia* lacks the high level of surface area seen in most mosses, making Sharma conclude that it a less useful accumulator than we might find in mosses and leafy liverworts.

Perhaps the most useful role of *Marchantia polymorpha* (Figure 1-Figure 12) is its use in the laboratory. The gemmae (Figure 153-Figure 165) of liverworts such as *M. polymorpha* represent isogenic progeny that can be used to experiment with gene expression (Kubota *et al.* 2013). The most common system used is to supply *Agrobacterium* (Figure 20) to regenerating thalli produced from these gemmae. These bacteria are able to transfer genes into the liverwort.

Interactions

Seed plants have an array of structural defenses as well as biochemical defenses against herbivores. Bryophytes, on the other hand, generally lack structural defenses, at least the elaborate ones such as spines, thick cuticle, and dense, lignified tissues. But the bryophytes, instead, are endowed with an extremely varied array of biochemical defenses.

Despite knowing about the wide diversity of secondary compounds in bryophytes, especially in liverworts, the research on their functions in the ecosystem and their sources, particularly in cooperation with microorganisms, has been rather neglected until recently (Stelmasiewicz *et al.* (2021). Noting that bryophytes produce many compounds unique to bryophytes, Stelmasiewicz and coworkers used a volatile extract to isolate the volatile compounds produced by the *Marchantia polymorpha* (Figure 1-Figure 12)-microorganism symbiosis. They isolated cuparane-, chamigrane-, acorane-, and thujopsane-type sesquiterpenoids from *Marchantia polymorpha*. These compounds proved to be active against some types of human cancer. But what do they do for the liverwort?

Poveda (2020a) touted the use of *Marchantia polymorpha* (Figure 1-Figure 12) as a model organism in studies of plant-microorganism interactions. He reviewed the published literature on these interactions.

Bacterial Interactions

As new studies are emerging, we are learning of the great dependence of bryophytes on other organisms. Bacteria are among these partners. Kutschera and Koopmann (2005) found that epiphytic methylobacteria promote the growth of *Marchantia polymorpha* (Figure 1-Figure 12). While living on the surfaces of plants these bacteria secrete cytokinins. The bacterial extracts had no effect on seeds of maize or sunflower, but did promote the growth of isolated *M. polymorpha* gemmae (Figure 153-Figure 165) on agar plates.

Alcaraz *et al.* (2018) identified *Bryobacter*, *Lysobacter* (Figure 175), *Methylobacterium* (Figure 176), *Paenibacillus* (Figure 177), *Pirellula*, *Rhizobium* (Figure 178-Figure 179), and *Steroidobacter* from *Marchantia polymorpha* (Figure 1-Figure 12) as well as from *M. paleacea* (Figure 14; see part 1 of this chapter). These plant symbionts are known for plant-growth promotion, complex exudate degradation, nitrogen fixation, methylophiles, are disease-suppressive bacteria, and are hosted within the plant thallus.

Bryophytes are used in some cultures as medicinal plants. Some groups of Indonesian people use *Marchantia polymorpha* (Figure 1-Figure 12) as a traditional medicine to treat skin infections (Ramadhan & Agustien 2019). The species has flavones and flavone glycosides as well as simple terpenoids that are able to inhibit the multiplication of bacteria. These researchers chose to isolate endophytic bacteria from *Marchantia polymorpha*. Six species of endophytic bacteria that have the potential to produce antibiotics were successfully isolated from the thallus; these bacteria were successful against *Staphylococcus aureus* (Figure 180).

Figure 180. Colorized SEM of bacterium *Staphylococcus aureus*, a species that is inhibited by antibiotics produced by other bacteria endophytic in *Marchantia polymorpha*. Photo by Janice Haney Carr, CDC, through public domain.

Himanshu *et al.* (2007) found that acetone-soluble extracts of *Marchantia polymorpha* (Figure 1-Figure 12) had antibiotic activity against the Gram negative bacteria *Escherichia coli* (Figure 16) and *Salmonella typhi* (Figure 181) and two fungi *Aspergillus niger* (Figure 182) and *Candida albicans* (Figure 183-Figure 184), all human pathogens. Such antibiotic activity makes this species of interest for finding applications to replace the ever-growing number of antibiotics that are helping to create "super bugs" with antibiotic resistance. But do they help the bryophyte? One indication that they might not, at least as antibacterial agents, is that the water soluble extracts did not show any inhibitory effects on the pathogens tested.

Using specimens from Vietnam, Son *et al.* (2020) isolated lunularin, marchantin A, isoriccardin C, luteolin, and apigenin from *Marchantia polymorpha* (Figure 1-Figure 12). Isoriccardin C had "remarkable" antibacterial activity against *Staphylococcus epidermidis* (Figure 185). Several extracts exhibited anticancer activity.

Figure 185. *Staphylococcus epidermidis*, a species that experiences strong negative effects from isoriccardin C from *Marchantia polymorpha*. Photo from NIAID, through Creative Commons.

Ivković *et al.* (2021) identified terpenes, oils, sugars, and bis-benzyls in methanol extracts of *Marchantia polymorpha* (Figure 1-Figure 12). These extracts were effective in inhibiting Gram-positive bacteria but had no effect on Gram-negative bacteria.

Mewari and Kumar (2008) tested antibacterial activity using crude methanol and flavonoid extracts of *Marchantia polymorpha* (Figure 1-Figure 12) against three strains of bacteria [*Escherichia coli* (Figure 16), *Proteus mirabilis* (Gram negative; Figure 186), and *Staphylococcus aureus* (Figure 180) (Gram positive)] and four of fungi [*Aspergillus flavus* (Figure 187), *A. niger* (Figure 182), *Candida albicans* (Figure 183-Figure 184), and *Trichophyton mentagrophytes* (Figure 188)]. All the microorganisms proved to be sensitive to all of the extracts, suggesting that *M. polymorpha* had a good potential as a source of antimicrobial drugs.

Figure 188. *Trichophyton mentagrophytes*, fungal species that is sensitive to crude methanol and flavonoid extracts of *Marchantia polymorpha*. Photo by Dr. Libero Ajello, CDC, through public domain.

Wang *et al.* (2016) found that the total flavonoid content of the archegoniophore was ten times that of the thallose gametophyte. This correlated with greater bioactivity in the archegoniophore, potentially protecting the reproductive structure from bacteria, fungi, and perhaps even herbivory.

Most of the work on antibacterial activity by secondary compounds in bryophytes has been done on human pathogens. The question remains, what can they do for bryophytes? De *et al.* (2015) noted that bryophytes lack the mechanical protections available to tracheophytes and that instead use secondary metabolites as protectants. If such is the case, then we should see greater selection for higher concentrations in bryophytes from habitats where there are more herbivores or pathogens present. However, few studies have attempted to address this hypothesis. De and coworkers compared secondary compounds from *Marchantia polymorpha* (Figure 1-Figure 12) from five different altitudes in Darjeeling Himalayas. To my surprise, they found higher antibacterial activity at higher altitudes. This suggests to me that their antibacterial activity is not the most important factor operating in selection for these secondary compounds.

Protozoa Interactions

Protozoa are also inhibited by extracts from *Marchantia polymorpha* (Figure 1-Figure 12). Jensen *et al.* (2012) found that marchantin A extracted from this liverwort inhibited the proliferation of the protozoan *Plasmodium falciparum* (Figure 189). *Trypanosoma brucei rhodesiense* (Figure 190), *T. cruzi* (Figure 191), and *Leishmania donovani* (Figure 192), all human pathogens, likewise experienced inhibition by marchantin A.

Fungal Interactions

The associations of fungi with bryophytes was a long-neglected topic in bryology. In fact, many seemed to assume that fungi could not live with bryophytes, or that the bryophytes had too low a nutrient concentration to be of value to the fungi. But this view has now been disproved.

endophytes

Döbbeler (1979) found fungal infections in the rhizoids of *Marchantia polymorpha* (Figure 1-Figure 12). Duckett and Ligrone (2003) further reported that the living smooth rhizoids of *Marchantiales* contained the hyphae of fungal endophytes (Figure 193). Benkert (1998) reported a fungus (*Octospora inthacaensis*) growing on *M. polymorpha*. But what does this relationship mean for the bryophyte?

Figure 193. Rhizoids of *Marchantia polymorpha* with fungus in lower rhizoid. Photo by Walter Obermayer, with permission.

Döbbeler (2002) reported that the Ascomycetes (fungi) growing on the gametophytes of bryophytes typically did not form ascomata on general locations on their bryophyte hosts, but instead occupied distinct locations that were specific for the host species. These microsites usually offered protection against rapid water loss by the fungus and permitted enough exposure to permit unhindered spore dispersal of the fungus by air currents. Among the thallose liverworts, the ascomata were typically immersed in the spongy thalli. But what do they do to or for the liverwort?

Fungal actions may be subtle, and certainly fungi can inhabit *Marchantia polymorpha* (Figure 1-Figure 12). Guminska and Mierzenska (1992) reported that the fungus *Loreleia marchantiae* (= *Gerronema marchantiae*; Figure 194) was associated with this species and with *Nostoc* sp. (Cyanobacteria).

Figure 194. *Loreleia marchantiae* growing with *Marchantia polymorpha*. Photo by Alexey Sergeev, with permission.

Nelson and Shaw (2019) found a very diverse fungal community that was distinct between patches of *Marchantia polymorpha* (Figure 1-Figure 12). Only a few core fungi were the same across widely separated populations across the USA. However, they found that the two methods used detected different species.

symbiosis?

Trees are usually dependent on fungal partners in their roots as a means of scavenging nutrients from a much larger soil volume than that available to roots. Hanke and Rensing (2010) considered that *Marchantia polymorpha* (Figure 1-Figure 12), with what is now a sequenced genome, provided many genetic tools by which to establish the association of fungi such as *Glomus intraradices* with gametophyte plants, including culturing, infection strategies, and staining procedures.

Marchantia species, including *M. polymorpha* ssp. *montivagans* (Figure 34) (Ligrone *et al.* 2007), often form mycorrhizal associations (Bowman *et al.* 2016). However, such associations are not known in *M. polymorpha* ssp. *polymorpha* or ssp. *ruderalis* (Figure 6-Figure 8, Figure 17-Figure 19). Bowman and coworkers (Bowman *et al.* 2017) attribute this independence to increased transport capacity in the subspecies, permitting them to be weedy colonizers of newly disturbed habitats.

pathogens

Certainly not all fungi have a friendly relationship with the bryophytes. Verkley *et al.* (1997) reported the ascomycete *Bryoscyphus atromarginatus* (Figure 195) as a new species parasitizing the thallus of *Marchantia polymorpha* (Figure 1-Figure 12) in the Netherlands. The type specimen of the species named as *Bryoscyphus marchantiae* (Figure 196) was actually collected from *Reboulia haemisphaerica* (Figure 197). The description given by Naumov (1964) of the collection he reported as *Hymenoscyphus marchantiae* (Figure 198) on *M. polymorpha* agrees well with the new species described by Verkley *et al.* Naumov commented that it appeared that this could be a new species.

Fraiture and Ertz (2007) reported that the fungus *Didymosphaeria marchantiae* (Figure 199) was a parasite on *Marchantia polymorpha* (Figure 1-Figure 12).

Figure 199. *Didymosphaeria marchantiae* infecting leafy liverwort, but also known to be a parasite on *Marchantia polymorpha*. Photo by Dragiša Savić, with permission.

Nelson (2017; Nelson *et al.* 2018) noted the lack of studies on fungal endophyte interactions with bryophytes while at the same time realizing that the reactions of the plants to these organisms is quite varied. They found that such fungi in *Marchantia polymorpha* (Figure 1-Figure 12) ranged from "aggressively pathogenic to strongly growth-promoting." Nevertheless, most of them seemed to cause no change in host growth. Furthermore, those that promoted growth were dependent on nutrient concentrations and their effects on growth were inhibited by inoculation of the liverwort with multiple fungi. Some of the fungi that are known as pathogens in tracheophytes were actually beneficial to the liverworts.

With the large arsenal of secondary compounds, we should consider it to be likely that some of these are effective against fungal pathogens. Takikawa *et al.* (2014) inoculated several powdery mildews on the thallus and gemmae (Figure 153-Figure 165) of *Marchantia polymorpha* (Figure 1-Figure 12). The conidia and germ tubes of *Erysiphe trifoliorum* (Figure 200) were destroyed. The germ tube tip was destroyed in four hours when it reached the gemma leaf surface. After six hours the conidial bodies were destroyed as well. On the other hand, *Oidium neolycopersici* (see Figure 201) continued growth with no destruction of conidia and produced normal appressoria on the surface of the gemmae.

Figure 200. *Erysiphe trifoliorum* on *Trifolium pratense* leaves; this fungus is destroyed when inoculated on thallus or gemmae of *Marchantia polymorpha*. Photo by John Plischke, through Creative Commons.

Figure 201. SEM of *Oidium* sp; *Oidium neolycopersici* continued growth with no destruction of conidia and produced normal appressoria on surface of gemmae of *Marchantia polymorpha*. Photo by Gerald Holmes, through Creative Commons.

Peumans *et al.* (2007) found the surprising result that a **lectin** (protein that binds to carbohydrates – features that lectins use to defend plants in nature may cause problems during human digestion; lectins resist being broken down in gut and are stable in acidic environments, features that protect lectin-containing plants in nature) identified in *Marchantia polymorpha* (Figure 1-Figure 12) had never been found in any plant, but that instead it closely resembles one from the common edible mushroom *Agaricus bisporus* (Figure 202), *i.e.*, it is a lectin that was hitherto considered to be exclusive to fungi. It was also confirmed in the moss *Syntrichia ruralis* (Figure 203).

Figure 202. *Agaricus bisporus*, common edible mushroom that has lectin similar to one found in *Marchantia polymorpha*. Photo by Мышь Денис, through Creative Commons.

Figure 203. *Syntrichia ruralis*, species that shares same lectin as that found in *Marchantia polymorpha*. Photo by Alexis Orion, through Creative Commons.

Carella *et al.* (2019) explored the molecular response of *Marchantia polymorpha* (Figure 1-Figure 12) to oomycete infection. These early land plants necessarily had to defend against pathogens with their new exposure to land. We know of many pathogens and defenses in tracheophytes, but we know little about the plant-pathogen interactions in these early land plants. Whereas we have explored their medical use and even uses as fungicides for

tracheophytes, we know relatively little about their functions in the bryophytes that produce them. Carella and coworkers traced the response of this liverwort to the oomycete pathogen *Phytophthora palmivora* (Figure 204). They found that the liverwort shared a set of orthologous microbe-responsive genes with tracheophytes. These include members of the phenylpropanoid metabolic pathway. Using both knockout and induction techniques, they determined that MpMyb14 leads to the accumulation of anthocyanin-like pigments (**auronidin**) while greatly enhancing the resistance of *Marchantia polymorpha* to *Phytophthora palmivora* infection. The auronidin prevented the penetration of the fungal hyphae into the pigmented portions of the liverwort.

Figure 204. *Phytophthora palmivora* infecting papaya; *Marchantia polymorpha* was used to identify the mechanism of resistance to this plant pathogen. Photo by Scot Nelson, through Creative Commons.

Gahtori and Chaturvedi (2011) used methanol and chloroform extracts to test the activity of *Marchantia polymorpha* (Figure 1-Figure 12) against three bacterial and four fungal species. The extracts exhibited antimicrobial activity with potency that differed among organisms that were pathogenic to both plants and animals. Some were inhibitory toward multiple organisms, and others showed potential.

In other experiments, Mewari and Kumar (2011) made similar tests and found that *Marchantia polymorpha* (Figure 1-Figure 12) completely inhibited the mycelial growth of the fungal pathogen *Rhizoctonia solani* (Figure 205). Furthermore, most extracts also caused 100% inhibition of spore germination of fungal pathogens *Alternaria solani* (Figure 206) and *Fusarium oxysporum* (Figure 207).

In China, Niu *et al.* (2006) isolated seven bis[bibenzyl]-type macrocycles, including three new ones. They assessed their antifungal activities against *Candida albicans* (Figure 183-Figure 184), using TLC bioautography. This fungal species is an opportunistic pathogenic yeast that is the most prevalent cause of fungal infections in humans. Several of the compounds proved to be active against this fungus.

Purkon *et al.* (2022) reported the medicinal use of *Marchantia* in China, North America, Ancient Greece, and Indonesia for treatment of open wounds, burns, hepatotoxicity (damage to liver caused by medicine, chemical, or herbal or dietary supplement), and infection prevention.

Matsui *et al.* (2020) found antagonism between salicylic acid and jasmonate in the fungal pathogen interaction with *Marchantia polymorpha* (Figure 1-Figure 12). They isolated *Bjerkandera adusta* (Figure 208), *Irpex lacteus* (Figure 209), and *Phaeophlebiopsis peniophoroides* (Figure 210) from diseased *M. polymorpha*. They found that salicylic acid promotes infection by *I. lacteus*, but this action is suppressed when jasmonate is treated at the same time.

Hipol and Broñola-Hipol (2016) screened 22 fungal associates of *Marchantia polymorpha* (Figure 1-Figure 12) for their carboxyl esterase activity. Half were endophytes and half were epiphytes on the liverwort. All of the isolates produced this enzyme, with the fungus *Colletotrichum boninense* (see Figure 211) producing the lowest levels of the enzyme and *Nodulisporium* sp. (Figure 212) produced the highest levels.

Figure 212. *Nodulisporium cecidiogenes* on rotten wood; species of *Nodulisporium* produced highest levels of carboxyl esterase activity among 22 fungi isolated from association with *Marchantia polymorpha*. Photo by Alexey Sergeev, with permission.

Poveda (2020b) asked if the arbuscular-mycorrhizal fungal (AMF) association with *Marchantia polymorpha* ssp. *ruderalis* (Figure 6-Figure 8) was beneficial or harmful. Despite all the studies on this species, this is one of the many questions remaining unanswered. They found that *in vitro*, the interaction is detrimental, causing reduced growth and tissue viability, with only those elements involved in plant defenses increasing in nutritional content. These changes were coupled with increases in reactive oxygen species (ROS) content. One such fungus is *Rhizophagus fasciculatus* (Figure 213) – a species present only when there is evidence of thallus damage. Hence, this fungus appears to be a pathogen to *Marchantia polymorpha* ssp. *ruderalis*. Further examination of fungi with bryophytes could reveal interesting symbiotic relationships, modes of infection, and defenses against fungi. *Marchantia polymorpha* (Figure 1-Figure 12) is large enough, cultures easily, and is known to respond in a variety of ways to fungal invaders. Hence, it would be a good initial test organism to help us understand these relationships and their effects in their ecosystem.

Invertebrate Interactions

Herbivory (Figure 214) on liverworts seemed to be a blind spot in older bryological studies, but recent reports tell us it is real. Sawangproh *et al.* (2016) reported the feeding of *Scatopsciara cunicularius* (Diptera: Sciaridae) larvae on *Marchantia polymorpha* (Figure 1-Figure 12). They found that larvae fed at 12°C fed more slowly than those at 22°C, but those at the lower temperature fed over a longer period of time, ultimately causing more damage to the liverwort. The researchers suggested using these larvae to control the invasion of the liverwort in plant nurseries and greenhouses. I wonder what other plants they eat?

Figure 214. *Marchantia polymorpha* female eaten on one of the receptacle fingers. Photo by Li Zhang, with permission.

Koeduka *et al.* (2022) found that allene oxide synthase (AOS) from *Marchantia polymorpha* (Figure 1-Figure 12) is important in inhibiting the survival rate and oviposition of the spider mite *Tetranychus urticae* (see Figure 215). When mutants lacking the AOS gene were subjected to these spider mites, survival of the mites was greater than in the wild type. Their research indicated that defense system signalling pathways respond to spider mite presence.

Figure 215. *Marchantia polymorpha* gemmae cups with mite, possibly spider mite. Photo By Bernard de Cuyper, with permission.

Some invertebrates commonly live among bryophytes, *Marchantia polymorpha* (Figure 1-Figure 12) included. A common bryophyte inhabitant is the isopod (Figure 216). In some cases these might actually eat the bryophytes. In other cases, there is no evidence of herbivory. Spiders also build webs (Figure 217), perhaps catching some of the other inhabitants of the thallus community.

Figure 216. *Marchantia polymorpha* and isopod; there does not seem to be any evidence of herbivory – yet. Photo by Walter Obermayer, with permission.

Figure 217. *Marchantia polymorpha* males with gemmae cups and spider web. Photo by Nancy Leonard, with permission.

The importance of bryophyte herbivory in the ecosystem is virtually unknown. This seems to be particularly true for *Marchantia polymorpha* (Figure 1-Figure 12). As the climate shifts and herbaceous plant communities change, it is possible some herbivores could shift to consumption of bryophytes. Few studies have addressed the effects of temperature or precipitation patterns on the interaction of invertebrates with bryophytes.

Tracheophyte Interactions

Little has been written about the interaction between bryophytes and tracheophytes. Bryophytes are not good competitors with tracheophytes because of the small size of

the bryophytes. How, then, do the tiny bryophytes survive in habitats dominated by tracheophytes?

Whittemore (1991) suggested that bryophytes such as those in the **Marchantiales** might be toxic not only to herbivores and pathogens, but also to competing plants such as tracheophytes. On the other hand, Asakawa *et al.* (1982) found that compounds from the tracheophyte family Apiaceae could inhibit the growth of *Marchantia polymorpha* (Figure 1-Figure 12).

Nakayama *et al.* (1996) tested the inhibitory effects of lunularic acid and its analogs on the growth of *Marchantia polymorpha* (Figure 1-Figure 12), *Rorippa nasturtium-aquaticum* (watercress; Figure 218), and *Phleum pratense* (timothy grass; Figure 219). The analogs proved to be more inhibitory than lunularic acid, suggesting that the liverworts that produce this hormone might have less growth inhibitory activity than tracheophytes, or they are somehow protected from its inhibitory effects.

Figure 219. *Phleum pratense*, species that has less inhibition by lunularic acid than more advanced analogs. Photo through Creative Commons.

Sharma *et al.* (2009) used *Marchantia polymorpha* (Figure 1-Figure 12) water extracts as one of the bryophyte species they tested for allelopathic effects on the flowering plant *Bidens biternata* (Figure 220). Although there was 100% inhibition of seed germination in the lipophilic extract, germination was not delayed significantly in water extracts. Sharma and coworkers reasoned that hydrophilic allelochemicals would be released more easily into the environment, but that these would also leach from the soil more quickly, thus favoring hydrophobic allelopathic compounds as a better defense.

Figure 220. *Bidens biternata*, species for which seed germination is 100% inhibited by lipophilic extracts of *Marchantia polymorpha*, but not by water extracts. Photo by J. M. Barg, through Creative Commons.

Kaihara and Takimoto (1990) found that a water extract of *Marchantia polymorpha* (Figure 1-Figure 12) could inhibit the flower-inducing activity of L-pipecolic acid. This L-pipecolic behaved synergistically with water extracts of *Lemna aequinoctialis* (duckweed; Figure 221) and *Ipomoea hederacea* (ivy-leaved morning glory; Figure 222) to enhance flowering, but all other tested plants suppressed it. This flowering inhibition is a sneaky way for the liverwort to compete with tracheophytes, but we have no field assessment of its effectiveness.

Marchantia polymorpha (Figure 1-Figure 12) can even become a pest in domestic gardens. The need to control weeds can provide new spaces where this liverwort can easily invade through gemmae or spores brought to the surface by the disturbance or as companions when new plants are introduced. Callaghan (2009) assessed domestic gardens in Britain and found that more than 80% of them included six moss species, but that *Marchantia polymorpha* was present in only 30% of the gardens. Nevertheless, Caron (1972) emphasized the need to fight such bryophytes as *Marchantia polymorpha* in arboriculture.

At least some herbicides tend to have different effects on different groups of plants. Bryophytes are no exception. Balcerkiewicz and Rusinska (1987) found that *Marchantia* actually expanded its populations in areas treated with herbicides. This may be due to the elimination of the competing tracheophytes, but the possibility existed that the herbicides could actually promote the growth of the liverworts. Iwata *et al.* (1992) subsequently suggested that *Marchantia polymorpha* (Figure 1-Figure 12) suspension cultures would be an excellent system for herbicide assays because of the rich chlorophyll content of the liverwort and its ability to grow in both **mixotrophic** (deriving nourishment from both autotrophic and heterotrophic mechanisms) and **autotrophic** (producing complex organic compounds using carbon from simple substances such as carbon dioxide) conditions.

Biochemistry

In a species that has been fundamental in so many studies to represent bryophytes, it is not surprising that there have been many biochemical studies as well. Those included here are only representative of the many publications.

Konno *et al.* (1987) isolated three classes of pectic polysaccharides from *Marchantia polymorpha* (Figure 1-Figure 12): rhamnogalacturonan polymer class, glucose rich polymer class, and galacturonan core. The cell walls are low in arabinosyl residues, unlike those of flowering plants.

Boisselier-Dubayle and Bishler (1989) reported on the presence of esterases, peroxidases, acid phosphatases, and glutamate-oxaloacetate transaminase as revealed by their

electrophoretic studies on *Marchantia polymorpha*. Izumi *et al.* (1995) identified esterase secreted from suspension cell culture of *Marchantia polymorpha*.

flavonoids

Singh *et al.* (1987) confirmed the presence of saponins, tannins, and flavonoids in *Marchantia polymorpha* (Figure 1-Figure 12). However all tests for alkaloids were negative, thus eliminating one of the chemical groups used in antiherbivory in some tracheophytes.

Markham and Porter (1974) identified major flavonoids of *Marchantia polymorpha* ssp. *polymorpha*. Flavonoids exhibit properties of antiherbivory and UV filters (Johnson 1983; Treutter 2006). Treutter (2006) reviewed the literature on their roles in plants and found that they act as stress protecting agents, attractants, or feeding deterrents, and have a significant role in plant resistance.

Flavonoids are important compounds that enabled the first land plants to interact with their environment (Davies *et al.* 2020). Hence, it is hypothesized that the flavonoid pathway must have evolved during the colonization of land by early plants, about 450 million years ago, providing essential protection against abiotic stress (Albert *et al.* 2018). The flavonoids are important reactants that permitted early plants to tolerate both abiotic and biotic stresses. Their production in plants can be induced by cold, UV-B light, strong white light, nutrient deficiency, desiccation, salinity, metal toxicity, senescence, and attack by pests and pathogens (Agati & Tattini 2010; Cheynier *et al.* 2013; Landi *et al.* 2015; Davies *et al.* 2018, 2020). They provide signals to microbes, serve as **allelochemicals** (chemical produced by living organism, exerting detrimental physiological effect on individuals of another species when released into environment), and can be important **nutraceuticals** (any food substance that provides medical or health benefits, including prevention and treatment of disease) in the animal diet (Taylor & Grotewold 2005).

Kubo *et al.* (2018) demonstrated that the regulation of gene expression as a stress response was already present in *Marchantia polymorpha* (Figure 1-Figure 12). They found that overexpression of one regulatory gene greatly increased the amount of riccionidins, a flavonoid. The gene was up-regulated by UV-B irradiation, nitrogen deficiency, and NaCl treatment.

Clayton *et al.* (2018) monitored the biosynthesis of flavonoids in *Marchantia polymorpha* (Figure 1-Figure 12), using three different UV-B regimes and mutant cultures. They found that the **chalcone** isomerase-like compound was one of greater importance. Mutants with a disrupted pathway for this enzyme were more easily damaged by UV-B. Those mutants with increased flavonoid content demonstrated greater UV-B tolerance.

The flavonoid pathway starts with **chalcones** as the first flavonoids (Davies *et al.* 2020). Since their origin, more than 8,000 different flavonoid structures have been reported (Andersen & Markham 2006). The major flavonoid classes are the flavones, flavonols, isoflavonoids, aurones, 3-deoxyanthocyanins, anthocyanins, proanthocyanidins (condensed tannins), and auronidins (Davies *et al.* 2020). Most flavonoids go to the vacuoles as water-soluble glycosides, but in some species they are

transported to the cell wall or are released to the environment.

Many flavonoids can absorb UV light, but the colored anthocyanins and auronidins can screen visible light (Lee & Gould 2002; Landi *et al.* 2015; Berland *et al.* 2019). Thus far, flavonoids have not been found in hornworts. They seem to have no role in development in bryophytes; a mutant of *Marchantia polymorpha* (Figure 1-Figure 12) lacking flavonoids has normal developmental patterns (Clayton *et al.* 2018).

In *Marchantia polymorpha* (Figure 1-Figure 12), nitrogen deprivation and increased white light exposure both induce the accumulation of auronidin (Albert *et al.* 2018; Kubo *et al.* 2018), a phenomenon similar to that of seed plants for anthocyanin accumulation in *Arabidopsis* and apples (Rubin *et al.* 2009; Wang *et al.* 2018). But in *M. polymorpha* auronidin also greatly increases the resistance of the plants to infections by *Phytophthora palmivora* (Figure 204), with hyphae apparently unable to penetrate into highly pigmented regions of the plant (Carella *et al.* 2019). Thus their roles are widespread.

Berland *et al.* (2019) reported **auronidins** for the first time. These flavonoid pigments seem to be important in protecting the plants from such environmental stresses as high light, drought, and nutrient deprivation. We initially thought that the red pigments bound in the cell walls of the early land plants were anthocyanins, but recent studies have revealed that they are in fact a group of phenylpropanoids that Berland and coworkers named **auronidins**. Their colors are similar to those of anthocyanins, but they are synthesized differently and have different optical properties. It appears that they contribute to the ability of *Marchantia polymorpha* (Figure 1-Figure 12) to survive extreme environments.

Excess light of any quality enhances the biosynthesis of flavonoids in plants, performing multiple functions at the expense of the antioxidant flavonoids and hydroxycinnamates (Agati & Tattini 2010). Several research groups have provided indications that common oxidative signal components may up-regulate flavonoid biosynthesis, regardless of their origins (Taylor & Grotewold 2005; Fujita *et al.* 2006; Quattrocchio *et al.* 2006) and may link the REDOX potential of the cell to the control of flavonoid accumulation (Taylor & Grotewold 2005). It appears that the main purpose of the flavonols is their involvement in responses to abiotic and biotic stresses (Roberts & Paul 2006; Kilian *et al.* 2007; Mellway *et al.* 2009). More research is needed on their involvement in reducing oxidative stress.

Using knockout genes, Albert *et al.* (2018) determined that all pigmentation was lost from the flavonoid riccionidin A in *Marchantia polymorpha* (Figure 1-Figure 12), but when overexpression was used these plants produced large amounts of flavones and riccionidin A and exhibited red pigmentation. Light- and nutrient-deprivation stress induced flavonoid pigmentation in the thallus, as these stresses do for the anthocyanins in flowering plants.

In evolutionary theory, red leaves represent a signal of the health status of a tree, providing a signal to insects to migrate when trees change color in autumn (Cheynier *et al.* 2013). Could similar signals be active in bryophytes, with red plants signalling nutrient deficiency or other poor

health condition? Red can also signal toxicity and is known as **warning coloration**.

phenolics

From the beginning of my interest in antiherbivory, I understood that phenolics were the important antiherbivore compounds in plants. But Close and McArthur (2002) challenged that thinking. They contend that it is not antiherbivory, but photoprotection, that makes these compounds so important for plants. They suggest that phenolics accomplish this role by acting as antioxidants and that their levels may vary with environmental conditions to provide this protection. Thus, their level of phenolics in the plants is dependent on the risk of photodamage and not on resources in the environment.

Cheynier *et al.* (2013) noted that for the successful colonization of land plants needed UV light screens. These were apparently achieved by phenolic compounds. These compounds play no role in the developmental and growth processes, but they are vital for survival in the interaction of the plants with their environment, for their reproductive strategy, and reputedly, for their defense. These survival mechanisms are controlled by plant phenolics that respond to potentially overlapping regulatory signals. Some of these effects are likewise associated with the growth hormone auxin.

Soriano *et al.* (2019b) found that bryophytes rarely exhibited a quick response to UV radiation in their production of UV-absorbing compounds. They experimented with *Marchantia polymorpha* (Figure 1-Figure 12) and measured the phenolic content under three realistic UV levels on day 1 and day 22 (Figure 223). The levels of UV-absorbing compounds mostly responded with linear or hyperbolic relationships with the UV level (Figure 224). They identified thirteen flavones (apigenin and luteolin derivatives) and two hydroxycinnamic acids (p-coumaric and ferulic acids) in the soluble and insoluble fractions, respectively. The speed of response depended on the compound, but those identified in *M. polymorpha* were slow responders.

Figure 223. UV-absorbing compounds and time. White bars = UVBE low; grey bars = medium; black bars = high. Letters that are same represent means that are not significantly different from each other. Image modified from Soriano *et al.* 2019b.

Figure 224. *Marchantia polymorpha* phenolics produced with increasing levels of UV-B. Photo modified from Soriano *et al.* 2019b.

light effects

Roberts and Paul (2006) introduced the concept that light serves to modulate plant defenses, in some cases being essential for the development of that resistance. They suggest that this interaction is multifaceted, extending across both temporal and biological scales. This needs further exploration in bryophytes and might explain our (false?) assumption that phenolic compounds have antiherbivore properties. Perhaps they accomplish both light protection and antiherbivory.

phenolics - phenanthrenes

Adam and Becker (1993a) reported phenanthrenes and other phenolics from cultured *Marchantia polymorpha* (Figure 1-Figure 12). Phenolics are secondary compounds that were widely considered to be antiherbivory compounds, but now their importance in antiherbivory is questionable. Phenanthrenes, on the other hand, have been used in traditional medicine, including usefulness in cytotoxicity, antimicrobial, spasmolytic, anti-inflammatory, antiplatelet aggregation, antiallergic activities, and phytotoxicity (Kovács *et al.* 2008), suggesting that they could serve as antiherbivore compounds as well as antibiotics. But perhaps their role in allelopathy toward tracheophytes is also feasible.

Anton *et al.* (1997) also found phenanthrene in the leafy liverwort *Plagiochila* (Figure 225), suggesting that it might be somewhat widespread in liverworts. Phenanthrene seems to have an interesting relationship with plants. It is one of the PAHs – phenols that occur naturally in coal, crude oil, and gasoline. PAHs are released from burning coal, oil, gas, wood, garbage, and tobacco and are toxic to both plants and animals (Wei *et al.* 2014). For example, phenanthrene inhibits seed germination and affects growth and chlorophyll levels of wheat seedlings. They also decrease the effects of antioxidants. Dupuy *et al.* (2016) also found that phenanthrene exposure causes developmental perturbation in maize roots. In the environment, they are degraded by bacteria (Anton *et al.* 1997). Corgié *et al.* (2003) demonstrated that root exudates are able to stimulate the degradation of PAHs in soil. In fact, it appears that the presence of the phenanthrene stimulates the release of more of these exudates, thus increasing the bacterial populations that accomplish the breakdown of the phenanthrene (Muratova *et al.* 2009).

Thomas *et al.* (2019) also noted that plants can stimulate microbial degradation of PAHs, using phenanthrene as the test compound. The soil bacteria **Proteobacteria** (*Pseudomonadota*; Figure 16), **Actinobacteria** (Figure 226), and **Firmicutes** (bacterial groups that are also common on bryophytes; Figure 227) are phenanthrene degraders. Plant root exudates enhanced the development of these phenanthrene-degrading bacteria.

Figure 225. *Plagiochila strombifolia*; phenanthrene occurs in at least some members of this genus. Photo by John Walter, through Creative Commons.

Figure 226. *Actinomyces israelii*, member of **Actinobacteria**, group often associated with bryophytes and soil; some are phenanthrene degraders. Photo by Graham Beards, through Creative Commons.

Figure 227. A member of **Firmicutes**, group often associated with bryophytes and soil; some are phenanthrene degraders. Photo by Argonne National Laboratories, through Creative Commons.

This raises the question of the presence of phenanthrenes in liverworts. Does it help, harm, or have a neutral action on them? Or like many of these compounds, might it have multiple roles? Perhaps the work with grassland plants might suggest a possible interaction. Chiapusio *et al.* (2007) found that in grasslands the phenanthrene did not generally affect plant biomass. In fact, red clover biomass was enhanced by it. This apparently resulted by a stimulation of its *Rhizobium* partner, a nitrogen-fixing bacterium. On the other hand, phenanthrene had a drastic negative effect on the mycorrhizal colonization of both ryegrass and red clover. As in other studies, the phenanthrene stimulated the PAH degraders in the soil.

This raises a possibility for *Marchantia polymorpha* (Figure 1-Figure 12) and its production of phenanthrene. It could stimulate the bacterial partners that are so common among the bryophytes (see Volume 2 chapter on bacterial interactions). In this role, it could play a critical role in their development. This won't be discovered in a sterile lab culture.

sesquiterpenoids and terpenes

Matsuo *et al.* (1985) isolated a series of ent-sesquiterpenoids that were stereoisomers of those compounds known in the tracheophytes, supporting the ancient origin of many of the defense compounds.

In 1990, Asakawa *et al.* described three new ent-sesquiterpenoids from German populations of *Marchantia polymorpha* (Figure 1-Figure 12). The chemistry of this species, including other isolates in this study, suggest that the German populations are close to the Japanese *M. polymorpha* and *M. paleacea* ssp. *diptera* (Figure 228).

Figure 228. *Marchantia paleacea* ssp. *diptera* females with capsules, Arima, Japan, 7 August 1988 – subspecies that has chemistry similar to that of *M. polymorpha* from Germany. Photo by Janice Glime.

Terpenes are volatile unsaturated hydrocarbons that constitute the essential oils and are aromatic compounds found in plants. Kumar *et al.* (2016) noted that despite their ability to accumulate structurally diverse terpenes that are "believed" to serve in deterring disease and herbivory, the genes and enzymes responsible for this chemical diversity of terpenes in *Marchantia polymorpha* have never been described. They were able to identify four diterpene synthase genes by function that were related phylogenetically to those in diverged plants. However,

there were also nine "rather unusual" monoterpene and sesquiterpene synthase-like genes.

lectins

Adam and Becker (1993b) tested *Marchantia polymorpha* (Figure 1-Figure 12) for **lectins**. **Lectins** are proteins that bind to carbohydrates. They are defense compounds in plants, but can cause problems in human digestion because they are able to resist being broken down in the gut and remain stable in acidic environments. In some cases they interfere with the absorption of other nutrients. These capabilities make them good antiherbivore compounds. They are in many human foods, especially dried beans, and those extracted from *Marchantia polymorpha* agglutinate the erythrocytes of various mammals and exhibit carbohydrate specificity against complex carbohydrate structures. This was the first report of lectins in liverworts. On the other hand, they are important in attracting specific *Rhizobium* species toward roots of host plants, suggesting they could possibly have a similar role in bryophytes.

bibenzyls

Asakawa *et al.* (1987) isolated two new cyclic bis[bibenzyls] from Indian populations of *Marchantia polymorpha* (Figure 1-Figure 12). Bis[bibenzyls] are rare products of plants, but more than 125 types have been discovered among liverworts (Asakawa *et al.* 2021). They are biosynthesized from lunularic acid, perhaps explaining why this compound has remained in even those liverworts such as *Marchantia* that also have ABA. The known biological activities of cyclic bis[bibenzyls] include antimicrobial, antifungal, cytotoxic, muscle relaxation, antioxidant, tubulin polymerization inhibitory, and antitrypanosomal activities.

Niu *et al.* (2006) isolated and identified seven bis[bibenzyl]-type macrocycles from Chinese populations of *Marchantia polymorpha* (Figure 1-Figure 12). Several of these compounds exhibited antifungal activities against *Candida albicans* (Figure 183).

The **marchantins** are bis[bibenzyls]. As far as we know, these are unique to bryophytes and are cytotoxic, having cancer treatment applications (Kodama *et al.* 1988). Kámory *et al.* (1995) isolated marchantin A from *Marchantia polymorpha* (Figure 1-Figure 12). This was followed later by isolation of a number of different marchantins. At least some of these have proven antibacterial activity.

Fang *et al.* (2007) described three new bibenzyl (=1,1'-(ethane-1,2-diyl)bisbenzene) derivatives from Chinese populations of *Marchantia polymorpha* (Figure 1-Figure 12). Its polymorphin A was a new type of bis[bibenzyl] and one compound was described as the first discovery of a bibenzyl that is oxidatively coupled to a phenylmethanol.

Friederich *et al.* (1999) elaborated on the pathway from lunularic acid to formation of marchantin C and CO₂ and the hydroxylation of marchantin C to marchantin A. Both of these reactions depend on the presence of O₂ and NADPH. Both are also inhibited by CO in the dark.

Marchantins are another example in which Kubo *et al.* (2018) demonstrated that the regulation of gene expression as a stress response was already present in *Marchantia polymorpha*. They found that overexpression of one

regulatory gene greatly increased the amount of several marchantins. The gene was down-regulated by NaCl.

antibacterial

Zehr (1990) found that ether extracts of *Marchantia polymorpha* (Figure 1-Figure 12) inhibited bacteria at 84.4%, whereas the ethanol extract lacks inhibitory ability. Those most affected were *Bacillus subtilis* (Figure 229) and *Escherichia coli* (Figure 16), whereas *Enterococcus faecalis* (Figure 230) was least inhibited. Zhu *et al.* (2006) noted that the antibacterial activity of *Marchantia* was "particularly prominent." As in many antibacterial studies with bryophytes *Staphylococcus aureus* (Figure 180) was the most resistant of the seven bacterial species tested. *Bacillus subtilis* was the most sensitive species to liverwort extracts.

Figure 229. *Bacillus subtilis* Gram stained, one of bacteria most affected by extracts of *Marchantia polymorpha*. Photo by Y. Tambe, through Creative Commons.

Figure 230. *Enterococcus faecalis*, one of bacteria least affected by extracts of *Marchantia polymorpha*. Photo by Dr. Sahay, through Creative Commons.

Gahtori and Chaturvedi (2011) likewise touted the usefulness of extracts of *Marchantia polymorpha* (Figure 1-Figure 12) as antimicrobial agents, some killing the

organisms and others simply arresting growth. Among those affected were the Gram-negative bacterial strains *Pasteurella multocida* (Figure 231), *Salmonella enterica* (Figure 232), and *Xanthomonas oryzae* pv. *oryzae* (Figure 233), and the four fungal strains *Fusarium oxysporum* f. sp. *lini* (Figure 207), *Rhizoctonia solani* (Figure 205), *Sclerotium rolfsii* (Figure 234), and *Tilletia indica* (Figure 235). They found a unique activity against *X. oryzae* and *P. multocida*. They also acted against the fungi *S. rolfsii* and *F. oxysporum*. *Marchantia polymorpha* showed different potencies against micro-organisms that are pathogenic to both plants and animals.

antifungal

Hamashima *et al.* (2019) noted the development of many techniques using *Marchantia polymorpha* (Figure 1-Figure 12). They used S-Agar Trap to genetically transform the species, using spores. They were able to insert a T-DNA mutant and isolate and characterize a gain-of-function mutant. This mutant hyper-accumulates the flavonoid riccionidin A, verifying that this technique is a powerful tool in the genetic tool library, including production of antibiotics.

In a comprehensive study on published antifungal activities of bryophytes, Miranda *et al.* (2022) found that in the period of 2000 to 2019 *Marchantia polymorpha* (Figure 1-Figure 12) was included in the most publications.

glycosides

Qu *et al.* (2007) isolated four new glycosides and three known aromatic glycosides from *Marchantia polymorpha* (Figure 1-Figure 12) and described their structures. Many drugs and poisons derived from plants are glycosides, such as the several cyanogenic glucosides used by the Heliconius butterfly that incorporate these plant compounds in their tissues as a defense against predators

(Nahrstedt & Davis 1983). I wonder if anything eats bryophytes to gain their secondary compounds for their own defense.

medicinal uses

Dioscorides (De Materia Medica, 50-70 AD) extolled the value of *Marchantia polymorpha* (Figure 1-Figure 12) for treating liver ailments, based on its liver form (Doctrine of Signatures; in Schuster 1966). In Yunnan and Sichuan this liverwort is available in street markets (Wu & Yu 2003). It is used to cover the skin for curing jaundice and as an antipyretic. Asakawa (1981, 1982) reported that this species contains sesquiterpenoids that have anti-tumor activity. Hartwell (1982) referred to its use against cancer, referring to Pliny the Elder.

Fischer *et al.* (1995) verified the presence of chalcone synthase activity in *Marchantia polymorpha* (Figure 1-Figure 12), and the subsequent presence of naringenin. Chalcones are used medicinally in treatment of viral disorders, cardiovascular diseases, parasitic infections, pain, gastritis, and stomach cancer. **Naringenin** has strong anti-inflammatory and antioxidant activities and seems to be beneficial in treating obesity, diabetes, hypertension, and metabolic syndrome in humans.

Kumar *et al.* (2007) reported that *Marchantia polymorpha* (Figure 1-Figure 12) was among those liverworts useful for treating tumors and that it was among the traditional herbal medicines in India.

Culturing and Cultivating

With so many studies being performed on the species *Marchantia polymorpha* (Figure 1-Figure 12), the methods of culturing have been worked out well (Figure 236). Voth and Hamner (1940) grew *Marchantia polymorpha* on glass cloth in an open moist chamber. They tested 56 nutrient solutions to develop suitable conditions for culturing the species in the lab. Voth (1941) indicated that the omission of K, Ca, NO₃, or PO₄ ions caused differences in the gross appearance of the species. Mg and SO₄ are not indicated by any characteristic symptoms. Effects of calcium appear to be dose dependent. Almost immediate death occurs in its absence, whereas in 0.3 mM of calcium per liter of solution the thallus apices die and degenerate.

Figure 236. *Marchantia polymorpha* ssp. *ruderalis* in peat disc culture. Photo courtesy of Javier Martínez-Abaigar.

Molar concentrations that are adequate for good growth, based on Voth (1941) are:

K 0.0012 M L⁻¹
 Ca 0.0007 M L⁻¹
 Mg 0.0014 M L⁻¹
 NO₃ 0.0034 M L⁻¹
 PO₄ 0.0004 M L⁻¹
 SO₄ 0.0008 M L⁻¹

These can be provided in a 1 L, 0.5 M solution of the following forms:

KNO₃ 1.6 cc
 Ca(NO₃)₂ 1.4 cc
 Mg(NO₃)₂ 1.2 cc
 KH₂PO₄ 0.8 cc
 MgSO₄ 1.6 cc

Minor variations of the concentrations do not cause growth problems.

Voth (1943) contributed additional experiments on nutrient concentrations, finding that some were better for production of gemmae cups than others. High salt concentrations often killed the growing tips and thalli became translucent.

Schneider *et al.* (1967) further developed culture methods that attempted to standardize them and address some of the inconveniences of past methods. They found that five substrates worked well, including vermiculite, perlite, glass cloth, nutrient agar, and nutrient solution. These are compared for their maintenance, yields, and usefulness for particular experimentation.

Miller (1964) contributed to the culturing protocol by defining procedures for harvesting, surface sterilizing, and culturing of gemmae. He also described conditions for a high production of gemmae and large numbers of gemmae cups in stock plants. He described methods for culturing the gemmae axenically, noting that they did not fare well at temperatures above 25°C, but that they were tolerant of high light. Miller *et al.* (1962b) used five different photoperiods to determine the best photoperiod for developing gemmalings. The greatest size and weight were achieved in an 18-hour photoperiod. They experimented with X-rays, light intensity, various nutrients, amino acids, vitamins, and other supplements to determine their effects and ability to prevent damage to the plants.

Miller and Colaiace (1969) cultured gemmae to ultimately produce antheridiophores and archegoniophores, structures that developed after 3-6 weeks on 1% agar medium in 24-hour photoperiods at 23°C.

In his attempts to grow gemmae of *Marchantia polymorpha* (Figure 1-Figure 12), Gemmrich (1976) found that Fe and Ca(NO₃)₂ induced germination, but optimal germination occurred on Ca(NO₃)₂, KNO₃, and MgSO₄. Gibberellic acid failed to induce germination in the dark.

Sugawara *et al.* (1983) found that activated charcoal in the culture medium increases cell wall regeneration and subsequent cell division, suggesting that something in the medium is too strong for the plant, or that the plant's own by-product(s) become inhibitory. Charcoal is usually used to bid things, thus removing them from availability to plants.

Pedroza-Manrique and Caballero Arévalo (2009) recognized that bryophytes typically require lower nutrients than do tracheophytes and algae. They successfully grew

Marchantia polymorpha (Figure 1-Figure 12) propagules in 25% Murashige and Skoog (1962) mineral salt concentration, incubated at 25°C ± 1°C. They warned that when transplanting such cultures to their natural environment or other conditions, one should provide gradual adjustment to new humidity, temperature, and substrate conditions.

Katoh *et al.* (1980) used a modified Murashige and Skoog's medium to culture *Marchantia polymorpha* (Figure 1-Figure 12). They improved the medium for use with the liverwort, including only eight of the 24 original micro-organic constituents. This new medium resulted in richer chlorophyll and a higher growth rate in the exponential phase.

Xu *et al.* (2021) found that they could induce reproductive organs in *Marchantia polymorpha* (Figure 1-Figure 12) on agar plates. Cultures from gemmae were transplanted after 10 days onto soil at 22°C with a 16h:8h photoperiod using white light. After 14 days, they supplemented the cultures with far red light.

Gradstein (2006) reported the successful cultivation of *Marchantia* in the bryophyte garden of the Cibodas Botanical Garden, Java, Indonesia. Supplementary spray is needed during the dry season.

Control

Marchantia polymorpha (Figure 1-Figure 12) can be a serious weed in some types of gardens, especially in nurseries, and in greenhouses. Jin and Pyon (2007) noted the need to control it in ginseng gardens. Uva *et al.* (1997) even listed it in their publication on the weeds of the northeastern USA. Schofield (1997) listed the species as one obviously spread by human activity in British Columbia, Canada.

Sato *et al.* (1991), working in Japan, used Cyclohexanedione derivatives on *Marchantia*, causing photosynthetic inhibition in cultured cells. They suggest that indicated the usefulness of the liverwort in herbicide assays.

Fausey (2003) considered *Marchantia polymorpha* (Figure 1-Figure 12) to be highly invasive and difficult to control, becoming a concerning pest in ornamental containers. They compared pre-emergence and postemergence herbicides, using chlorothalonil, captan, ammonium chlorides, hydrogen dioxide, flumioxazin, oxyfluorfen, pelargonic acid, acetic acid (vinegar), Cu sulfate, cinnamaldehyde, prodiamine, and oxadiazon. Of these, only flumioxazin, oxyfluorfen, pelargonic acid, acetic acid, and oxadiazon elicited acceptable control. Sprayable preparations were more effective than were granular ones.

Newby *et al.* (2007) experimented with various herbicides as a means of controlling *Marchantia polymorpha* (Figure 1-Figure 12) in nursery containers. The effectiveness differed by location, with flumioxazin and oxadiazon being the most effective for control in Alabama, whereas flumioxazin and oxyfluorfen + oryzalin were the most effective for control in Oregon.

Since *Marchantia polymorpha* (Figure 1-Figure 12) benefits from the same high humidity and shading as that needed in most nurseries for growing native tree seedlings, it quickly becomes a pest species there (Navas *et al.* 2014). Navas and coworkers used a variety of treatments,

including sterilizing the soil, using three concentrations of acetic acid, using two concentrations of oxygenated water, and using the herbicides glyphosate and fomesafen. They also used pre-emergence application of diuron and trifluralina. Only the two pre-emergence applications caused a 100% control of *Marchantia polymorpha*.

Särkkä and Tahvonon (2020) suggested several means of control of *Marchantia polymorpha* (Figure 1-Figure 12) in nurseries where it appeared as a weed. In pots with growing horticultural plants it can reduce access to water and nutrients (Figure 237). Growth of the liverwort can be minimized with mulches. Särkkä and Tahvonon used *Sphagnum* (Figure 238) and 1-cm blackcurrant stem pieces. Highbush blueberry and blackcurrant controlled the liverwort for two years, whereas rhododendron controlled it for only one year. Blueberry and rhododendron require an acid medium that is beneficial for the liverwort. Blackcurrant mulch was nearly 100% effective, whereas other treatments ranged 78-99%.

Figure 238. *Sphagnum capillifolium*; *Sphagnum* can be used in layers to discourage growth of *Marchantia polymorpha* in pots. Photo by Bernd Haynold, through Creative Commons.

Khamarea *et al.* (2021) used a method of substrate stratification and fertilizer to control *Marchantia*

polymorpha (Figure 1-Figure 12) growth. They used pine bark and other layers with different physical properties to manipulate the soil moisture dynamics and improve irrigation and fertilizer efficiency. This proved to also work as a tool of weed management. Each of the stratified techniques reduced the liverwort coverage by nearly 100%.

Summary

Marchantia polymorpha is perhaps the most studied bryophyte on the planet. It is a teaching model for liverworts, has had its genome sequenced, and is common in both wet habitats and as an invader after fires. It has been the subject of many physiological studies, including hormone effects and capillary movement of water among rhizoids. Growth hormones such as IAA elicit responses like those in tracheophytes. The thalli exhibit circadian rhythms that regulate the IAA levels. Lipxygenase also contributes to control of cell growth. Gibberellins respond to photoperiod. Ethylene causes larger gemmae, induces more gemmae cups, and promotes the dormancy of the gemmae, whereas the precursor ACC inhibits gemma growth and development by suppressing cell division. Cytokinins control formation of both gemmae cups and rhizoids during thallus development and seem to influence distribution of air pores and shape of thallus margin, implicating control of cell division. Desiccation causes oxidative stress. *Marchantia polymorpha* has both lunularic acid and ABA, important hormones in desiccation tolerance. Light affects senescence, but spermine, spermidine, and putrescine reduce it. Ethylene induces senescence. Nitrate and phosphate deficiency cause the ventral layers of cells to develop a red-violet color. Thalli can grow on vertical surfaces, but gemmae cups exhibit gravitropisms.

Adaptations are a coordinated set of resistance to effects of drying. These include rhizoids, scales, thick thallus, thin cuticle, air pores with a waxy ring, and oil bodies, as well as a suite of biochemical adaptations.

It is dioicous and prolifically produces sexual structures. However, gemmae are usually the most important means of reproduction and enable it to colonize rapidly after a disturbance. Short photoperiods favor production of gemmae, whereas long photoperiods favor the production of gametangiophores and greater growth. Developmental stage is important in determining the accumulation of UV-absorbing compounds in *Marchantia polymorpha* ssp. *ruderalis*. High temperatures can change the ratios of fatty acids and cause a reversible depression of photosynthesis; there seems to be limited thermostability. They are much more cold tolerant and don't suffer frost damage. The ω -3 polyunsaturated fatty acids increase as the temperature decreases and ABA seems to play a role in cold survival.

Marchantia polymorpha produces sesquiterpenoids that are active against some fungi and bacteria. Some methylobacteria promote the growth of gemmae. Other bacteria promote thallus growth, fix nitrogen, and inhibit pathogens. Extracts of the liverwort have antibiotic properties. The

archegoniophore is particularly well protected, with a flavonoid content ten times that of the thallose gametophyte. Antibacterial properties increase with altitude. The antibacterial compounds also inhibit protozoa. Fungi can occur as endophytes and pathogens, but others might contribute to symbiosis. The subspecies *montivagans* develops mycorrhizal associations with some fungi, but this relationship is not known in subspecies *polymorpha*. The liverwort protects the fungi from water loss and can have a number of species living in association with it.

We have a meager understanding of the invertebrates that depend on *Marchantia polymorpha*. At least one fly (*Scatopsciara cunicularius*) feeds on it as larvae. Extracts of allene oxide synthase inhibits oviposition and survival rate of the spider mite *Tetranychus urticae*. Spiders and isopods inhabit them, but herbivory needs to be studied.

Some members of the **Apiaceae** can inhibit growth of *Marchantia polymorpha*, whereas the liverwort can inhibit seed germination in *Bidens biternata*.

It appears that the species has evolved numerous biochemical adaptations. Anthocyanins and auronidins can screen visible light, protecting it from strong sunlight. Auronidins seem to be important in protecting the liverwort in the extremes of its environmental conditions. Flavonoids protect against UV light and herbivory. They may provide antibiotics benefitting animals in nature. Their phenolic compounds are important in UV protection and might not have the importance in antiherbivory we once thought.

Large increases in CO₂ cause a number of changes in the *Marchantia polymorpha* photosynthetic system, but the net result is that there is little change in photosynthetic rate. High light intensity inhibits photosynthesis. Light quality can affect growth and gemma production. The red:far red ratio affects chlorophyll concentration and senescence and is mediated by phytochromes.

The species accumulates heavy metals, but not in large quantities like mosses do, due to lower surface area. Its best role seems to be in the laboratory. It is easy to culture, so easy that in greenhouses it is necessary to find ways to discourage its growth in pots for trees and other plants. Chronic gamma radiation causes inhibition of the development of sex organs in *Marchantia polymorpha* and its responses can be used to monitor radiation effects. Rapid and easy growth and haploid condition make the species useful to test the function of plant genes.

Acknowledgments

Lars Söderström helped me find the current acceptable names for a number of older taxa. Thank you to Rui-Liang Zhu, Brent Mishler, and Yoan Coudert for providing me with the publications on gene sequencing in *Marchantia polymorpha*. Nils Cronberg alerted me to important papers on dN/dS and problems with gene matching. Masaki Shimamura alerted me to nomenclature problems in *Marchantia paleacea* vs. *M. polymorpha*. Thank you to Brent Mishler and Anders Hagborg for providing me with access to the article by Åkerman (1910). Marc Favreau,

Marc-Frédéric Indorf, Jean Gagnon, Geert Raeymaekers, Michael Haeusler, Yoan Coudert, and Stephen Rae helped me interpret "lumière rouge-fonce." Bart van Tooren took pictures for me to illustrate a wadden polder, with the help of Heinjo During in coordination.

CHAPTER 1-25

AQUATIC AND WET MARCHANTIOPHYTA, CLASS MARCHANTIOPSIDA: MARCHANTIACEAE, PART 3

Figure 1. *Marchantia quadrata* on dripping cliff, a wet habitat with a more constant set of conditions than open areas. Photo courtesy of Keir Wefferling.

Marchantiaceae, cont.

Marchantia quadrata (Figure 1-Figure 5)

(= *Preissia quadrata*)

Most readers may be more familiar with the synonym *Preissia quadrata*. However, Stotler and Crandall-Stotler (2017) have moved it to the genus *Marchantia* and this seems to be the name the bryological community has accepted. But Zheng & Shimamura (2022) just published a paper that once again offers support for the separation of this species into the genus *Preissia*. And they have added another species to that genus, *Preissia platycarpa*. This conclusion on their part is based on several differences in morphology, including the absence of gemmae cups and the presence of only one archegonium and sporophyte per arm in the female receptacle. This genus argument among bryologists seems to depend on the degree of difference accepted, both morphological and genetic, to define a different genus.

Boisselier-Dubayle *et al.* (1997) reported that there was an incongruence between molecular data and morphological characters in the **Marchantiales**. They recommended a weighting of the morphological character data and were able to resolve the contradictions by so doing. They suggested that this might mean that the molecular sampling is too limited.

Distribution

Marchantia quadrata (Figure 1-Figure 5) is known from Australia, Europe, Northern and Southern Asia, Central America, North America, Oceania, and South America (ITIS 2022). It was recently reported as new to Turkey (Şimşek *et al.* 2014).

Aquatic and Wet Habitats

In North America, *Marchantia quadrata* (Figure 1-Figure 5) occurs along calcareous rivers in Connecticut, USA (Nichols 1916). I have seen it at the top of a waterfall in shallow water on bedrock (Figure 6) in the Keweenaw Peninsula, Michigan, USA. Forrest (2018) found it at the edge of a stream at the top of Snowbird Mountain in Utah, USA. McNeilus and Sharp (1975) reported it from limestone bluffs with dripping water in Tennessee, USA. Nichols (1918) reported it along a rock ravine streambank, Cape Breton Island, Canada. In western Canada, it occurs submerged, in hemicalciphilous montane streams (Vitt *et al.* 1986) and also on streambanks (Figure 7) (Glime & Vitt 1987).

Figure 6. *Marchantia quadrata* habitat in river gorge at top of falls, Keweenaw County, Michigan, USA. Photo by Janice Glime.

Figure 7. *Marchantia quadrata* growing with mosses beside water. Photo by Claire Halpin, with permission.

Watson (1919), in his discussion of aquatic bryophytes, reported that *Marchantia quadrata* (Figure 1-Figure 5) usually occurs on rocks (Figure 8-Figure 9) (Watson 1919). Near Lacko in the Western Carpathians, it is part of the ground community in streams (Figure 10) (Mamczarz 1970). In the River Tweed, UK, it is not common (Holmes & Whitton 1975), but occurs on the river bank of River Tees, UK (Holmes & Whitton 1977a) and occurs in the upper upstream of River Swale, Yorkshire, UK (Holmes & Whitton 1977b). It is again infrequent in River Tyne, UK (Holmes & Whitton 1981).

Figure 9. *Marchantia quadrata* on rock at waterfall, Michigan, USA. Photo by Janice Glime.

Figure 10. *Marchantia quadrata* with archegoniophores, growing on soil. Photo by Hermann Schachner, through Creative Commons.

Lee and Greenwood (1976) reported that *Marchantia quadrata* (Figure 1-Figure 5) was able to occupy calcareous waste deposits in the UK in areas where there were no natural calcareous substrata.

Marchantia quadrata (Figure 1-Figure 5) occurs in the travertine *Cratoneuron* (Figure 11) association in the Lorraine River, Belgium, (de Sloover & Goossens 1984), in streams in Greece (Papp 1998), and at springs in the Tara river canyon and Durmitor area, Montenegro (Papp & Erzberger 2011).

Figure 11. *Cratoneuron filicinum*, a species associated with *Marchantia quadrata* on travertine rock. Photo by Hermann Schachner, through Creative Commons.

Contrasting with these limestone habitats, Haupt (1926) reported *Marchantia quadrata* (Figure 1-Figure 5) on thin soil (Figure 10) over granitic rocks, particularly along stream banks. It tends to occur in drier situations than *Marchantia polymorpha* (Figure 12) or *Conocephalum* (Figure 13-Figure 14), but they can occur intermixed. Nevertheless, it can occur close to the water (Figure 15-Figure 17).

Figure 17. Wet *Marchantia quadrata* near falls at Tahquamenon Falls, Michigan, USA. Photo by Janice Glime.

In the Netherlands, *Marchantia quadrata* (Figure 1- Figure 5) occurs on the **trilveen** (Kooijman & During 1989). The **trilveen** (Figure 18) is a bog that is a rare, with thin, extremely soft "soil" and vegetation type with sedges

and grass roots. It floats on water or soft mud and occurs in low moor areas such as peat meadows.

Figure 18. Trilveens in The Netherlands. Note the person pushing one across the water surface. Photo from Wikiwand, through Creative Commons.

Keir Wefferling found it growing on dripping sandstone cliffs in Wisconsin, USA (Figure 1-Figure 5, Figure 19).

Figure 19. *Marchantia quadrata* (bottom) forming a zone above the base of a dripping cliff in Wisconsin, USA. Photo courtesy of Keir Wefferling.

In Turkey *Marchantia quadrata* (Figure 1-Figure 5) occurs on moist calcareous rocks (Figure 20) of the subalpine zone (Şimşek *et al.* 2014).

Figure 20. *Marchantia quadrata* growing among calcareous rocks. Photo by Michael Lüth, with permission.

I have also seen the species on a rock ledge of a cliff in New York, USA (Figure 21). It can occur on rock and cavern walls (Figure 22-Figure 26).

Figure 21. *Marchantia quadrata* on ledge in New York, USA. Photo by Janice Glime.

Figure 26. *Marchantia quadrata* on a rock depression – a common habitat for the species. Photo by Oskar Gran, through Creative Commons.

Others have found it in open areas on soil, as seen in these pictures by Michael Lüth (Figure 27-Figure 28).

Figure 27. *Marchantia quadrata* with archegoniophores, growing on open soil. Photo by Michael Lüth, with permission.

Physiology

Tyler *et al.* (1995) found that soluble phosphate was important to the occurrence of *Marchantia quadrata* (Figure 1-Figure 5) on limestone soil. It produced 7 times as much biomass when phosphate was added to the soil. Perhaps this is due to the ability of the calcium carbonate of the limestone to be an effective binder of phosphate (Yanamadala 2005). Furthermore, the liverwort is likely to be phosphate limited without the high levels of phosphate. The mix of CaCO_3 and phosphate could also encourage certain bacteria, particularly nitrogen-fixing bacteria, that are beneficial to the liverwort. The reaction with limestone further releases water and CO_2 , the latter being a limiting factor in submersed plants:

Fletcher (1982) reported that *Marchantia quadrata* (Figure 1-Figure 5) was among the *Marchantia* species from several areas that sustained no frost damage when other bryophytes suffered blackening, bleaching, or growth cessation in cultivation down to -5.5°C . In nature, it can survive winter under the snow and ice in the 5-6 months of snow cover in the Keweenaw Peninsula, Michigan, USA (Figure 29).

Figure 29. Snow covering *Marchantia quadrata* habitat at top of Manganese Falls, Keweenaw County, Michigan, USA. Photo by Janice Glime.

Heat is less kind, but it can have reversible damage effects on *Marchantia quadrata* (Figure 1-Figure 5) (Weis *et al.* 1986). Mild heat treatment suppresses photosynthesis. More severe heat causes irreversible damage of PSII similar to that known in tracheophytes. Exposure to high but sublethal temperatures does not increase the heat stability of these liverworts, indicating an extremely low heat-hardening capacity.

Adaptations

Marchantia quadrata (Figure 1-Figure 5) has a thallus that is multiple cells in thickness (Figure 30-Figure 31). The upper layer and the epidermis cells (Figure 32) contain chloroplasts, but these are absent in the cells surrounding the pores (Walker & Pennington 1939). The thickness is likely to aid in moisture retention during drought periods.

Figure 32. *Marchantia quadrata* thallus showing epidermis with pores. Photo from Bioimages, through Creative Commons.

Rhizoids (Figure 33) are known to create capillary spaces that conduct water in the **Marchantiales**. McConaha (1941) suggests that the more numerous rhizoids present in *Marchantia quadrata* (Figure 1-Figure 5) compensate for its less compact arrangement of the capillary system. It also does not have its capillary system over the wings of the thallus to the extent seen in *Marchantia* s.s. Thallus areolation in *M. quadrata* exposes a greater surface to water loss despite having pores that are able to achieve partial closure; there is little regulation of the transpiration.

Figure 33. *Marchantia quadrata* thallus cross section with scales and rhizoids projecting from the lower surface. Photo by Kristian Peters, with permission.

Like other *Marchantia* species, *M. quadrata* (Figure 1-Figure 5) has both smooth and pegged rhizoids (Figure 33) as well as appendaged scales (Figure 33-Figure 34) on the lower surface (Cavers 1904). Presumably, these serve the same functions in conduction as those of *M. polymorpha* (Figure 12).

Figure 34. *Marchantia quadrata* ventral scale. Photo by Hugues Tinguy, with permission.

Like other species of *Marchantia*, *M. quadrata* (Figure 1-Figure 5) has air pores (Figure 35-Figure 43) in the thallus that permit more rapid gas exchange than the thallus epidermis does (Haupt 1926). In this species, the pore is barrel-shaped with cells in four or five tiers (Figure 38, Figure 40, Figure 43) (Walker & Pennington 1939). The upper opening is always wide open (Figure 40, Figure 41, Figure 43), but the inner part is narrower and can be closed (Figure 41-Figure 43). Each cell of the basal tier, referred to by Walker and Pennington as **motor cells**, has a papilla which projects freely inward. The papilla has a thinner wall than the remainder of the motor cell. Movements of the papillae are responsible for changes in the size of the opening.

Figure 41. *Marchantia quadrata* pore closing. Note that the motor cell on the right is not functioning, presumably due to injury. Image modified from Walker & Pennington 1939.

Growth occurs at the apical notch, which is covered by a small scale that is usually purplish (Figure 44-Figure 45). The thallus can dry out or senesce while the reproductive branches continue to grow (Figure 46). Red coloration on the thallus margins (Figure 47) is common in this species and could indicate that it has experienced stress.

Figure 44. *Marchantia quadrata* in Europe, showing purple covers of the apical growing region. Photo by Michael Lüth, with permission.

Figure 47. *Marchantia quadrata* with red margins, indicating stress. Photo by Allen Norcross, with permission.

One feature that seems to lack documentation for liverworts, but present in *Marchantia quadrata* (Figure 1-Figure 5), is the presence of scattered sclerotic cells in the ventral part of the thallus (Haupt 1926). These are elongated, thick-walled, dark brown, fiber-like cells with pointed ends. Their significance is not clear. Cavers (1904) suggests that their primary function is conduction and storage of water. These fibers are absent in the plants that grow in a moist atmosphere (Haupt 1926).

Isolated mucilage cells can be found in all parts of the thallus, but mucilage canals are absent (Haupt 1926). Starch grains seem only to accumulate in the older female receptacles where they presumably are available to the growing sporophytes. Oil globules occur in the apical region, particularly in the epidermal cells, and in the epidermis of the receptacles.

Reproduction

Marchantia quadrata (Figure 1-Figure 5) is usually considered to be **dioicous** (Haupt 1926). However, Haupt (1926) also found a few **monoicous** plants, comprising about 1% of the material studied. Zheng and Shimamura (2022) furthermore noted that dioicous plants are known to be widely distributed in the temperate boreal region and monoicous plants are usually found in the Arctic (Schuster 1972, 1985, 1992; Long & Crandall-Stotler 2020). Are these different races, or different expression of genes in the cold Arctic with its long summer days?

However, all the Japanese *M. quadrata* plants that Zheng and Shimamura (2022) examined and found during fieldwork were **monoicous**. Because the growing season of archegoniophores and antheridiophores is different and the archegoniophores do not grow unless fertilization is successful (Haupt 1926) it is easy to falsely conclude that one sex is absent in the population.

In spring in Japan, thalli with young antheridiophores arise from the apex of the ventral side of previous thalli with a well-stalked female receptacle bearing sporophytes (Zheng and Shimamura (2022)). In summer, a new thallus with a new archegoniophore occurs in the same way from the underside of the apex of the previous thalli with a well-stalked male receptacle and the oldest archegoniophore withers after spore dispersal. That is, each time a new branch is formed, the sexuality alternates. Only by following the same population throughout the year can the true sexuality condition be determined.

Usually the antheridia are produced on a separate stalk, the **antheridiophore** (Figure 48-Figure 50), and archegonia are produced on **archegoniophores** (Figure 51-Figure 58). When the plants are **monoicous**, antheridia occur on the upper surface of the anterior portion of the receptacle and the archegonia occur on the under side of the posterior portion (Haupt 1926). Haupt, presumably in North America, found that antheridia begin to appear in late spring, with archegonia developing somewhat later in early summer.

Figure 49. *Marchantia quadrata* antheridiophores. Photo from Bioimages, through Creative Commons.

Figure 50. *Marchantia quadrata* antheridiophores. Photo from Bioimages, through Creative Commons.

Benson-Evans (1964) reported that in the UK *Marchantia quadrata* (Figure 1-Figure 5) is a long-day plant for sexual reproduction. In 16 hours of light, 66% of

the plants expressed sexual structures; in 18 hours of light this increased to 80%. Light of 16.1-87.6 lux was suitable for gametangia development. However, when the temperature was dropped to 10°C in 18 hours light, the plants exhibited few sexual structures and had slow growth. These were even more limited at both 10°C and 21°C in 6 hours light. This species is, however, mostly influenced by photoperiod, operative within a somewhat broad temperature range (Longton 1990).

Both sexual organs continue to form during the entire growing season, with young archegonial receptacles in northern New York, USA, appearing as late as the end of September (Haupt 1926). On 24 September, Haupt observed that nearly all of the plants had the same sexual condition. The male nucleus was within the egg and in contact with the egg nucleus, but not yet fused. These archegonial receptacles overwinter with sporogenous tissue that has just differentiated. In the spring, growth of the sporophytes continues and the female receptacle stalk continues growth. In this location, the spores mature in June.

Figure 51. *Marchantia quadrata* with developing archegoniophores. Photo by Hermann Schachner, through Creative Commons.

Figure 58. *Marchantia quadrata* with mature archegoniophores, showing how numerous they can be. Photo by Michael Lüth, with permission.

When the sporangia mature, they protrude from the archegonial head (Figure 59-Figure 63). They burst and elaters wiggle among the spores (Figure 64-Figure 65) in response to moisture changes, in some cases helping the spores to exit the capsule, but in others entangling them in clusters of tangled elaters.

Figure 59. *Marchantia quadrata* with mature archegoniophores. Photo by Michael Lüth, with permission.

Figure 64. *Marchantia quadrata* spores and elaters. Photo by Hermann Schachner, through Creative Commons.

Figure 65. SEM of *Marchantia quadrata* distal spore wall. Photo by William T. Doyle, with permission.

Unlike other members of the **Marchantiaceae**, *M. quadrata* (Figure 1-Figure 5) has no gemmae (Boisselier-Dubayle & Bischler 1997; Zheng *et al.* 2020). Nevertheless, members of an individual colony were genetically identical, suggesting vegetative reproduction was important, achieved by growth and division of the thalli. There was little indication of any genetic exchange between colonies growing in proximity.

Fungal Interactions

Haupt (1926) reported intracellular fungi in the lower part of the *Marchantia quadrata* (Figure 1-Figure 5) thallus (see also Golenkin 1902). These occur mostly along the median line and are more abundant in older tissues. This fungal zone frequently occupies one-half to two-thirds the thickness of the thallus, sometimes reaching the air chambers. In the ventral region, the hyphae form parallel strands that extend longitudinally. Above this area they form compact tangled masses inside the shorter thallus cells.

Biochemistry

Gorham (1977) reported the presence of lunularic acid in all parts of *Marchantia quadrata* (Figure 1-Figure 5). This presence was greatest in continuous light. Gorham suggested that either the lunularic acid was not inhibited in continuous light or the inhibition was overcome by products of photosynthesis.

König *et al.* (1996) reported that the main constituent of a southern German chemotype of *Marchantia quadrata* (Figure 1-Figure 5) is the labile sesquiterpene hydrocarbon germacrene C. These researchers also observed several rare ent-sesquiterpenes as major constituents.

Asakawa *et al.* (1997) reported a number of sesquiterpenes and the cyclic bis(bibenzyls) riccardin B and

neomarchantin A from *Marchantia quadrata* (Figure 1-Figure 5).

Marchantia treubii

(syn. = *Marchantia sciaphila*)

Distribution

Siregar *et al.* (2013) reported on *Marchantia treubii* from Sumatra. This species is among the most common *Marchantia* species on Mount Sibayak, found from lowland to high altitude. It is relatively widespread in Indonesia (Sumatra, Java, Lesser Sunda Island), Borneo, and Malaysia (Bischler-Causse 1989; Chuah-Petiot 2011).

Aquatic and Wet Habitats

Marchantia treubii occurs in the spray of waterfalls in the tropics (Ruttner 1955). *Marchantia treubii* occurs on soil and rocks in open places and semi-shaded places in Indonesia (Siregar *et al.* 2013; Haerida 2017). Raihan *et al.* (2018) reported that this liverwort occurs almost everywhere on rocks at their study area at Peucari Bueng Jantho Waterfall in the Aceh Besar District of Indonesia.

Azwir *et al.* (2022) reported its environmental parameters from Mesjid Raya in Indonesia. The site was humid, with pH ranging 4.9-7.3 (mean 6.3) and a low light intensity of 0.07-0.09 lux, mean of 0.08 lux. Since the light intensity also affects the temperature and humidity, this indicates lower temperatures and higher humidity in its habitat.

Adaptations

Most of the adaptations described for other species of *Marchantia* apply here. *Marchantia treubii* from Indonesia had purplish lines on the thallus and fine hair at the edge (Raihan *et al.* 2018). I was unable to find much specific information on this species.

Reproduction

Fritsch (1991) reported a chromosome count of $n=9$ for *Marchantia treubii*. It is **dioicous** (Siregar *et al.* 2013). Raihan *et al.* (2018) found *Marchantia treubii* with gemmae cups as well as sporophytes in Indonesia, exhibiting female receptacles with 3-5 lobes.

Summary

Marchantia quadrata was classified in the genus *Preissia* and might return there. It lacks gemmae, but occurs in similar habitats to some of the *Marchantia* species. Its distribution is similar (Australia, Europe, Northern and Southern Asia, Central America, North America, Oceania, and South America). It occurs on wet rocks and soil of stream banks, waterfalls, and dripping cliffs, including limestone. It benefits from phosphates, especially on limestone. It survives winter under the snow, but does not do well in high temperatures. Its adaptations are similar to those of other *Marchantia* species, with thick thallus, pores, photosynthetic chambers, rhizoids that either anchor or provide capillary spaces for conduction, and scales that help move and conserve water.

Marchantia treubii occurs in a small, tropical portion of Asia. It is best known from waterfalls, but in some areas of Indonesia it is the most common liverwort on the mountain. It is dioicous and has gemmae.

Acknowledgments

I appreciate the email discussions with T. Zheng and M. Shimamura on the classification of *Marchantia quadrata*.

CHAPTER 2-5

STREAMS: LIFE AND GROWTH FORMS AND LIFE STRATEGIES

Life and Growth Forms

Definitions and Habitats

In bryophytes, **growth forms** are genetically determined forms of adult individual gametophyte plants (Meusel 1935; Mägdefrau 1982). **Life forms** are the environmental expressions of those plants and refer to the growth pattern of the colony. But for many species, perhaps most, a single protonema, developing from a single spore, develops multiple buds that develop into stems and thus form a colony from the onset, giving rise to a **life form** as that colony develops.

A number of bryologists have stressed the importance of life forms as adaptations to habitat conditions. Bryophyte growth forms and life forms can be used to indicate conditions of hydrologic permanence in non-polluted mountain streams (Fritz *et al.* 2009; Vieira *et al.* 2012a). In 165 locations in Portuguese water courses, Vieira *et al.* (2012a) found 11 life forms, with a mean of 2.7 per sample. There was a clear dominance of **smooth mats** (Figure 2; 37%), **tall turfs** (Figure 3; 25%), **fans** (Figure 4; 10%), and **short turfs** (Figure 5; 10%). As habitat zones were less frequently submersed, the number of life forms increased. The deepest or most permanently submersed regions had **mats** and **streamers** [Figure 1; long, dangling stems (Glime 1968)].

Figure 5. *Marsupella emarginata*, an aquatic liverwort that forms a short turf. Photo by Hermann Schachner, through Creative Commons.

When Vieira *et al.* (2012b) assessed life forms in mountain streams of Portugal, they found that **thallose liverworts** (Figure 6) typically avoided the flowing water, occurring in shaded locations where they were only seasonally submersed or splashed. These forms were easily damaged by submersion and drag forces. On the other hand, some leafy liverworts that formed **smooth mats** (Figure 2) occurred submersed. Those permanently submersed bryophytes tended to be **streamers** (Figure 1) and **smooth mats**, found up to 30 cm of depth in streams. The **streamers** tended to occur mostly in slower currents of the streambed in full sunlight, whereas **smooth mats** seemed to prefer the torrential water zones in deep shade. Bryophytes subject to frequent water level fluctuations, *i.e.* close to the water, were characterized by a more 3-dimensional life form, but one that was resistant to desiccation and drag forces. These included well anchored **fans** (Figure 4), **dendroids** (Figure 7), and **short turfs** (Figure 5), often occupying vertical surfaces of rocks short distances from the water, but able to benefit from the splash.

Figure 9. *Aulacomnium palustre* leaf lamina showing thick-walled cells. Photo by Kristian Peters through Creative Commons.

In the seasonally flooded habitats Vieira *et al.* (2012b) found **tall** and **open turfs** (Figure 8) that have stiff texture, multi-layered tissues, and thick cell walls (Figure 9). These permit them to resist both desiccation and water abrasion. On the upper zones of stones where strong currents are less frequent and in exposed streambeds, bryophytes are represented by **smooth densely-packed cushions** (Figure 10) and **short turfs** (Figure 5) that can resist drought stress (Gimingham & Birse 1957; Muotka & Virtanen 1995; Barrat-Segretain 1996; Vieira *et al.* 2012b). Here and at higher zones on boulders, but in the shade, smooth **mats** (Figure 2) and **fans** (Figure 4) develop (Vieira *et al.* 2012b). Above the level of maximum flooding annuals join the bryophytes, displaying **loose rough mats** (Figure 11) or **wefts** (Figure 12).

Figure 12. *Trichocolea tomentella* wefts, a species of fens and low areas that can become submersed. Photo by Li Zhang, with permission.

In this same top or higher zones of the boulders, if shaded conditions prevailed for most of the year, **smooth mats** (Figure 2) along with **fans** (Figure 4) developed. Additionally, microhabitats higher than the normal level of maximum floods could be recognized by the co-existence of **annuals** (must grow new plants every year), loose **rough mats** (Figure 11) or **wefts** (Figure 12) that developed mostly associated with deposited sediments.

Birse (1958) related life form to habitat. She found that **wefts** (Figure 12) were typical in freely drained habitats and conditions of intermediate moisture. **Tall turfs** (Figure 3) were more common when water was close to the soil surface. **Wefts** (Figure 12) and **dendroid** (Figure 7) life forms occupied habitats with moisture available from the water table in summer. The semi-aquatic emergents are more likely to be **tall turfs**. Truly aquatic mosses are rarely **tall turfs**, but may be **streamers** (Figure 1, Figure 15), a term introduced by Glime (1968).

Jenkins and Proctor (1985) considered aquatic bryophytes to have two main life forms: **turfs** of densely-set shoots such as those of *Scapania undulata* (Figure 13) and *Hygrohypnum luridum* (Figure 14) that cling to boulders experiencing turbulent, fast-flowing water; **streamers** (Figure 1, Figure 15) such as *Fontinalis* more typical of slower, more streamlined flow. On the other hand, *F. dalecarlica* (Figure 15) can occur on boulders in rapids, defending itself with numerous rhizoids and wire-like strong stems.

Thalloid liverworts (Figure 6) grow in zones that are rarely submersed. These liverworts are intolerant of the physiologic stress of continuous submersion or drought and the mechanical stress of mechanical scouring (Gimingham & Birse 1957; Kimmerer & Allen 1982; Martinez-Abaigar & Núñez-Olivera 1991). Rather, they develop in abundance in a more humid and shaded environment above the upper limit of flood-water impact.

Vieira *et al.* (2012b) found that **colonial** growth often occurred through shoot innovations that were firmly attached to the substrate (Figure 16), permitting them to remain in place during heavy flow (During 1990; Grime *et al.* 1990; Muotka & Virtanen 1995). **Ephemeral colonists**, on the other hand, indicate stream zones that are submersed by shifting currents that create abrasive events (Vieira *et al.* 2012b). They survive in tiny rock crevices where they are

protected from the torrential currents (Muotka & Virtanen 1995). **Colonists** and **pioneer colonists** are positively correlated with a moderate distance to water and its impact, *i.e.*, in zones that are seasonally flooded with strong discharges (During 1979; Kimmerer & Allen 1982; Vieira *et al.* 2012b). Some **fugitives**, **annual shuttles**, and **stress-tolerant perennials** are able to tolerate slight and infrequent submergence.

Figure 16. *Fontinalis novae-angliae* with new shoots beginning where a stem has been scoured and broken, forming a new colony. Photo by Janice Glime.

Although mountain streams are very different habitats from slow-moving lowland streams, it appears that the life forms defined by Gimingham and Robertson (1950) for English mountain streams can be broadly applied. They identified **large cushions**, **small cushions** (Figure 10), **large turfs** (Figure 3, Figure 8), **small turfs** (Figure 5), **dendroids** (Figure 7), **compact mats** (Figure 2), **thalloid mats** (Figure 6), and **wefts** (Figure 12). As noted, Glime (1968) added **streamers** (Figure 1).

In terrestrial situations, unstable environments are often characterized by acrocarpous mosses such as *Bryum* (Figure 17), *Pottia* (mostly now in *Tortula*; Figure 18), and *Gigaspermum* (Figure 19) (Ramsay 2006). Pleurocarpous taxa such as *Hypnum* (Figure 20) and *Thuidiopsis* (Figure 21) seem to require more stable environments. Similar relationships hold in streams, where small, acrocarpous mosses such as *Blindia acuta* (Figure 22) live in disturbed areas with movable substrata, whereas the large, pleurocarpous moss *Fontinalis* spp. (Figure 23) is characteristic of stable boulders (Muotka & Virtanen 1995). Furthermore, the large **streamers** (*Fontinalis*; Figure 1) occur on the lower parts of stream rocks where they are continuously submersed, whereas the tops of the boulders support growths of low, but not mat-forming, mosses (Virtanen *et al.* 2001).

In the Victorian temperate rainforest streams of Australia, all seven of the Gimingham and Robertson (1950) life forms were represented, but not **streamers** (Carrigan 2008), **pendants**, or **tails** (Mägdefrau 1982).

However, only two species were of the **cushion** (Figure 10) life form. **Mats** (Figure 2, Figure 11) and **turfs** (Figure 8) were the most represented, with 36 and 32 species, respectively. Wood and sediment had approximately the same distribution of life forms. No life forms stand out on the various sizes of rocks, with approximately the same distribution of life forms on each as for the total set. **Turf** was the only life form that appeared to have significant differences among the rock sizes, with the greatest representation on the medium-sized rocks.

Functional Groups

Monteiro *et al.* (2019) determined the functional structure of bryophytes in headwater streams in Portugal, as represented by life forms. The rock dwellers are typically **rough mats** (Figure 11). Truly aquatic species are mostly perennial, pleurocarpous mosses in **smooth mats** (Figure 24); they rarely produce capsules, and those are typically submerged. The very dynamic mountain flushes, springs, and ephemeral streams support pioneer colonists and **turfs**. Streamsides support **dendroid** (Figure 7) mosses and **thalloid liverwort mats** (Figure 6). At high altitudes, leafy liverworts and competitive perennials predominate. Basic substrates typically have **tufts** and **colonists** of **basophilous** (living or thriving in alkaline habitats) species.

Figure 24. *Hypnum cupressiforme*, **pleurocarpous** moss forming a **smooth mat**. Photo by Michael Lüth, with permission.

Fernández-Martínez *et al.* (2019) noted the importance of structure and function of bryophytes in the ecosystem. However, the authors lamented that knowledge of these roles is far behind that for other plants. To help in alleviating this lack of knowledge, they investigated 303 moss assemblages in aquatic and semi-aquatic habitats of natural springs in the northeastern Iberian Peninsula. The study encompassed 30 moss species and 17 traits using phylogenetic comparative methods and an extended RLQ analysis. They found that **life forms** (results of life conditions, including growth form, influence of environment, and assemblage of individuals) and, especially, morphological traits were well preserved

phylogenetically and responsive to water chemistry and climate. "That combined with spatial autocorrelation in environmental variables resulted in a clustered distribution of phylogenetically closely related mosses in space."

Mosses living in springs with a warm, dry climate and hard water were dominated by species with needle-like leaves, were denser, and had lower water absorption capacity (Fernández-Martínez *et al.* 2019). In cold, humid, soft-water springs, the opposite characters were present. The researchers concluded that among the springs in their study, climate and water chemistry are the main determinants of both traits of hygrophytic mosses and of species distributions. They suggested that their data indicate a potential **sclerophylly** (leaf hardness) continuum in moss traits, and they hypothesize that these may be mainly related to physical and physiological constraints produced by water chemistry. The gradient of the moss sclerophylly in a gradient of water conductivity is similar to that in tracheophytes relative to water availability and temperature. The researchers emphasize that more research is needed before we can make generalities for bryophytes.

Factors Influencing Life Forms

Life forms are important in determining the drag coefficient and in attenuating the flow velocity, especially within the clump. Dodds and Biggs (2002) showed that even **periphyton** (freshwater organisms attached or clinging to plants and other objects) attenuated the flow velocity with depth. In fact, dense colonies of diatoms (primarily *Cymbella*; Figure 25) had more effect than did filamentous green algae or red algae. Macrophytes also attenuated the flow rates, but less than the periphyton, and their attenuation was more variable.

Figure 25. *Cymbella*, a member of the periphyton that can attenuate the flow velocity. Photo by Janice Glime.

One of the factors that influences successful life forms is the **diffusion resistance** to CO₂ uptake. Jenkins and Proctor (1985) measured this resistance in the mat-forming leafy liverworts *Nardia compressa* (Figure 26) and *Scapania undulata* (Figure 13), both species typical of headwaters. The researchers suggested that the high leaf-area index compensates for the diffusion resistance and permits these mats to effectively exploit low boundary-layer resistance at high velocities while at the same time protecting the liverworts from drag. In the **mats**, boundary-layer resistance limits photosynthesis at flow rates less than ~0.1 m s⁻¹. *Fontinalis antipyretica* (Figure 27), on the other hand, is not limited until rates slow to 0.01

m s⁻¹. They attribute this to the **streamer** (Figure 1, Figure 15) life form of *Fontinalis*.

Figure 26. *Nardia compressa*, a mat-forming liverwort that can reduce drag. Photo by Barry Stewart, with permission.

Figure 27. *Fontinalis antipyretica*, having a **streamer** life form that permits it to live in both relatively fast and almost still water. Photo by Hermann Schachner, through Creative Commons.

Proctor (1984) summarized both physiological and structural adaptations of bryophytes for the aquatic habitat. Priddle (1979) reported that bryophytes of still or slow-flowing water had open, slender, elongated life forms. Fast-flowing streams favor tight **mats** (Figure 13) or **cushions** (Figure 10) that mimic or even reduce the drag coefficient of the rocks (Jenkins 1982; Proctor 1984; Jenkins & Proctor 1985). *Nardia compressa* (Figure 28) and *Scapania undulata* (Figure 29) provide such **compact mats** (Proctor 1984). These two species show reductions in photosynthesis in flow rates below 10 cm s⁻¹; this is most likely due to the need for turbulence to penetrate the spaces between the leaves. But by contrast, as will be seen below, *Fontinalis* species typically have trailing shoots (**streamers**; Figure 1, Figure 15) that are able to move easily with the water flow, permitting water to enter the clump. *Fontinalis antipyretica* (Figure 30) shows little change in the rate of photosynthesis with flow reduction down to 1 cm s⁻¹.

Morphological Plasticity of Life Form

Life forms can differ for a species when its habitats vary. *Climacium dendroides* (Figure 31) changes from an upright **dendroid** plant to a **creeping**, non-dendroid plant after a long submergence. The Southern Hemisphere species of *Hypnodendron* (Figure 32) and *Hypopterygium* (Figure 33) behave similarly.

Figure 31. *Climacium dendroides*, in a genus that changes from an upright **dendroid** plant to a **creeping**, non-dendroid plant after a long submergence. Photo by Li Zhang, with permission.

Bates (1998) reminded us that life forms "minimize evaporative water loss and maximize primary production." Many species show plasticity of life form according to environmental conditions. One of the common characteristics of aquatic bryophytes is the ability to express different life forms when being grown in different conditions. This can be sufficient to cause erroneous descriptions of new species.

Scapania undulata (Figure 13) occupies a range of habitats from full submersion to rocky ledges in streams of Poland (Samecka-Cymerman 1990). The ledge populations typically are 2-3 cm long, whereas the stream populations are usually 5-10 cm, up to 20 cm. Samecka-Cymerman suggested that low nitrogen might account for the smaller plants on the ledges, a phenomenon known from tracheophytes (Czerwiński (1976; Gumiński 1976). It exhibits a range of morphology that has caused at least one of its forms to be described as separate species (*e.g.* *Scapania dentata*) (Hiesey 1940), now considered a synonym (Hiesey 1940).

Higuchi *et al.* (2003) reported **mat-forming** green plants from acidic rivers in Japan. When cultured, these produced bryophyte gametophyte buds, indicating that the filaments were protonemata (Figure 34). The large subunit of ribulose-1, 5- biphosphate carboxylase/oxygenase indicated the moss was 98% similar to *Dicranella heteromalla* (Figure 35). This species is common in acidic habitats, including woodland banks, tree stumps, tree roots, hedge banks, dry peaty banks, and sheltered soil of crevices on crags and gullies in the mountains (Royal Botanic Garden, Edinburgh 2019). In Illinois, it occurs also on sandstone walls along streams (Hilty 2017). Its protonemal growth in the water may be a habitat response that inhibits gametophore development.

Life Strategies and Reproduction

I was surprised at how few studies appeared when I searched Google for aquatic bryophyte reproduction. But at least some studies exist. Field observations have suggested that production of capsules in submersed bryophytes is relatively rare (Carrigan & Gibson 2004; Ares *et al.* 2014). Instead, fragmentation has seemed to be a major strategy.

Like the life forms, the number of life strategies increases as the frequency of submergence decreases for bryophytes associated with Portuguese streams (Vieira *et al.* 2012a, b). Water velocity and hydrologic zone are the primary influences on the life strategies present (During 1979; Lloret 1986; Vieira *et al.* 2012b). The communities that were mostly submersed were characterized by **perennials** and **ephemeral colonists** (Vieira *et al.* 2012b). Those communities that were more frequently emergent had more diversity of life strategies. At higher altitudes, **perennials** seemed to be favored. Hence, **perennials** are more likely in permanent fast-flowing currents, whereas **pioneer colonists** and **colonists** are more common in the lower currents or emergent positions. In those habitats emerged for brief periods each season, **fugitives**, **annual shuttle species**, and **stress-tolerant perennials** were able to colonize deposited sediments.

In their study of environmental drivers for stream bryophytes, Lang and Murphy (2012) concluded that bryophyte abundance in high-latitude streams was typically a function of predominant growth morphology and life strategy. Ock (2014) included life cycle strategies among the adaptations to rheophytic conditions in bryophytes. He described them as mostly **dioicous** (having separate male and female plants) with rare or uncommon sporophytes. This results from the difficulty of travel for the sperm from the **antheridium** (Figure 36) as it attempts to overcome water flow on its way to the **archegonium** (Figure 37- Figure 38) that is located on a different plant.

Figure 36. *Fontinalis duriaei* antheridia on 13 September 1979 in Coles Creek, Houghton County, Michigan, USA, cultured at 20°C in artificial stream. Photo by Janice Glime.

Figure 38. *Fontinalis* archegonia, with the enlarged one indicating it has been fertilized. Photo by Janice Glime.

Thamnobryum alopecurum (Figure 39) is **dioicous**. During (1978b) found the largest numbers of inflorescences in places with constantly high air humidity. These places also tend to have greater mixing of male and female plants. In drier air, the plants remain mostly sterile. Instead, they develop into large sprouting systems that have little contact between each other. Some even form moss balls in these conditions.

Sexual Strategies and Gametangia

Leitgeb (1868) found antheridia on *Fontinalis antipyretica* (Figure 27) from spring until fall, a pattern similar to that which I found in several *Fontinalis* species in the Keweenaw Peninsula of Michigan, USA and the long period of development for antheridia is typical of antheridia (see Volume 1, Chapter 5-8). Degree of **apical dominance** (physiological behavior in which the main axis grows more strongly than side branches) is important in determining the location of antheridia and archegonia in *Fontinalis* (Berthier 1968). With weak apical dominance, the sexual shoots occur at the axils of the first leaves on side branches. By contrast, when there is strong apical dominance, the main stem forms narrow leaves and these have densely branched first-order sexual shoots in their axils. These first-order shoots occur naturally when the free CO₂ decreases rapidly in the water of late spring, a phenomenon repeated at 8°C in the laboratory. Apical dominance of the vegetative stem can be increased by cutting off some of the leaves or by using weak illumination.

Carrigan and Gibson (2003) compared the sexuality of species that occurred both streamside and on stream rocks at Cement Creek in the Yarra Ranges National Park, Victoria, Australia. They found that streamside populations had higher numbers of stems, inflorescences, and **gametangia** [archegonia (Figure 37-Figure 38) and antheridia (Figure 36)] than did the same species on stream rocks. The streamside populations of species tested produced more sporophytes than those species on stream rocks. *Cyathophorum bulbosum* (Figure 40), however, produced more sporophytes on the stream rocks than did its

populations on streamside locations. The gender was generally female-biased for stem numbers and numbers of inflorescences.

Figure 40. *Cyathophorum bulbosum*, a species that can produce more sporophytes on the stream rocks than do its populations on streamside locations. Photo by John Braggins, with permission.

Berthier (1966) explored the role of light in initiation and development of the sexual organs in *Fontinalis* (Figure 27). He found that light influenced both the density and development of buds, with antheridia forming on branches. A low growth rate enabled formation of these antheridial branches. Increased light intensity increased both the density and initiation of these antheridial branch buds.

Fertilization

Goebel (1913, 1915-1918) illustrated development in some of the water mosses, including *Fissidens* (Figure 41), *Fontinalis* (Figure 27), *Hygroamblystegium* (Figure 42), and *Thamnobryum* (Figure 39). His drawings included details of archegonia and antheridia. I translated one of his statements to mean that fertilization in *Fontinalis* took place in a "glass" of water. A better translation is that the gametangia are suppressed but can be richly formed. The sperm are easily swept away in flowing water. If both archegonia and antheridia are in small water volumes, the *Fontinalis* fruits richly. If the sporophytes are not under water, the spores perish. These observations of Goebel emphasize the importance of timing as part of the life strategies. For example, fertilization is likely to be more successful when the water level is low and they can swim without being washed away. In other cases, fast water might be required to splash sperm from males to females. This might mean that only emergent females get fertilized, but at least some should receive sperm.

Scapania undulata (Figure 13) is among the widely distributed species of aquatic bryophytes. It grows in shallow streams from boreal regions to subtropical zones (Holá *et al.* 2014). It is dioicous, making fertilization difficult, particularly in its typical submersion in rapid water. But Holá *et al.* (2014) found that it had an "overproduction" of males in 10 streams in southern Finland (100 plots) and suggested that this might be a strategy to overcome sperm dilution in the flowing water,

"ensuring" fertilization over longer distances in the water. This male bias contrasts with most dioicous species and seems to relate to its flowing-water habitat. The males and females differ in branching pattern, but no size difference exists. They found few females sex-expressing in the female-only plots and female plants had only one sexual branch per female shoot. The low number of sex-expressing shoots in female-only plots, no co-occurrence of gemmae and female sex organs on a single branch, large number of male plants, and only one sexual branch per female shoot suggest a trade-off between sexual and asexual reproduction and a higher cost for female reproduction.

Figure 42. *Hygroamblystegium fluviatile*, in one of the genera for which fertilization was described by Goebel. Photo by Hermann Schachner, through Creative Commons.

Belkengren (1962) further learned that sexual reproduction in *Leptodictyum riparium* (Figure 43) was induced by a CO₂-free period, followed by addition of CO₂ or sugar. It is a little more difficult to suggest how this might apply in nature, but it could be a change from high temperatures, hence low CO₂, followed by cooler temperatures in which more CO₂ can dissolve in water. Subsequently, it appears that senescence of the plants may induce the formation of sporophytes, perhaps by stopping

the production of some inhibitory substance or reduction of photosynthesis.

Sporophytes

Aquatic moss sporophytes can be divided into two groups (Vitt 1981). In one group, the gametophytes are aquatic, but the sporophytes are not, often being produced during periods of low water. This includes such taxa as *Scorpidium* (Figure 44), *Hygrohypnum* (Figure 14), *Platylomella* (Figure 45), *Platyhypnidium riparioides* (Figure 46), and *Drepanocladus s.l.* (Figure 3). The other group produces sporophytes that are adapted to the aquatic habitat. This group of species includes *Blindia* (Figure 47), *Fontinalis* (Figure 27, Figure 50), *Scouleria* (Figure 48), *Wardia* (Figure 49), and others with reduced or absence of peristomes, ovate or oblong, smooth, immersed capsules, enlarged perichaetial leaves, and pachydermal exothecial cells.

Carrigan and Gibson (2004) followed 9 mosses and 7 liverworts, representing 8 and 6 families respectively. They found sexual reproduction, but not in all species. As in the 2003 study, they found that sexual reproduction was lower on stream rocks than in more terrestrial habitats. Asexual reproduction was most important in maintaining colonies compared to sexual reproduction, with all species exhibiting asexual reproduction. There was a female sex bias in all but 2 species. There seemed to be no synchrony of phenological stages.

Landry (1973) collected field-grown capsules of *Fontinalis dalecarlica* (Figure 15) in June, 1973, in Plymouth, New Hampshire, USA. These immature capsules were permitted to develop in culture until 27 July

1973, but they remained green and did not appear to be completely mature. Capsules were sterilized, opened, and spores spread on a Chlorophyta medium with 3 ppm tannic acid added. There was still no germination on 10 August when it became necessary to terminate the experiment. This was an unusually late date for capsule maturation compared to what had been observed in prior years, and the sterilization process with 0.1N potassium permanganate may have damaged the spores. The other problem is that the capsules had been transported from New Hampshire to Houghton, Michigan and may have experienced excessive temperatures during the trip.

Figure 49. *Wardia hygrometrica* with capsules, a species that typically produces sporophytes while the plant is below water. Photo by Sanbi, with online permission.

Kortselius (2003) found that *Fontinalis antipyretica* (Figure 27) produces capsules when it is submerged (Figure 50), but he considered dry conditions to be necessary for dehiscence (Figure 51). When desiccation occurs, the operculum is torn loose and lifted off by the hygroscopic movements of the exostome teeth (Figure 52). Spores are released during reversible shape changes in the capsule (Figure 53). It seems that this would require careful timing so that capsules were still pliable when they were desiccated. old capsules have thick walls and are quite hard, seemingly unable to change shape significantly.

During (1978a) found capsules on *Fontinalis antipyretica* (Figure 27) 30 April-2 May, but his short note did not indicate the degree of maturity. In my own studies I did not find this species with capsules, but this species was not nearly as common as other *Fontinalis* species in the areas that I studied.

Although *Fissidens fontanus* (Figure 41) produces capsules in the USA and Europe, capsules were unknown in Mexico. Pursell (1992) reported these in Mexico for the first time. However, no data were available on timing of capsule production. The capsules were illustrated, demonstrating the short seta compared to some species of *Fissidens*. The capsule likewise was quite small, with an urn only about 0.2-0.3 mm long in the one illustrated.

Lawton (1966) reported capsule production in *Hygrohypnum bestii* (Figure 54). This was the first time that the sex organs and capsule had been described in this dioicous species. The species occurs in montane streams, typically at 1500-3000 m elevation, on wet rocks that are often covered with silt.

Figure 54. *Hygrohypnum bestii*, a **dioicous** species that rarely produces capsules. Photo by Robin Bovey, with permission through Dale Vitt.

One of the reasons for the lack of capsule observations may be the timing of their presence (Glime 2014). In a stream in New Hampshire, USA, both *Fontinalis dalecarlica* (Figure 15) and *F. novae-angliae* (Figure 23) produce their capsules in the freezing waters of winter. The capsules are badly eroded by the spring runoff, and it seems likely that this is a major vehicle for spore dispersal. By the time the snow is gone, most of the capsules have disappeared, and only a few damaged capsules remain. Their appearance at that time suggests that it is abrasion, not loss of operculum, that permits spore dispersal.

The timing in Finland does not seem to fit this pattern. Kotilainen (1927) found capsules on *Fontinalis dalecarlica* (Figure 15) on 6 July 1925 in Finland.

Dispersal

Few studies have addressed dispersal in aquatic bryophytes. Miller (1985) examined subfossils of a number of bryophyte fragments in late Pleistocene deposits buried in sediments in the northeastern United States. These suggested that the fragments had served as propagules dispersed by wind and melting glaciers. Many of the fragments had shoots extending from them, supporting the notion that these were serving as propagules.

Elssmann (1923-1925) commented on the fact that capsules of *Fontinalis antipyretica* (Figure 27) retained their lids (Figure 51). He noted that Grimme had mentioned that the shedding of the operculum may be delayed until April of the next year, attributing this to the fact that the plants remain submersed. Rather, at least in culture, the capsules themselves were eventually shed several months after maturity, falling to the bottom of the culture dish. There they gradually died, as did the spores inside. Grimme had reported capsule ripening in August, so Elssmann harvested capsules from his cultures at the beginning of July and found them to contain spores with abundant chlorophyll. When the spores were then cultured, nearly all had germinated within 18 days. Elssmann also cultured capsules on moist sand starting in April. These drier capsules likewise failed to lose the operculum. But the spores developed as they had in the submersed capsules. The same behavior occurred in *Cinclidotus fontanus* (*C. fontinaloides*?; Figure 55), *Fissidens fontanus* (Figure 41), and *Platyhypnidium riparioides* (Figure 46). This begs the question, then, how do the spores escape the capsule? The image in suggests that they do indeed dehisce in nature.

Figure 55. *Cinclidotus fontinaloides* with capsules that have lost their opercula. Photo by Hermann Schachner, through Creative Commons.

Hydrochory

Hutsemekers *et al.* (2013) addressed the question of dispersal somewhat indirectly by examining gene flow in *Platyhypnidium riparioides* (Figure 46). They summarized

the assumed effects of **hydrochory** (dispersal by water): decreases or erases patterns of isolation by distance, increases outbreeding, and results in downstream increase in genetic diversity. They found that the geographical partitioning of genetic variation was "substantial" in the river basin. Using this as indirect measurement of dispersal, they found that the overall dispersal ability of moss diaspores, including fragments, was weaker than that of pollen or windborne seeds. Thus, these spore-producing plants suffer from the severe limitations of clonal dispersal and establishment. Hydrochory does not enhance dispersal and fertilization, at least in *P. riparioides*. Instead, the genetic structure suggests clonality and discrete events of spore migration, with the **unidirectional diversity/dispersal hypothesis** (downstream hydrochoric spread of propagules of aquatic and riparian plant species, without upstream compensation, can be expected to result in downstream accumulation of population genetic diversity) being unsupported by this species. Rather, **metapopulation** (group of populations separated by space but are same species) processes apply to this aquatic moss. As the concept of metapopulation implies, such spatially separated populations interact as individual members move from one population to another. This can occur through spores, fragments, or specialized vegetative propagules.

Certainly *Fontinalis* species benefit from downstream dispersal in flow. This is possible because vegetative propagation is usually successful in these species (Welch 1948). In fact, biologists with the Burley Irrigation District in Cassin County, Idaho, USA, complained that it (*Fontinalis duriaei* – Figure 56-Figure 57) "catches on almost anything and holds silt, forming mounds in the canals. It is hard to kill, and costs considerable to keep it out." When wounded, stems of *Fontinalis* will produce protonemata at the site of a broken stem (Figure 58). Removal of the stem tip can result in new branches below the apex in several *Fontinalis* species (Figure 59-Figure 61).

Figure 61. *Fontinalis squamosa* with broken tip and a new branch initiating just below that break. Photo by Janice Glime.

Welch (1948) noted that *Fontinalis sphagnifolia* (Figure 62) produces "rhizomes" with numerous rhizoids. This permits it to spread, but also provides a base ready for establishment in a new site when it gets carried downstream by water flow. The effectiveness of flow dispersal is suggested by observations of *Fontinalis* in a series of connected moraine ponds (Sayre 1945).

Figure 62. *Fontinalis sphagnifolia*, a species that produces rhizomes with numerous rhizoids. Photo by Will Van Hemessen, through Creative Commons.

Korpelainen *et al.* (2013) used genetic markers in three clonal aquatic moss species in a connected lake system. They found a mean genetic diversity per population of 0.138 for *Calliergon megalophyllum* (a quiet water species; Figure 63), of 0.247 for *Fontinalis antipyretica* (slow to moderately rapid water; Figure 27, Figure 30), and of 0.271 for *Fontinalis hypnoides* (moderately rapid water; Figure 64). The total diversity of their populations in the connected lake system was 0.223, 0.385, and 0.421, respectively. Although the differences were significant, there was evidence of a moderate amount of gene flow within this system. The researchers suggested that both water flow and animal vectors, including water flow, dispersed these three bryophytes. Furthermore, the genetic structure suggests that fragments are the major contributors to this dispersal.

Adaptations for Hydrochory

Boedeltje *et al.* (2019) assessed the floating ability, shoot length, and abundance as drivers to facilitate

hydrochory dispersal of bryophyte fragments. Using a 200 μm net they followed dispersal of viable bryophyte fragments for one year in a navigation canal in the Netherlands. They examined the relationship of dispersal to fragment buoyancy, shoot length, growth form, abundance in the vegetation, and discharge. They found that 77% of their 144 samples contained bryophyte fragments, comprising 54,514 fragments and 18 species of bryophytes. *Riccia fluitans* (Figure 69), a floating liverwort, was the most abundant species, followed by *Brachythecium rutabulum* (Figure 65). Variation for most (total of 55% of variation) of attached species could be explained by abundance in the vegetation, buoyancy, and shoot length. Among those sessile species, mean floating time was 5.9 days and mean shoot length 79 mm. Species that occurred in the canal but were poorly represented or absent in the net collections had a significantly lower buoyancy and shoot length.

Figure 65. *Brachythecium rutabulum*, an attached streambank species that is common in drift water. Photo by Robert Klips, with permission.

Dispersal Vectors

One of the problems of dispersal in aquatic habitats is isolation (Figuerola & Green 2002). While streams can carry propagules downstream, they cannot carry them to a different stream or disconnected lake. Many rarely produce spores that could be transported by wind to a different water body. But recent studies have indicated that waterbirds can facilitate dispersal. Fortunately, even small fragments of leaves can develop new plants, and these can easily be transported by feathers and feet. And some may survive gut transport.

Lazarenko (1958) considered long-distance dispersal of moss spores unlikely, considering their dispersal to follow patterns like those of tracheophytes. Rather, he considered there to be polytopic origins to account for disjunctive species. While the dispersal of spores in *Fontinalis* (Figure 56-Figure 62) seems to be facilitated by abrasion and flowing water (Glime *et al.* 1979), the lack of dehiscence in most capsules would seem to support Lazarenko's suggestion. On the other hand, fragments can travel relatively long distances in the flow, and water birds

might carry the moss fragments in their feathers. It is likely that bears and other mammals can carry the fragments in their fur and claws.

Proctor (1961) demonstrated that the liverwort *Riella* (Figure 66-Figure 67) spores can be dispersed by waterfowl. Mallard ducks were placed in a pen with *Riella* having mature spores. The ducks consumed the liverworts immediately. Feces were collected 50 minutes later and examined. Many individual spores were present, but there were no intact sporophytes and all the fragments were dead. Spores subsequently stored in water at 24°C germinated after 60 days.

Figure 66. *Riella helicophylla* showing capsules. Photo by NACICCA through Creative Commons.

Figure 67. *Riella cossoniana* showing spores that can be dispersed by ducks. Photo by Jan-Peter Frahm, with permission.

Laaka-Lindberg *et al.* (2003) reviewed dispersal of asexual propagules in bryophytes. They also noted that migrating birds, especially waterfowl, can carry vegetative attached to the mud on their feet (see also Davison 1976). Such a possibility for the floating liverworts *Ricciocarpos natans* (Figure 68) and *Riccia fluitans* (Figure 69) was suggested by Buch (1954). It would be interesting to see if these two species are eaten by waterfowl, especially as they accompany duckweed, and if they can germinate from the feces. Frahm (2007) also assumed that the worldwide distribution of *Ricciocarpos natans* had been facilitated by waterfowl.

Figure 68. *Ricciocarpos natans*, a floating liverwort with the potential of dispersal by waterfowl. Photo by Janice Glime.

Figure 69. *Riccia fluitans*, a floating liverwort with the potential of dispersal by waterfowl. Photo by Štěpán Koval, with permission.

Lewis *et al.* (2014) brought further credence to these suggestions by showing correlations between transhemispherical migratory routes of shorebirds and the bipolar disjunctions in bryophytes. They then examined a number of birds in their Arctic breeding grounds, finding bryophyte propagules, among other propagules, clinging to the feathers. Eight species of these migrant waders had bryophyte diaspores among their feathers. The propagules were so common among the feathers that they suggested the entire population could potentially carry viable plant parts during migration.

It is possible that fish aid in the dispersal of aquatic mosses. Since the mosses provide cover for a number of aquatic insect species (Glime 1994; see Volume 2), they are a good site for foraging by fish. It is likely that at least occasionally the fish may ingest bits of mosses. Paulson (1980) collected a "packet" of feces (Figure 70) from

Rainbow Trout (*Oncorhynchus mykiss*) that was comprised mostly of *Fontinalis duriaei* (Figure 56). The moss was bright green when it was expelled. It was placed in a baby food jar in the artificial stream, but by the second day it had lost its green color. If it had been deposited in a stream instead of such a confined space, the associated gut contents would have been diluted and might not have the same effect on the moss, perhaps permitting its survival. If so, this would be a potential mechanism for moving the mosses upstream as well as downstream for dispersal. However, I must point out that the moss had to be force-fed to the fish, so I suspect this mode of dispersal is rare.

Figure 70. *Fontinalis duriaei* in feces from force-fed Rainbow Trout. Photo by Janice Glime.

Boch *et al.* (2013) reasoned that slugs might be good dispersal agents for bryophyte spores since they often eat spores (Figure 71). But could the spores survive the digestive tract? They fed capsules of several bryophyte species to three species of slugs. They found an overall germination rate of 51.3% of bryophyte spores from the 117 samples. Among these was the streambank species *Apopellia endiviifolia* (Figure 72). There was little difference evident among the bryophyte species, but there was strong variation among the spores from the three slug species (Figure 73): *Arion vulgaris* (Figure 74), *Arion rufus* (Figure 75), *Limax cinereoniger* (Figure 76).

Changes in Distribution

Frahm and Abts (1993) demonstrated the rapidity of dispersal of a number of aquatic species in the lower Rhine, Germany. From 1972 until 1992, the initial eight species were joined by ten more. The greater number of species in 1992 was attributed to improvement in water quality.

Frahm (1997) documented the distributional increase of aquatic mosses in the Rhein, Germany. *Cinclidotus danubicus* (Figure 78) has spread from its 1911 location to the Upper Rhine and Netherlands in 1997. *Cinclidotus riparius* (Figure 79) has spread northward. *Fissidens arnoldii* (Figure 80) spread from the Upper Rhine to the Lower Rhine in 70 years. *Fissidens fontanus* (Figure 41) was first recorded in the Upper Rhine in 1968 and by 1997 it had spread extensively along rivers in Central Europe. *Hyophila involuta* (Figure 81) spread 100 km northward along the Upper Rhine from 1927 to 1964. *Fissidens rivularis* (Figure 82) and *Orthotrichum sprucei* (Figure 83), both previously known only from British Isles, Belgium, and The Netherlands, have spread to the Rhine and its tributaries.

Not only do bryophyte fragments get dispersed by wind and water, but so do their inhabitants. Bitušík *et al.* (2017) demonstrated that larvae of the chironomid (midge) *Micropsectra uliginosa* (Figure 77) travel in fragments of aquatic mosses, including *Hygrohypnum* sp. (e.g. Figure 14, Figure 54). This facilitates short-distance dispersal of the species, including the flightless males, albeit in their larval stage. They found detached moss tufts with chironomid larvae in their pan traps and assumed that these mosses had been flushed first by water, then trapped behind rocks or other obstructions in shallow water. Subsequently strong winds and gusts could lift the mosses and their inhabitants to mossy habitats above water nearby.

Small Dispersal Units and Long-distance Dispersal

Heino *et al.* (2012) concluded that organisms with small propagules such as ferns and bryophytes may have weak geographical variation over broad areas due to unlimited dispersal. They found that environmental factors were most important in boreal headwater streams. The

bryophyte data seemed to be better explained by environmental variables than by spatial characters.

Finlay (2002) contended that organisms less than 1 mm in size generally occur worldwide (the "everything is everywhere" hypothesis; see Vol. 1, Chapt. 4-8), whereas larger organisms are more restricted. He supported this with data on 1278 species of freshwater pond eukaryotic organisms showing that they were cosmopolitan. It follows that if the propagules are less than 1 mm, like bryophyte spores, they should follow the same principle. Kyrkjeeide *et al.* (2014) demonstrated a negative correlation of range with spore size of bryophytes in Europe based on spores up to 40 μm in diameter. In this case, those bryophytes reproducing (producing spores) less frequently had greater genetic differentiation than did bryophytes with frequent reproduction ($p=0.04$). Van Zanten (1978a, b) supported the possibility of long-distance travel of at least some species by placing the spores on airplane wings for trans-oceanic travel. Among these were the aquatic *Warnstorfia fluitans* (Figure 84) and *Leptodictyum riparium* (Figure 43), which could survive desiccation up to 13 months.

Figure 84. *Warnstorfia fluitans*, a species in which spores can survive conditions necessary for long distance travel. Photo by Hermann Schachner, with permission.

Santos *et al.* (1996) collected airborne spores and other propagules on agar in Petri dishes. Once germinated, the collections revealed the presence of the bryophytes *Fossombronia angulosa* (Figure 85), *Pellia epiphylla* (Figure 6), *Leptodictyum riparium* (Figure 43), *Bryum dunense* (Figure 86), *Ditrichum* sp. (Figure 87), *Gymnostomum calcareum* (Figure 88), *Pottia* sp. (probably now in *Tortula*; Figure 18), and *Trichostomum brachydontium* (Figure 89). Of these, *Pellia epiphylla* is a common streambank species and *Leptodictyum riparium* lives submersed in quiet water. It is also notable that a number of *Cyanobacteria* (Figure 90) arrived, providing potential nitrogen-fixers to associate with the bryophytes. Of the taxa collected, 75% were spores <25 μm . These successful spores suggest that diaspore banks can be important sources to recolonize a stream when it is disturbed or changes channel location.

Spore Germination and Protonema Development

Spore germination and protonema development have been studied in a number of bryophytes, including aquatic species (Kanda & Nehira 1976). These are illustrated and early stages following germination are described for the aquatic mosses *Leptodictyum riparium* (Figure 43) and *Cratoneuron filicinum* (Figure 91).

Figure 91. *Cratoneuron filicinum*, one of the aquatic species for which protonema development was described by Kanda and Nehira (1976). Photo by J. C. Schou, with permission.

Glime and Knoop (1986; Glime 2014) concluded that *Fontinalis squamosa* (Figure 92) is an opportunist that releases spores (Figure 93) from multiple capsules over a relatively long period. This extended period of spore release may be the result of having fertilization over an extended time. Glime (1984) demonstrated that *F. dalecarlica* (Figure 15) produces mature archegonia over several months. A single collection of *F. squamosa* likewise provided both antheridia (Figure 36) and archegonia (Figure 37-Figure 38) in various stages of development. Capsules were also present in this single collection and similarly were in various stages of development. This spread of maturation could provide spores at different conditions of flow, and increase opportunities for at least some spores to meet favorable conditions. Elssmann (1923-1925) found that spores in capsules exposed to air ripened several weeks earlier than those that were submersed, providing further variability in response to changing water levels.

Figure 92. *Fontinalis squamosa*, a species that produces both chloronemata and caulonemata. Photo from <www.photofauna.com>, with permission.

Figure 93. Longitudinal section of *Fontinalis squamosa* capsule showing green spores. Photo by Janice Glime.

Fontinalis squamosa (Figure 92) exhibits another potentially adaptive trait. Its spores within a single capsule (Figure 93) do not all mature at the same time. As the spores develop, some abort (Figure 94) (Glime 1983; Glime & Knoop 1986; Glime 2014). Others enlarge and are bright green, while some remain smaller and may be only partially green. Both can germinate, but the larger ones germinate more quickly (5 days) and have a higher germination success than the small ones (18 days). The protonemata in this species are also negatively **phototropic** (Figure 95) (Glime 2014). This habit of growing away from the light source may be adaptive in keeping them under water. It would be interesting to see if there is a threshold light level that elicits this phototropic response.

Figure 94. *Fontinalis squamosa* spores; those with clear areas on the left and yellow areas on the right are abortive. Those on the right are indicating chlorophyll fluorescence, showing red. Photos by Janice Glime.

Figure 95. *Fontinalis squamosa* protonemata singles typical of those grown at 3°C. Light is coming from the lower right corner, indicating these protonemata are negatively phototropic. Photo by Janice Glime.

Glime and Knoop (1986) described the spore germination and development of *Fontinalis squamosa* (Figure 92). This moss develops both **chloronemata** (Figure 96) (protonemal filaments with many well developed chloroplasts and perpendicular cross walls) and **caulonemata** (protonemal filaments with fewer, less well developed chloroplasts and oblique crosswalls; portion of protonema that generates buds when both protonemal types are present). They can grow straight with no branches or have multiple branches, depending on lighting conditions. But buds failed to develop in the laboratory cultures until some of the abandoned plates became contaminated with fungi, suggesting that some developmental hormone might be supplied by the fungi.

Figure 96. *Fontinalis squamosa* branched protonema, with **caulonemata** forming at the tips of the branches, exhibiting lighter coloring due to fewer chloroplasts. This growth form was typical of cultures at 20°C. Photo by Janice Glime.

Physiological conditions and environmental signals that are important to the developmental stages of aquatic bryophytes are poorly known. Belkengren (1962) experimented with *Leptodictyum riparium* (Figure 43) under a variety of conditions. Yeast inhibits its shoot growth in culture. But protonemal growth is not affected. Yeast causes death to shoot buds. As a result, the moss grows in the presence of yeast and never reaches another stage. Could this be the sort of interaction that maintains *Dicranella heteromalla* (Figure 35) in a protonema stage in

the water (Higuchi *et al.* 2003)? The acid environment would be favorable to growth of fungi. Or is it some nutrient level?

Temperature can play a role in both germination success and form of the protonemata (Glime & Knoop 1986). At 3°C, no spores germinated in culture, although distention occurred. At 20°C, the protonemata grew aerially away from the agar and toward the light source, subsequently forming balls of irregular filaments with rounded cells. The best growth was exhibited by cultures at 14°C, with greater growth on the unshaded side of the plate. Growth forms differed with temperature (Figure 95-Figure 97). Nishida and Iwatsuki (1982) considered the protonema type to be adaptive, reflecting habitat more than its taxonomic affinity. Bud development did not occur until 3 months after the cultures were started, and the presence of buds was restricted to contaminated cultures, suggesting that the fungus might provide a needed stimulant to the bud development (Glime & Knoop 1986). Rhizoids formed before leaves at about an 8-cell stage.

Figure 97. *Fontinalis squamosa* protonemata with mostly 2 branches from the spore, typical of protonemata grown at 14°C. Photo by Janice Glime.

Asexual Reproduction

Carrigan and Gibson (2003) concluded that reproduction of stream bryophytes is primarily asexual. This is supported by evidence that most fragments of these bryophytes seem able to develop new plants in nature. For example, Glime (1970) found a fragment of *Scapania undulata* (Figure 13, Figure 98) leaf with a new plant growing from the center of the leaf, even though this species is also able to produce gemmae. I don't know if it was able to develop rhizoids to attach, but as the new shoot got larger, I would expect it to be able to develop rhizoids at the leaf nodes.

Figure 98. *Scapania undulata* plantlets from detached leaves of *S. undulata* in March 1969 in a stream near Plymouth, NH, USA. Drawings by Flora Mace.

It is likely that aquatic species are more successful at making new colonies from fragments because of their aquatic habitat. If a fragment arrives in a new location, it most likely arrived with flowing water and lodged somewhere that was wet. This would permit it to develop a new plant while it remains wet, whereas in the terrestrial environment new arrivals have a much greater chance of drying out and losing vigor before a new plant can begin growth or become established.

Regeneration

With the difficulty of accomplishing sexual reproduction and spore dispersal, fragmentation becomes more important. For this to succeed, these fragments must be able to dedifferentiate and regenerate new branches and whole colonies.

Regeneration is common among bryophytes. Giles (1971) describes the dedifferentiation and regeneration. Kreh (1909 in Giles 1971) demonstrated that every part of a liverwort except the antheridia could be induced to regenerate. Even diploid gametophytes can develop from pieces of a seta. In *Plagiomnium affine* (Figure 99), if a leaf remains on the stem it does not dedifferentiate. However, if it is removed from the stem in appropriate light, the leaf will dedifferentiate and redifferentiate to form **secondary protonemata**.

Figure 99. *Plagiomnium affine*, a species that can regenerate from a detached leaf. Photo by Hermann Schachner, through Creative Commons.

Gimeno and Puche (1998) followed the responses of *Platyhypnidium riparioides* (Figure 100) in a polluted stream to assess damage to the moss and regeneration. They found that it produces caulonemata at the leaf bases of apical branches. Buds form while these filaments are still attached. When these sets of leaves become detached following **necrosis** (cell death), they can disperse. Rhizoids eventually develop, permitting these fragments to attach in a new location. In the lab, newly cut fragments developed the caulonema in only 5 days and buds arose in 11 days. Rhizoids developed in 21 days. Fragments and damaged leaves were common in the stream and the researchers suggested that in the apparent absence of sporophytes this was the major means of reproduction.

Figure 100. *Platyhypnidium riparioides*, a species that can form new buds and rhizoids on detached pieces. Photo by Hermann Schachner, through Creative Commons.

Heald (1898) was unsuccessful in his attempts to regenerate *Fontinalis antipyretica* (Figure 27). He cultured leaves and stems in water, on earth, and with varying amounts of moisture with no success. On the other hand, I have successfully cultured broken stems of *Fontinalis squamosa* (Figure 60), *F. hypnoides* (Figure 64), and observed protonemata growing at the broken tips (Figure 58) of the latter. *Fontinalis dalecarlica* instead produced rhizoids from detached terminal buds (Figure 101) and leaves (Figure 102). I was also able to grow 2-cm pieces of *F. antipyretica* in artificial streams.

Figure 101. Unattached tip of *Fontinalis dalecarlica* developing rhizoids, hence serving as a propagule. Photo by Janice Glime.

Figure 102. Rhizoids on detached leaf of *Fontinalis dalecarlica*. Photo by Janice Glime.

The aquatic moss *Fontinalis antipyretica* (Figure 27) is capable of regeneration from nearly every part of the gametophyte (Ares *et al.* 2014). She was able to regenerate plants from cortical cells in the bases of detached shoots, margins and abaxial surfaces of leaves, stems with leaves removed, and laminae of detached leaves. These plant parts produce a variety of filament systems, including protonemata with short rectangular cells with transverse crosswalls, and unbranched rhizoids.

Fissidens fontanus (Figure 41) can regenerate even from its calyptra (Figure 103, Britton 1902). The capsules fall from the plants before they mature and the calyptra is still retained. Both the capsule and calyptra can float, so both can act as dispersal units. Goebel (1915-1918) also reported such a capsule of *Fissidens fontanus* with a young shoot emerging from beneath the calyptra (Figure 103); it even is producing an archegonium.

Gemmae and Bulbils

Little has been written about gemmae and bulbils in truly aquatic bryophytes, especially in mosses. One study

of interest is the induction of vegetative propagules in *Porella pinnata* (Figure 104). The leafy liverwort *Porella pinnata* did not fare well when cultured in moist chambers, with fungi and algae developing (Fulford 1944). However, when two cultures were transferred to nutrient media and given regular nutrient treatments and dim light, they developed vegetative propagules, ranging from bulging leaf cells to leafy shoots.

Figure 104. *Porella pinnata*, a floodplain species that develops growths of fungi and algae when cultured in moist chambers. Photo by Alan Cressler, with permission.

Ares *et al.* (2014) discovered that the aquatic moss *Fontinalis antipyretica* produces gemmae. Filamentous gemmae are freed by **schizolysis** (splitting and breaking apart). Spherical brood cells are produced in ageing and desiccating cultures. Ares and coworkers suggested that these asexual propagules may occur in response to falling water levels in nature. These previously unknown means of reproduction may be important in spread and spatial genetic structure. These researchers also suggested that differences between axenic and contaminated cultures may be due to positive associations between the moss and bacterial or fungal contaminants.

Could there be other protonematal gemmae from other aquatic species hiding in the ecosystem, undiscovered because the protonemata are so difficult to find in nature?

Longevity

For many bryophytes that are not securely attached to the substrate, the living portion may only reflect a few years, whereas older basal portions are senescing or dying at the same rate. However, for a stream bryophyte, attachment makes decomposition of the basal portions a bigger problem. It is not unusual, however, to find basal portions that have lost their leaves, but the apical portions are vibrant, living plants. Therefore, **longevity** of the whole plant is an important part of a successful strategy, especially for **streamer** life forms.

Estimating the age of aquatic bryophytes can be challenging. Frye (1928) estimated the ages of a number of bryophytes based on apical regions that survived the winters, but none of these was submersed. These terrestrial bryophytes, including several streambank species, ranged up to 6 years of age present. I would estimate that *Fontinalis* (Figure 27) lives considerably longer than that,

although the basal portions may be devoid of leaves. I grew a number of species in the lab and found that they could rebranch 1-2 times in just 15 weeks, so it does not appear that counting branches would be a useful indicator.

Life Cycle Strategy

All of these life cycle strategies work together to make a successful life cycle (Figure 105). Spore germination in the field is unknown for most aquatic species, but for *Fontinalis novae-angliae* and *F. dalecarlica* the capsules are produced in the winter and can release spores during early spring runoff. At the same time, the plants experience scouring and dispersal of fragments. In the later spring, when there is good sunlight and the trees do not yet form a canopy, growth and branching are at their best. In the summer, when temperatures rise and water levels drop, the rhizoids have their greatest growth. By fall, water levels rise again, temperatures cool, and days are shorter. Archegonia mature, reaching maturity as the longer-developing antheridia also mature. If the water level permits some branches to be wet, but above water, sperm can be splashed to new plants and accomplish fertilization.

Figure 105. *Fontinalis novae-angliae* (Figure 23) and *F. dalecarlica* (Figure 15) seasonal life cycle. Diagram by Janice Glime.

Heino and Virtanen (2006) provide a good summary of the interrelationship of life strategies and stream bryophyte success. They considered that bryophytes could be divided into dominants and transients/subordinates. These two groups had sharp differences in life-history strategies and growth/life forms. They concluded that the abundance-occupancy relationships suggest that dispersal limitation and metapopulation processes may be the governing factors for the dynamics of the aquatic bryophytes, whereas in the semi-aquatic habitat, habitat availability may be more important in contributing to regional species occupancy.

The next subchapter will further discuss the physiological factors relating to the reproductive cycle. These will include temperature and light effects on the induction of reproductive structures.

Summary

Life forms are environmental expressions, whereas **growth forms** are genetically controlled. Both help to determine the suitability of the species for survival in streams. In fast water, these life forms include **streamers**, especially in permanently submersed sites. Other dominant forms include **smooth mats**, **tall turfs**, **fans**, and **short turfs**. Plasticity of life forms permits a species to occupy a wider range of moisture habitats, with stem elongation typically occurring in submersed conditions.

Asexual reproduction predominates; fertilization is difficult under water, particularly for dioicous species. Sporophytes are often emergent, even if the leafy portion is under water. For those submersed capsules, there is evidence that dehiscence might only occur when the capsule becomes emergent, or not at all. Fragments are particularly common as propagules. These can be dispersed by flowing water and animals, and once on land some might be dispersed by wind. Waterfowl might be especially important vectors for long-distance dispersal. The life cycle strategy seems to optimize energy and take advantages of the changing conditions with seasons. For example, in several *Fontinalis* species, spring is important for growth, summer for rhizoids, fall for sexual reproduction, early spring for scouring and dispersal, and capsule production depending on whether it can take advantage of emergence or must disperse under water.

Acknowledgments

Many bryonettors have contributed to these aquatic chapters, permitting me to expand my world view of the taxa. My permission for the *Agriolimnax* feeding on *Asterella* required finding the email address for Tom Voltz. I started with Brent Mishler, who sent it to Amanda Heinrich, who sent it to Ken Kellman, who sent it to someone with the initials JJ, who sent it to Tom Voltz. And I got permission the same day this chain of emails started! Thank you to all of these people for their help!

CHAPTER 8-1

TROPICS: GENERAL ECOLOGY

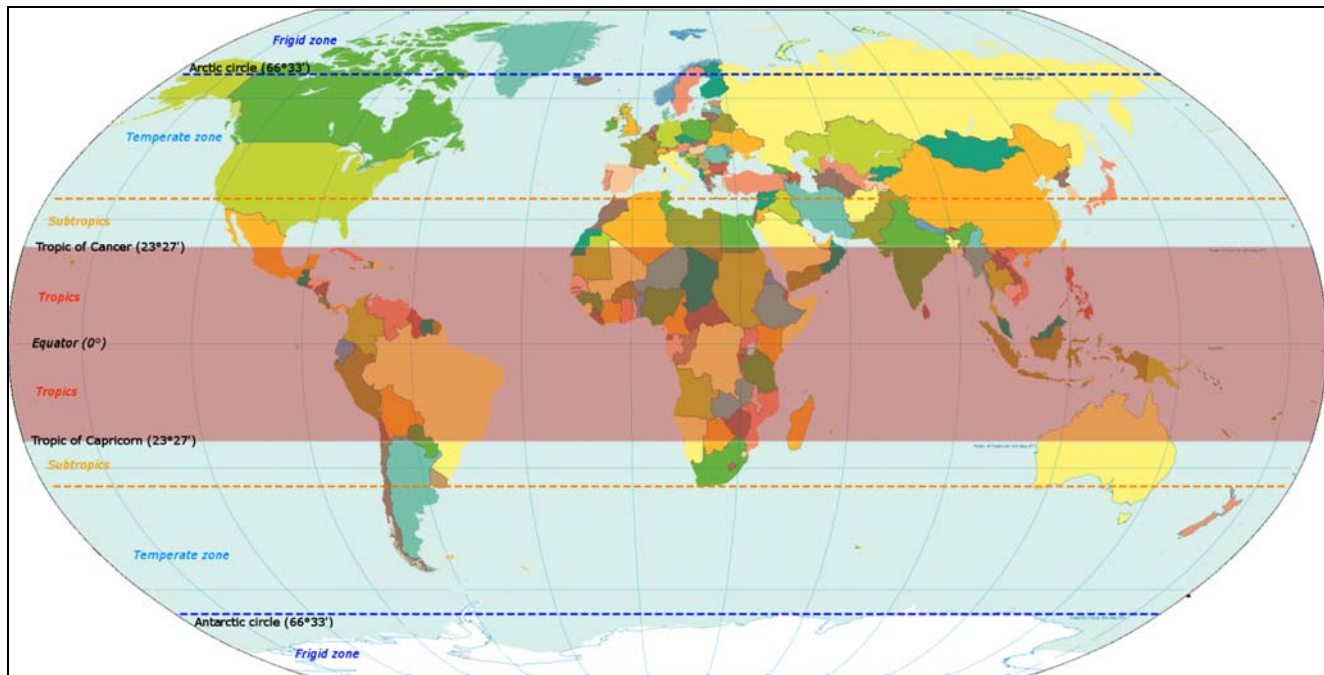

Figure 1. World map indicating tropics in pink band, subtropics in orange dotted line. Photo from KVDP, through Creative Commons.

General Ecology

Occupying the area between the Tropic of Cancer and the Tropic of Capricorn, the tropics comprise the most complex ecosystems of the world (Figure 1), extending 23°27' north and south of the Equator. The tropical land mass is nearly one-third of the land on the planet (Schuster 1988). Complex ecosystems provide multiple niches (Figure 2), and the tropics undoubtedly provide the highest number of niches anywhere with their multi-storied forests (Figure 3).

Figure 2. Tropical forest and waterfalls at Quebrada Cataguana, Honduras. Photo by Josiah Townsend, with permission.

Bryophytes in the tropics were largely ignored in early botanical studies. Resident botanists, lacking training by bryologists and preceding the development of taxonomic aids, largely ignored the bryophytes (Moreno 1992). Although bryophytes have been recorded from the tropics since the 18th century, tropical bryophyte ecology started to emerge only rather recently because keys to identify tropical bryophytes were long lacking. Early fieldwork in the tropics was done by foreign bryologists, *e.g.* Goebel (1888), Schiffner (1900), Fleischer (1904-1923) and Giesenhagen (1910) in Asia, and by Spruce (1884-1885) and Spruce and Wallace (1908) in tropical America. Spruce collected extensively in the Amazon regions and the Andes of Ecuador and Peru, and identified the liverworts himself, but gave his moss collections to William Mitten, who subsequently published them in *Musci Austro-Americani* (Mitten 1869).

Early studies on the ecology of tropical bryophytes has been summarized by Pócs (1982) and Richards (1984a). Some of the earliest studies were on **epiphyllous** (growing on leaves of other plants) bryophytes and will be discussed in the subchapter on epiphylls.

In Puerto Rico, Fulford *et al.* (1970, 1971) described liverwort communities in the elfin (cloud) forest (Figure 4). Griffin *et al.* (1974; Griffin 1979) reported on altimontane (Figure 5) bryophytes. Steere (1970) took advantage of the haploid condition of bryophytes to report on the effects of ionizing cesium radiation in Puerto Rico.

Figure 4. Elfin cloud forest fog, Luquillo Mountain, Puerto Rico, USA. Photo by Janice Glimme.

Once the bryophytes were better known, bryologists began asking ecological questions (*e.g.* Frahm & Gradstein 1990). Based on the results of elevational transect analyses throughout the tropics, Frahm & Gradstein (1991) recognized five tropical rainforest belts using bryophytes as indicators: lowland rainforests (Figure 6-Figure 7), submontane rainforests (=premontane rainforest; Figure 8), lower montane rainforests (Figure 9), upper montane rainforests (Figure 10), subalpine rainforests (Figure 11).

Figure 9. Lower montane forest in Colombia, rich in lignified vascular epiphytes. Photo by A. M. Cleef, courtesy of Robbert Gradstein.

To further complicate our ecological understanding, early differences in methodology made ecological comparisons nearly impossible, while poor understanding of the taxonomy gave that area of study priority and limited the kinds of ecological studies that were feasible. The earliest limited ecological studies have included the relationships among climate, mountain topography, vegetation zones (Pócs 1976), ecology, reproductive biology, and dispersal trends (Schuster 1988), biomass (Frahm 1990b), water relations, and CO₂ exchange (Zotz *et al.* 1997).

Figure 11. Subalpine dwarf mossy *Polylepis* forest in Ecuador. Photo by K. Romoleroux, courtesy of Robbert Gradstein.

Richards (1984a) provided a very useful overview of the ecology of tropical forest bryophytes, making it clear that studies at that time were limited and his coverage was superficial. One of the things that quickly becomes obvious is that most of the known ecological information relates to **epiphytes** (growing on other plants). This is because most of the tropical bryophytes are epiphytes, limited by low light levels and leaf burial on the forest floor.

In the Luquillo Mountains of Puerto Rico (Figure 12), three environmental factors cause contrasting communities of leafy liverworts (Bryant *et al.* 1973). Using area x area (**Q-mode**) analysis, they demonstrated that high-altitude liverwort communities contrast with those of low altitudes, shaded, moist habitats contrast with open, exposed habitats of all elevations, and disturbed low-elevation habitats contrast with less disturbed habitats of all elevations. **R-mode** analysis (species x species) produced nearly identical results to those of Q-mode.

Figure 12. Luquillo Mountains, Puerto Rico. Photo by Stan Shebs, through Creative Commons.

For recent species lists of tropical studies, see Gradstein *et al.* (2001) for tropical America, Churchill *et al.* (2010) on Bolivia, and many others. For additional older studies and reviews of tropical bryophyte species lists and ecology, see Delgadillo (1976) on Mexico; Lisboa (1976) on the Amazon; Egnyomi (1978) on distribution of pantropical *Octoblepharum albidum* (Figure 13) in Africa; Pócs (1982) on tropical forests; Gradstein *et al.* (1983) on Neotropical-African liverwort disjunction; Richards (1984a, b, 1988) on tropical forest ecology; Linares (1986) on the high Andes; Gradstein & Pócs (1989) on tropical rainforest bryophytes; Frahm & Gradstein (1990, 1991) on bryophytes as indicators of tropical rainforests; Frahm & Kürschner (1992) on tropical rainforests in general; Frangi & Lugo (1992) on biomass and nutrients in a Puerto Rico floodplain; Delgadillo (1993) on Neotropical-African disjunction; Miehe & Miehe (1994) on ecology in East Africa; Lösch *et al.* (1999) on Central African photosynthesis; Merwin & Nadkarni (2002) on tropical ecology, and others.

Water Relations

In general, tropical adaptations reflect moisture conditions, with light and other factors being secondary (Frahm 1990a). Hence, we find that lowland forests are dominated by **mats**, and montane and cloud forests by

wefts (loosely interwoven, often ascending growth form). Thiers (1988) reported the leafy liverworts *Radula* (Figure 111), *Frullania* (Figure 14), and various *Lejeuneaceae* (Figure 130-Figure 131) to exhibit the mat growth form on their bark substrate; these taxa tend to lack dominance in the main axis. Where they form extensive mats on tree boles, they are able to trap water as it runs down the tree.

Figure 14. *Frullania* sp. from the Neotropics, demonstrating mat growth habit. Photo by Michael Lüth, with permission.

Studies on water relations seem to have been more common than other areas of tropical bryophyte ecology. Pócs (1980) studied the water interception and retention by bryophytic cover (biomass) in different types of tropical forest, forming the basis for all other studies on the subject. He found a positive correlation between the amount of "surplus" rainfall (rainfall above 100 mm/month) and the epiphytic biomass in rainforest climates. Rainfall and epiphytes will be discussed in Chapter 8-3 of this volume.

When working on disturbance, Norris (1990) suggested four aspects of water relations that required consideration: hydration/dehydration frequency; hydration duration; dehydration duration; degree of water loss. We have since learned that rate of dehydration is important (Greenwood & Stark 2014). As Norris (1990) further surmised, these are all biomass-dependent functions, wherein large colonies typically maintain hydration longer than smaller colonies. Lateral branching of the colony allows lateral movement of capillary water. This spread of the water extends to clones that are in contact with each other. On the other hand, when tufts and cushions are separated, they contribute little to lateral spread of the water over the substrate.

Johnson & Kokila (1970) experimented with ten species of tropical mosses to determine their resistance to desiccation. These were exposed to relative humidities ranging 10-76% for four hours. After a recovery period of 24 hours, the researchers found the mosses could be divided into high and low resistance groups. Those species in the high resistance group occur in tropical forests with low humidity.

Pócs (1980) found a positive correlation between the amount of "surplus" rainfall (rainfall above 100 mm/month) and the epiphytic bryophyte biomass in rainforest climates. As demonstrated by Larson (1981) mosses with a large surface area to weight ratio are able to absorb water very rapidly.

Thompson *et al.* (1994) calculated the bryophyte cover on a single tree of *Sloanea woollsii* (Figure 15-Figure 16) in a notophyll forest of southeast Queensland, Australia (subtropical), to be 66 sq m. Water collected by the bryophytes in a single rainfall event exceeded that of the maximum daily transpirational loss from the host tree. Hence, bryophytes can contribute significantly to the relative humidity of the forest through evaporation. This is also a typical role in the tropics.

Figure 15. *Sloanea woollsii*, a species known for a large cover of bryophytes. Photo by Peter Woodard, through public domain.

Figure 16. *Sloanea woollsii* forest, where many bryophytes grow. Photo by Pete the Poet, through Creative Commons.

Frey *et al.* (1990) recognized three principles of water conduction and storage by plants. In the wet season, it is necessary to drain off surplus water. In the dry season, storage and use of condensation of water vapor are important. Above 1700 m, structures that encourage condensation from water vapor aid in water capture. They felt that leaves with grooves could permit support as well as a means of draining off excess water, an adaptation that seems to reach its maximum in the cloud forest and subalpine zone. In the lowland forest, water sacs, mats, and smooth bark combine to preserve water during short dry periods.

Karger *et al.* (2012) considered air humidity to be one of the most difficult and time-consuming climatic measurements to obtain. Thus, they tested the use of bryophyte cover as a proxy, a suggestion proposed by van Reenen and Gradstein (1983), van Reenen (1987), and Frahm and Gradstein (1991). Using 26 study sites in tropical forests, these researchers considered the possibility of using bryophyte cover as a surrogate for relative humidity as a climatic measurement. They found only a weak correlation between bryophyte cover and relative humidity across all the sites. However, when the highland (1,800-3,500 m asl) data were separated from that of the lowland (<1,800 m asl) sites, relative air humidity had a significant and distinct relationship to bryophyte cover ($R^2 = 0.36-0.62$). Temperature, on the other hand, was related to bryophyte cover only in the lowlands ($R^2 = 0.36$). The researchers concluded that epiphytic bryophyte cover can be used as a proxy for air humidity if both temperature and altitude are considered, but cover might not be a good proxy across extensive elevational gradients or wide temperature differences.

Proctor (1990) has demonstrated the reasons for bryophyte distributions through the use of physiological experiments. Whereas many bryophytes tolerate drying, even down as low as 5% water by dry weight, their photosynthesis declines rapidly as water is lost. Regaining photosynthesis can be rapid or slow upon remoistening, depending on the species and the drying conditions. In the tropics, it is important to know that most bryophytes are shade plants, even when they grow in habitats with lots of sunlight, due to their low chlorophyll *a:b* ratios. This means that they become light-saturated at relatively low light levels and do not benefit when the canopy opens up, admitting more light. But it also means that photosynthesis does not occur at a high rate, so having moist conditions provides them with a longer period of photosynthetic activity.

Both moisture and light relationships can be seen easily within a single tree as well as between habitats. For example, when Sillett and coworkers (1995) compared bryophyte diversity in a cloud forest and pasture in Costa Rica, they found 127 species of bryophytes (50 mosses, 76 liverworts, 1 hornwort) in the crowns of just 6 *Ficus tuerckheimii* (Figure 17) trees in the lower montane wet forest. Of these, 109 species were on 3 intact forest trees and only 76 on 3 isolated trees, the isolated trees having more macrolichen cover. The isolated trees were more subject to drought conditions, with higher evaporation in the inner crowns and more exposure to sunlight. The higher moisture of the intact forest supported not only a greater bryophyte species richness and cover, but also a

greater frequency of **pendants, tall turfs, tails, and fans**. Furthermore, 52 species were found only on the intact forest trees, whereas only 18 were exclusive to the three isolated trees.

Figure 17. *Ficus tuerckheimii*, a strangler fig, substrate for significant bryophyte cover in Costa Rica. Photo by Dick Culbert, through Creative Commons.

Cardosa (2012) described the hydrological cycle and the implications of climate change, using data from a La Réunion cloud forest. As already noted, the bryophytes intercept both fog and rainfall over their entire surface. This ability is important in the hydrological cycle of their ecosystems. Using two liverwort species, *Mastigophora diclados* (Figure 18-Figure 19) and *Bazzania decrescens* (see Figure 20), they determined biomass, water storage capacity, atmospheric and cloud water interception, and photosynthetic response to desiccation. Compared to *M. diclados*, *B. decrescens* stored water at approximately double the mean and maximum per hectare while at the same time occupying less than half the bryophyte volume of *M. diclados*. On the other hand, *M. diclados* had a greater ability to intercept the atmospheric moisture. Both species showed a significant relationship between photosynthesis and water content, with both species losing photosynthetic capacity at both low and high water contents. If the clouds lift, as they are predicted to do by the global climate change models, these bryophytes will most likely not survive and their role in the water cycle will be lost.

Figure 20. *Bazzania* sp. from the Neotropics. Photo by Michael Lüth, with permission.

In addition to decreasing diversity, tropical bryophyte productivity is already being impacted by global climate change (Zotz & Bader 2008; Jácome *et al.* 2011; Song *et al.* 2012; Pardow & Lakatos 2013). Jácome and coworkers

used transplanted communities to determine potential climate change effects on the ecology of these bryophyte species.

As a result of climate change, periods of drought are becoming longer and microclimatic conditions are drier (Pardow & Lakatos 2013). Unfortunately, few physiological studies are available on tropical bryophytes, and even less is known about community responses. Pardow and Lakatos, in the first pilot study for effects of climate change on bryophyte ecology in the tropics, used chlorophyll fluorescence to indicate recovery of bryophytes from a tropical lowland forest in French Guiana (Figure 21). They found that canopy species were well adapted to desiccation events, with 13 of the 18 species maintaining more than 75% of their photosynthetic capacity after recovery from 9 days of desiccation at 43% relative humidity. Understory species were sensitive and could recover only if the relative humidity did not go below 75%. Water vapor, as one might find in fog, was sufficient to rehydrate and reactivate photosynthesis in all of these bryophytes.

Additional discussions of water relations as they relate to habitat can be found in the following subchapters.

Light

Although moisture is the overriding factor in bryophyte distribution in most of the tropics, light is limiting near the forest floor in well-developed multi-story rainforests (Richards 1984a; Cornelissen & ter Steege 1989). Cornelissen and ter Steege demonstrated that true sun epiphytes increase in photosynthetic rates with

increasing light intensity, even when that intensity is very high and atmospheric humidity is low. Hosokawa *et al.* (1964) found that the vertical gradient of bryophyte and other cryptogamic species and growth forms is somewhat related to light and atmospheric humidity, with the lowermost canopy species being more limited by illumination and the uppermost occurrences of trunk species being limited by insufficient atmospheric humidity.

Although high temperatures may be detrimental to some species, Barkman (1958) considered that these are probably not damaging to the bryophytes, but rather that direct solar radiation may be harmful. He cited examples of adaptive coloration exhibited by some bryophytes. Cornelissen and ter Steege (1989) found red to black pigmentation represented in many sun epiphytic species, including *Orthotrichaceae*, *Frullania* spp., and several members of holostipous *Lejeuneaceae*. The upper canopy species *Frullania apiculata* (Figure 22), *F. kunzei* (Figure 23), and *F. nodulosa* (Figure 24) are always dark red I these locations. By contrast, *F. mucronata* from zones 3 and 4 is dark olive green and *F. obcordata* (Figure 25), a generalist, is more strongly pigmented with red color in zones 5 and 6 than in zone 4. Krinsky (1968) described photochemical pathways that can be used by colored pigments that protect plants.

Life and Growth Forms

Bryophyte life and growth forms reflect the habitat conditions, particularly that of available moisture. Life forms of tropical bryophytes were described in detail by Mägdefrau (1982). Aceby *et al.* (2003) found that 4-15-year-old fallows have a significantly decreased diversity of bryophyte families and mosses in Bolivia (Figure 26). Liverworts, on the other hand, have nearly as much diversity in the fallows as in the submontane rainforest. The life form is ~72% **smooth mat**, a much higher percentage than that found in the forest.

Pardow *et al.* (2012) used life forms as an indicator of high diversity in a tropical lowland cloud forest of the Guianas (Figure 27-Figure 28). These lowland cloud forests are hotspots of bryophyte diversity in tropical lowland areas compared to the common lowland rainforest, as shown in detail by Gradstein (2006) and Gehrig-Downie *et al.* (2011, 2013). The cloud forest benefits from the frequent early morning fog in the valleys. Pardow *et al.* compared the distribution of the functional groups of epiphytes across height zones in the lowland cloud forest and lowland rainforest and found a higher diversity of life forms of bryophytes in the cloud forest. In the cloud forest, **tail**, **weft**, and **pendants** are common, whereas in the

rainforest they are almost absent. The researchers suggested that identification of life forms could be used as a rapid method for identifying lowland cloud forests for conservation.

In our study (Li *et al.* 1989) of *Frullania* (Figure 14, Figure 22-Figure 25) in Papua New Guinea (Figure 29), moisture and elevation gradients were important in determining taxa assemblages. Although we suspected that light and temperature were likewise important, we had no data to test these directly. Pócs (1982) and Richards (1984a, b) and a review by Thiers (1988) likewise report that the most important influences on tropical rain forest liverwort (**Jungermanniales**) growth are relative humidity, rainfall, light, and temperature (Thiers 1988). Frahm (1990a) found compensation points for two mosses in controlled temperature regimes, relating these to the tropical temperature regimes. Within this group, growth habit and stem anatomy are often modified, but perhaps the most adaptive features are the development of both simple and complex saccate leaf lobules in liverworts such as *Frullania* (Figure 22-Figure 25), presumably for retention of water, and elongate, thin-walled leaf cells.

Figure 29. Papua New Guinea. Photo from eGuide Travel, through Creative Commons.

On the other hand, excess water can be a problem because it reduces diffusion of CO₂ and can encourage fungal growth (Frey *et al.* 1990). Trees in the tropics often have leaves with prolonged (**acuminate**) tips. This has been considered by some to be an adaptation that permits water to run off the leaf, thus reducing the colonization by fungi on leaves that are subjected to daily rains. **Pendent** bryophytes in rainforests have a somewhat similar adaptation, but the interpretation has been more debatable. For example, in north temperate forests, *Frullania* (Figure 30) is recognized as a liverwort that closely adheres to its bark substrate (**mats**). However, in the rainforest, several **pendent** species of *Frullania* (Figure 31) exist (Li *et al.* 1989). One interpretation of this is again the possibility of the water to be shed by running down the rope-like plant body. However, an alternate interpretation seems to be just the opposite. The **pendent** form is actually a response to the weight of water, first in weighing down taller plants with weak stems, and then in collecting the water at the tips of the branches where the dividing cells are. Thus, the tip of the moss, during the rainy season, may be bathed in water nearly all the time, giving it a nearly aquatic environment. This continual supply of water permits the cells to divide uninterrupted by periods of drought during the rainy season. Such bryophytes can be found not only in tropical and subtropical forests such as those of southern

Japan, but also in the rainforests of the Pacific Northwest in North America.

Figure 31. Pendent *Frullania* from the Neotropics. Photo by Michael Lüth, with permission.

Proctor (2002) found that the **pendent** mosses *Floribundaria floribunda* (Figure 32) and *Pilotrichella ampullacea* (Figure 33) hold large amounts of external capillary water. Nevertheless, both species are able to recover from 11 months of dry storage at 5°C (not a very likely temperature in lowland tropics, but possible at some higher elevations). Both require several days to recover, with *F. floribunda* taking somewhat longer. Short desiccation periods elicit rapid recovery, with *P. ampullacea* reaching a positive carbon balance after only 30-60 minutes following 20 hours of air drying. After six days, they require 2-5 hours, suggesting that they are adapted to the short periods of desiccation found in the humid tropical forests, but not to longer, frequent periods. *Floribundaria floribunda*, on the other hand, is best adapted for more shady and continuously moist forests.

Figure 33. *Pilotrichella ampullacea*, a species that holds large amounts of external capillary water. Photo by Jan-Peter Frahm, with permission.

In the leafy liverworts, Thiers (1988) recognized stem characters such as growth habit (projecting, prostrate, rheophytic) and anatomical characters such as epidermal thickenings, stem reduction, and stem flattening (often present in **mats**) as conserving moisture during dry periods. The flattened stems, such as those in *Pteropsiella frondiformis* (Lepidoziaceae), do most of the photosynthesizing, and accompanied by reduced leaves, the reduced life form would most likely conserve water during dry periods. Other leaf modifications include development of simple and complex saccate leaf lobules [e.g. *Pleurozia* (Figure 34-Figure 35) and *Colura* (Figure 36-Figure 37)] and presence of elongate, thin-walled, hyaline cells in the leaf margins [e.g. *Cololejeunea marginata* (Figure 38), *C. cardiocarpa* (Figure 39)], all of which help to hold or absorb water.

Further descriptions of life forms and growth forms as they relate to habitat can be found in the following subchapters. For an introduction to the topic, see Volume 1, subchapter 4-5.

Nutrient Relations

Nutrients are also affected by the rainy and dry seasons. Nutrient pulses occur as bryophytes dry and rewet. Damaged membranes leak nutrients and other substances such as sugars and polyols. Rainfall leaches these nutrients from the bryophytes, including their surfaces, and carries them to the forest floor (Lodge *et al.*). These pulses synchronize nutrient availability that maintains higher rates of nutrient mineralization, plant uptake, and forest productivity. It provides nutrients at the beginning of the growing seasons, a time at which they should be most beneficial to forest species. Thus the bryophytes serve as storage units that provide nutrients at the most critical time.

Coxson and coworkers (Coxson 1991; Coxson *et al.* 1992) noted the importance of wetting/drying cycles for the accumulation of sugars and polyols to more than 950 kg ha⁻¹ in the epiphytic bryophytes of the cloud forest canopy of Guadeloupe (French West Indies). These sugars can stimulate the growth of microbes and thus facilitate the breakdown of litter. These relationships suggest some of the importances of these wet to dry changes in nutrient release from the epiphytic bryophytes (and for some, probably ground-dwelling species as well) and their role in the forest dynamics.

Further support for these responses comes from differences between upper and lower canopy bryophytes. Coxson and coworkers (1992) found that the upper canopy leafy liverwort *Frullania atrata* (Figure 40) holds 17% of its dry weight as sugar and polyol reserves. [Note that the name *F. atrata* has been misapplied to a number of tropical *Frullania* specimens, so information regarding the species may actually belong to one of its look-alikes (pers. comm. Robert Gradstein).] By contrast the lower canopy moss *Phyllogonium fulgens* (Figure 41) holds these reserves as less than 6% of its dry weight. The upper canopy bryophytes seem better adapted at retaining these, with *F. atrata* releasing only 0.3 g m⁻² compared to 0.9 g m⁻² for *P. fulgens*. This relationship was supported by similar relationships of bryophytes under field conditions in the tropical montane cloud forest of Guadeloupe, French West Indies.

Frangi and Lugo (1992) studied the biomass and nutrient accumulation in ten-year-old communities in a flood plain at the Luquillo Experimental Forest, Puerto Rico. They found a higher bryophyte cover on streambanks where flooding was frequent but of short duration. The cover decreased toward the longer-lasting flood plain, with the minimum cover occurring in depressions where water remained and became stagnant. They measured nutrient accumulations in ash-free biomass of bryophytes. These accumulations in kg ha^{-1} were 14.5 for N, 0.8 for P, 5.3 for K, 2.7 for Ca, 2.7 for Mg, 0.5 for Mn, 18.5 for Fe, and 22 for Al. These numbers were similar to those found in fine litter. Nevertheless, these values were low compared to that of other bryophyte communities. Both biomass and nutrients were greater in streambank slope communities and slopes of tree mounds than that in depressions that remained wet for a long time.

The bryophytes in these tropical flood plain communities appear to retain nutrients and serve as filters during flooding in these communities.

In the coastal forests of Kenya, some bryophytes specialize on acid or alkaline substrates (Wilding *et al.* 2016). For example, *Tortella tortuosa* (Figure 42) is strongly associated with calcareous substrates, whereas *Racomitrium lanuginosum* (Figure 43) only occurs on acid ground. These preferences most likely relate to their ability to obtain their needed nutrients, without getting them in excess.

Further discussion of nutrient relations of tropical bryophytes is in the subchapters on Epiphytes.

Productivity

Productivity studies, in particular, are difficult to compare because of differences in methodology. Moreover, few exist.

Pócs (1987) was among the early productivity researchers, examining the changes in biomass among bryophytes in the East African rainforests. As we might expect from temperate studies (Proctor 1982), physiological and experimental studies indicate that net productivity drops rapidly as temperatures rise above 25°C (Frahm 1990b). Add low light levels to the high temperatures and the bryophytes are hindered by high

respiration rates and low photosynthetic rates, resulting in low or negative net assimilation. Due to differences in precipitation, humidity, temperature, and desiccation (Frahm 1990a, b), it is generally true that biomass of epiphytic bryophytes in equatorial latitudes increases from the tropical lowlands to the treeline. Thus, high temperatures, combined with low light intensities, can account for the low diversity of bryophytes in the lowlands. Richards (1952) found data indicating that during the wet, and thus cloudy, season, the maximum temperatures in the ground layer are lower than those in the dry season when the sun shines a greater proportion of the time.

This raises the question of how the limited numbers of species in the lowlands survive. Frahm (1990b) suggested this could involve a specialized phytochrome system or more effective storage of the photosynthetic products. Perhaps more realistically, the relatively high nutrient supply that arrives through abundant precipitation could support a positive net photosynthesis. Another factor that could contribute is that the forest floor can have high CO₂ concentrations due to enhanced decomposition of leaves in a hot, moist environment, but increased CO₂ levels are most beneficial in high light levels.

Zotz *et al.* (1997) provided further information on the CO₂ and water relations for net photosynthesis. Using six tropical bryophytes, these researchers measured the daily changes in water status and net CO₂ exchange in a submontane tropical rainforest in Panama (Figure 44). Daily variation of water content was "pronounced." Both high and low water content limited carbon gain. Low light during rainstorms was less important in limiting CO₂ exchange compared to water content. More than half the carbon gain was lost at night to respiration.

Figure 44. Panamanian submontane and montane forests. Photo by S. B. Matherson, through Creative Commons.

In a more recent publication, Chen *et al.* (2016) examined photosynthetic properties of epiphytes in Southwest China. These adaptations include higher total chlorophyll concentrations, specific leaf area, and chlorophyll per unit leaf N (Chl/N), lower ratio of chlorophyll *a:b*, and greater photosynthetic nitrogen-use efficiency. Measurements, in $\mu\text{mol m}^{-2} \text{s}^{-1}$, showed means for light-saturated net photosynthetic rate (0.55), light saturation point (106.72), light compensation point (4.17) and dark respiration rate (0.25). They demonstrated

photosynthetic down-regulation under high light conditions for these low-light epiphytes. These trunk-dwelling epiphytes are adapted for high resource retention rather than high resource gain. This is accomplished by low respiration rates and low light compensation points in shady habitats.

Waite and Sack (2010) hypothesized that leaf trait values would "reflect the distinctive growth form and slow growth of mosses, but also that trait correlations would be analogous to those of tracheophytes." Using ten species from Hawaii (Figure 45), they quantified 35 physiological and morphological traits of cell, leaf, and canopy level of bryophytes growing on the ground, trunk, and canopy. These bryophytes had low leaf mass per area (A_{mass}) and low gas exchange rates. Perhaps not surprisingly, but in contrast to that of tracheophytes, the moss light-saturated photosynthetic rate per mass did not correlate with habitat irradiance. However, leaf area, cell size, cell wall thickness, and moss canopy density all correlated with microhabitat irradiance. Waite and Sack furthermore found that costa size, canopy height, and A_{mass} were coordinated traits linked with structural allocation.

Figure 45. Hawaiian forest near Hanalei Bay, Kauai. Photo by Lukas, through Creative Commons.

Wagner *et al.* (2014) sought to explain the distribution of tropical bryophytes based on their physiological ecology. They noted the increase in bryophyte biomass with altitude in rain and cloud forests. They suggested that the low bryophyte abundance in the lowland rainforests is a result of the limitation of net carbon gain during fast drying and low light levels during daytime, coupled with the moist, warm nights. These moist, warm nights promote respiration and the daytime photosynthesis can be insufficient to balance the nighttime CO₂ loss. Wagner and coworkers concluded that the timing of hydration is crucial for net photosynthetic gain.

Datta Munshi (1974) studied seasonal changes in standing crop (chlorophyll) and annual net production of two moss communities at Varanasi, India. The mean bryomass in a perennial *Hydrogonium* (Figure 46) community was 95 g m⁻² and in the seasonal community of *Physcomitrium* (Figure 47) it was only 11 g m⁻². These values represent the first on non-epiphytic bryophytes in the tropics and were lower than those typical of bryophytes in temperate forests, being more like those in Arctic ecosystems.

Tropical forests generally have a larger biomass of epiphytic bryophytes than do temperate forests (Norris 1990). However, when trees are widely spaced or occur as lone trees, the greater penetration of wind can quickly desiccate the adhering bryophytes.

Overall, bryophytes comprised 40% of the epiphytic biomass in a Neotropical lower montane cloud forest at ca. 1600 m in Costa Rica (Nadkarni 1984) compared to 6% in the leeward rainforest (Ingram & Nadkarni 1993). In both forests, bryophytes were most abundant among the smallest branches. The gnarled, windblown trees and the frequent mist in the elfin forest provide extremely favorable conditions for bryophytic growth (see Lawton & Dyer 1980).

In an upper montane cloud forest at 3700 m in the Andes of Colombia (near the forest line), the bryophyte contribution to total epiphyte biomass was much higher, almost 70% (Hofstede *et al.* 1993) and total epiphytic biomass (including suspended soil) was a staggering 44 tons per hectare, the highest value ever reported.

Light is an important limiting factor for photosynthesis in the tropics. For three species of *Pogonatum*, chlorophyll content and chloroplast size differed with light intensities

where they predominated (Nasrulhaq-Boyce *et al.* 2011). For *P. cirratum* subsp. *macrophyllum* (Figure 48) and *P. subtortile*, the total chlorophyll and beta-carotene content are higher than that in *P. neesii* (Figure 49). The latter lives in the areas with much higher light intensities ($751 \pm 45 \text{ W m}^{-2}$), compared to 28 ± 4 and $230 \pm 39 \text{ W m}^{-2}$, respectively. The sun species, *P. neesii*, had a higher soluble protein content, likewise having a higher soluble protein to total chlorophyll ratio. *Pogonatum cirratum* subsp. *macrophyllum*, the species from the lowest light, had significantly larger chloroplasts as well as more grana and thylakoids per chloroplast than did the other two species. And the two species from the lowest light had more than double the numbers of starch grains. On the other hand, the leaf **lamellae** (vertical stack of cells on leaf; Figure 50) were shortest in the species receiving the lowest light levels. Nevertheless, the CO_2 assimilation rates were highest in *P. neesii* even when light intensities were low. Lamellae can provide more surface area for photosynthesis and capillary spaces to hold water longer. In low-light *P. cirratum* subsp. *macrophyllum*, these are rudimentary, whereas those of *P. subtortile* are 5-7 cells high.

Further discussions of productivity and biomass will be provided in the succeeding subchapters as they pertain to particular habitats.

Climate Effects

As noted above, moisture and temperature are important determinants of the types of bryophyte vegetation that survive. And precipitation events and cloud cover will diminish the light intensity. Among the early studies on the effects of these climate parameters on tropical bryophytes is a study by Biebel (1964, 1967). He examined temperature resistance of jungle mosses. Weber (1985) examined the effects of El Niño on bryophytes of the Galápagos. Furthermore, hurricanes can be devastating to epiphytes, ripping them from the trees or breaking branches and even toppling trees.

Rainy "seasons" are common in the tropics, punctuated by dry periods. If there are two periods in the year when the sun is overhead in the tropics, two wet seasons will occur (Richards 1952). If the two periods of overhead sun are close together, the two wet seasons will merge, but two maxima will still occur.

In the winters of many parts of the tropics, a dry season turns the area into near desert conditions. Akande (1984, 1985) attempted to understand the desiccation tolerance, or lack of it, among several tropical African bryophytes. Using the leafy liverwort *Mastigolejeunea florea* (now called *Spruceanthus floreus* according to Robert Gradstein; see Figure 51) and the mosses *Calymperes palisotii* (Figure 52) and *Entodontopsis nitens*, he concluded that these mosses were more desiccation-tolerant than the liverwort. It is interesting that bryophytes maintained at 0% relative humidity for one week and one month at 28°C were able to resume respiration more quickly than those kept at 32 and 54% relative humidity. He considered this ability to recover from 0% humidity so easily to be a case of **anhydrobiosis** (living state without water).

Figure 52. *Calymperes palisotii* on bark, a species that seems to be capable of anhydrobiosis in tropical Africa. Photo by Scott Zona, with permission.

Reproductive Biology and Phenology

As discussed earlier, the timing of reproduction must coincide with conditions favorable for dispersal. For example, both *Sematophyllum subpinnatum* (Figure 53) and *Octoblepharum albidum* (Figure 13) in the tropical Brazilian lowland forest have considerably more juvenile, immature, and mature gametangia during the rainy season than during the dry season, and that corresponds with an increase in the number of fertilized eggs in the archegonia

(Oliveira & Pôrto 2001; Pôrto & Oliveira 2002). One must keep in mind that unlike the desert, the dry season is subject to occasional, but short, rainfall events. In contrast to gametes, spores benefit from dry air for dispersal, and these two species derived that advantage by beginning sporophyte development during the rainy season, but completing it during the dry season.

Figure 53. *Sematophyllum subpinnatum*, a species that produces most of its juvenile, immature, and mature gametangia during the rainy season in tropical Brazil. Photo by Michael Lüth, with permission.

Despite our limited taxonomic knowledge, there have been several studies on the reproduction of tropical bryophytes. By their very nature, individual studies are limited to one or few species (e.g. Fatoba 1998). Nevertheless, Kürschner and Parolly (1998a, b), Kürschner *et al.* (1999), and Kürschner (2004) were able to review the life strategies and adaptations of bryophytes, noting that functional types are "important for the establishment, habitat maintenance, and dispersal of species," indicating relationships among site ecology, niche differentiation, and species evolution.

Bryophytes in tropical regions seem to have relatively fast population dynamics when compared to those of temperate species (Monge-Nájera 1989; Coley *et al.* 1993; Zartman 2004). This is often an adaptation to the ephemeral nature of many of their substrates.

Cerqueira *et al.* (2016) studied the seasonality of reproduction of epiphytic bryophytes in the flooded forests of the eastern Amazon. Of 54 species, 34 were fertile. They were unable to identify a pattern in the seven studied species when comparing those in dry vs rainy conditions. Two species, however, were associated with the seasonality. They concluded that some bryophytes may maintain constant fertility as an adaptation to these tropical forests.

Batista *et al.* (2018) found that in a humid forest in northeastern Brazil, with seasonal rainfall and dry season, the 76 bryophyte species were predominantly monoicous (67%) and exhibited reproductive traits that tolerated adverse conditions, permitting them to persist under the seasonal water availability of the forest. A total of 80% of the species had sporophytes, mostly among the monoicous species. Only 21% exhibited asexual reproduction,

including gemmae, regenerating fragments, and caducous leaves. Of these with asexual means, 75% were dioicous.

Life Cycle Strategies

Tropical forest substrata are usually rather temporary (Richards 1988), whether it be due to rapid decay, exfoliation, or soil erosion. In fact, Richards considers all substrata available to bryophytes in the tropics to be impermanent. Hence efficient short-distance dispersal is important. Epiphyllous species are frequently **colonists** with a short life span and production of numerous propagules. Species of *Fissidens* (Figure 71) and others that grow on termite mounds have a short-lived strategy. Richards (1988) carefully stated that the **perennial shuttle** with its relatively long life span and only moderate sexual or asexual reproduction is probably the commonest life strategy in the tropics, but that epiphylls are likely to be colonists because of the short duration of their substrate. **Fugitives** are rare, exceptions being the thallose liverwort *Riccia* (Figure 54) and the moss *Micromitrium* (Figure 55), as seen in West Africa.

Figure 54. *Riccia cavernosa*, a thallose liverwort; members of this genus are fugitives in West Africa. Photo by Des Callaghan, with permission.

Mosses

The earliest of the tropical reproductive studies I could locate were those of Odu (1979, 1981). Studies on the mosses *Racopilum* (Figure 56) and *Fissidens* (Figure 71), indicate the importance of temperature in early life stages, with germination occurring at 30°C and protonema growth at 25°C (Odu 1979). This temperature requirement coincides with the maturation and dispersal of spores in the dry season, favoring the establishment of new shoots.

Figure 56. *Racopilum africanum*, a tropical species that relies on the rainy season for sexual reproduction. Photo by Jan-Peter Frahm, with permission.

Where seasons alternate between rainy and dry seasons, the rainy season is critical for completion of reproduction in species that rely on sexual reproduction. Odu (1981) demonstrated this for four species in southwest Nigeria, showing that release of spores was timed to take advantage of the dry season. The reproductive phenology of several tropical African mosses (*Racopilum africanum* (Figure 56), *Fissidens weirii* (see Figure 71; syn.=*F. glauculus*), *Pelekium gratum* (Figure 57; syn.=*Thuidium gratum*), *Stereophyllum* sp. (Figure 58) illustrate this. Using populations in southwestern Nigeria, Odu found that gametangia develop at the onset of the rainy season (March-April), whereas the development of sporophytes occurs later, with capsule maturation occurring at the end of the same rainy season (October-December). This permits dispersal of spores during and after the dry season (November-April). Thus the entire reproductive cycle is completed within one year. A similar relationship occurred among four species in a savannah in southwestern Nigeria (Makinde & Odu 1994).

Figure 57. *Pelekium gratum*, a tropical moss species that relies on the rainy season for sexual reproduction. Photo by Manju Nair, through Creative Commons.

Figure 58. *Stereophyllum radiculosum*, a tropical moss species that relies on the rainy season for sexual reproduction. Photo by Juan David Parra, through Creative Commons.

Both Olarinmoye (1974) and Egunyomi (1979a) determined that in studied bryophytes of west tropical Africa moisture is the regulatory factor for both growth and sporophyte production. Nevertheless, differences between species exist (Odu 1982). Odu found that *Fissidens weirii* (see Figure 71) and *Racopilum africanum* (Figure 56) have the shortest fertilization period, occurring in May. This fertilization period is earlier in *Pelekium gratum* (Figure 57) and much later in *Octoblepharum albidum* (Figure 13; Figure 59) (July-September). Nevertheless, the sporophytes of all four species mature toward the end of the rainy season (October-November). Herbarium specimens of these mosses collected over an 11-year period support this pattern.

Maciel-Silva and Oliveira (2016) examined the seasonal relationships of *Octoblepharum albidum* (Figure 13; Figure 59) in Brazil. Among 100 sporophyte-bearing plants, representing ten populations, the development was clearly seasonal, relating principally to rainfall. The early stages (immature to post-meiotic) occurred primarily during the dry season. Dehiscence, on the other hand, occurred mostly during the rainy season. This seems to be the opposite of that found for the species in Africa.

Octoblepharum albidum (Figure 59) is an autoicous pantropical species. Thus, its handling of various climatic regimes can help us to understand adaptations of reproductive strategies. Maciel-Silva *et al.* (2013) compared reproductive traits of this species in two Atlantic rainforests and two coastal sites in northeastern Brazil. This species not only produces spores frequently (Figure 59), but also produces gemmae at the leaf tips (Figure 60). In the coastal sites, the shoots had higher numbers of sporophytes, male and female branches per shoot, male gametangia per sexual branch, and longer setae than in the forest sites. Numbers of female gametangia per sexual branch did not differ between the two habitats and the male-biased sex ratio was present at all sites. Longer shoots produced more sporophytes, protonemata, and/or buds than did shorter ones, compared to production of gemmae, but only in the forest sites. The researchers suggested that the longer setae could favor spore dispersal, aiding colonization in coastal sites.

Figure 60. *Octoblepharum albidum* with gemmae on the leaf tips. Photo by Li Zhang, with permission.

Oliveira and Pôrto (2005) examined sporophyte production and population structure of two moss species in the **Pottiaceae** in Brazil. Both *Hyophila involuta* (Figure 61) and *Hyophiladelphus agrarius* (Figure 62) produce capsules in the Atlantic forest at Recife, Pernambuco, Brazil (see Figure 63). Both species had a significantly female-biased sex ratio. The ratio of sterile to fertile shoots was close to 1:1. *Hyophila involuta* had a mean shoot density of 19 cm⁻², whereas it was 27 for *Hyophiladelphus agrarius*. Furthermore, *H. involuta* had only 48% sporophyte production, whereas *H. agrarius* had 55%. Neither species seemed to change its sporophyte production based on any of the environmental parameters measured. The males and females do not clump by sex, favoring sporophyte production.

Antheridia and Archegonia

Pôrto and Oliveira (2002) did a more intensive study on the reproductive **phenology** (study of cyclic and seasonal natural phenomena) of *Octoblepharum albidum* (Figure 59) in the Atlantic Forest in Brazil. In this 2-year study, they found an average of 13.4 antheridia per **perigonium** (envelope of modified leaves surrounding antheridia) and 6.7 archegonia per **perichaetium** (ensheathing cluster of modified leaves surrounding archegonia). All stages of gametangia were much greater in the rainy season, with a concomitant increase in fertilized eggs in archegonia. The sporophytes began development during the rainy season and matured in the dry season, at which time spores were dispersed.

Even in the moss *Sematophyllum subpinnatum* (Figure 53), in which antheridia and archegonia initiate, mature, and achieve fertilization throughout the year, the frequency increases in the rainy season (Oliveira & Pôrto 2001). Sporophytes (see Figure 64) initiate primarily in June through September, indicating that the rainy season is the most favorable time for fertilization.

Figure 64. *Sematophyllum substrumosum* with capsules; capsules in *Sematophyllum subpinnatum* initiate in June through September in tropical Brazil, following fertilization in the rainy season. Photo by Michael Lüth, with permission.

Maciel-Silva and Valio (2011) found that in two different sites in the Brazilian rainforest, the phenology was somewhat different. Examination of eleven species of bryophytes indicates that the reproductive organs are active year-round. Female gametangia often mature before the onset of the rainy season. Male gametangia, however, tend to mature at the end of the dry season. Furthermore, at sea level, the highest production of immature male gametangia occurs at the start of the rainy season, whereas in the montane region, the highest production of immature male gametangia is at the end of the dry season. The researchers suggested that high temperatures could damage the development of male gametangia during the rainy season. Sporophytes dehisce before the rainy season begins, a time when spores can be dispersed farther by dry winds.

In summary, tropical gametangia mature primarily at the end of the dry season or beginning of the rainy season, most fertilizations occur during the rainy season, and spore dispersal occurs during the dry season.

The pantropical moss *Sematophyllum subpinnatum* (Figure 53) is **autoicous** (having both sex organs on same plant but different branches) (Oliveira & Pôrto 2001). Sampling of two populations for two years in northeastern Brazil revealed that the average number of antheridia per perigonium ranges 9-20; archegonia per perichaetium ranges 3-26.

Monoicous vs Dioicous

As one might expect, **monoicous** (having both sexes on same plant) species have the highest levels of sporophyte production compared to **dioicous** (having sexes on separate plants) (Maciel-Silva *et al.* 2012a). Nevertheless, in the tropics, as elsewhere among mosses, the dioicous condition prevails in the tropical north Queensland, Australia, and most likely elsewhere in the tropics (Ramsay 1987).

Gradstein (1975, p. 29) found the highest level of sporophyte production in the autoicous *Acrolejeunea fertilis* (Figure 65) and *A. pycnoclada*, with 15% presence of sporophytes in 100 collections of each of the two species studied. In other *Acrolejeunea* species mature sporophytes were present in less than 10% of collections studied, and sporophytes were not seen in two dioicous species. In their study of fertilizations in 11 species from a Brazilian Atlantic rainforest, Maciel-Silva and coworkers found that female-biased sex ratios and low rates of fertilization are typically balanced by high production of reproductive structures at the beginning of the reproductive cycle.

These same 11 species expressed sexual organs continuously over the 15-month period of study (Maciel-Silva & Valio 2011). Nevertheless, male gametangia are typically mature by the end of the dry season, with fertilization occurring during the wettest months. Female gametangia, on the other hand, are receptive over the entire period, with many maturing before the rainy season begins. Male gametangia experience a high abortion rate and take longer to develop. This pattern of male gametangia taking longer to develop is typical of bryophytes in many parts of the world. Sporophytes subsequently develop during the dry season, dispersing their spores toward the end of the season. Although the patterns of gametangia and sporophyte development differ among the species, it does not differ between the sea level and montane sites.

Figure 65. *Acrolejeunea fertilis*, an autoicous species with good sporophyte production. Photo by Heino Lepp, Australian National Botanic Gardens, with online permission for non-commercial use.

In Mexico, two dioicous species of *Syntrichia* [*S. fragilis* (Figure 66), *S. amphidiacea* (Figure 67)] are abundant (Mishler 1988). Both produce sporophytes only in limited circumstances within their range. Nevertheless, they are just as abundant in areas where sporophytes are rare or absent. This suggests that they must rely heavily on asexual reproduction in these areas.

Dwarf Males

The genus *Macromitrium* is well known not only for its two sizes of spores (see below), but also for its dwarf males. Having tiny males (<1 mm tall) permits the spores to germinate and the tiny plants to reach maturity on the female plants, often very close to the archegonia of the female. This does present a serious inbreeding probability, but the great advantage of having many more sperm be successful in reaching a female seems to outweigh the disadvantages, particularly for epiphytes (Ando 1977) where sperm dispersal is especially difficult.

Ramsay (1987) reported that at least 23 genera of mosses in tropical north Queensland, Australia, have dwarf males. Some are facultative (physiologically determined), being dwarf only when the spore germinates on a female plant. Others are obligate (genetically determined), always forming dwarf males from the male spore. Both types are present in among species of *Macromitrium* (Ramsay 1979; Une 1985).

Propagules and Regrowth

Some widespread tropical bryophytes do not produce capsules and spores, usually due to absence of the opposite sex, poor gamete dispersal, or unsuccessful development of the sporophyte. Olarinmoye (1986) examined survival strategies of the mosses *Hyophila crenulata* (see Figure 68), *Barbula lambarenensis* (see Figure 69-Figure 70), and *Fissidens asplenioides* (Figure 71) in Ibadan, Nigeria. He established that survival strategies during unfavorable periods of drought could be as spores (only in *Hyophila crenulata*), gemmae, and regrowth from the gametophores, as well as regrowth from rhizoids, shoot bases, apices, and the main stem. Rhizoids produce more regrowth than do shoot apices and main stems. He considered the production of spores in *H. crenulata* to give it a competitive advantage. Nevertheless, the gemma production and success of the other two species seems to more than compensate for lack of spores, as witnessed by their abundance and widespread distribution there.

Propagule Forms

Tropical moss gemmae do not seem to have the same limited number of forms as do liverwort gemmae. Odu (1987) found a "great multiplicity of forms" among the gemmae in tropical West African mosses. These occur in a variety of locations, including leaf and leaf axils, and sometimes occur in more than one type of location. Odu concluded that gemmae are of "immense ecological importance" to the tropical mosses. This is facilitated in **Calymperaceae** (Figure 52) by rapid germination – within 1-2 days after becoming dislodged from the leaves. In **Bryaceae**, asexual propagules are often produced as multicellular rhizoidal tubers (Figure 72). In addition to these, there may be gemmae in leaf axils and on rhizoids. As in **Calymperaceae**, gemma germination is rapid, within 2-3 days. In southern Nigeria, some species of **Pottiaceae** (Figure 68-Figure 70) have few male plants and hence rely on gemmae.

Figure 72. *Bryum dichotomum* rhizoidal tuber, a common means of reproduction in West Tropical Africa. Photo by Des Callaghan, with permission.

Calymperes (Figure 52) is one of the prominent gemmiferous mosses in the tropics. When examining *C. afzelii* (Figure 73) and *C. erosum* (Figure 74) Odu and Owotomo (1982) found that the shoots are **dimorphic** (having two forms). That is, the first leaves to develop do not produce gemmae. Later leaves are gemmiferous (Figure 74), and these alternate in coordination with the dry and rainy seasons.

Figure 74. *Calymperes erosum* with gemmae; this species does not produce gemmae on its first shoots. Photo by Li Zhang, with permission.

Egunyomi (1984) surveyed the asexual **diaspores** (propagule; any structure that functions in plant dispersal) of mosses in Nigeria. He recognized two major categories: caducous shoots and gemmae. Species with one or more of these asexual diaspores comprise 15% of the Nigerian moss flora. He considered this means of reproduction to be especially important for mosses that do not produce sporophytes in all or part of their range. Seven of these species are sexually sterile.

The miniature **caducous** (can break away from the stem) shoots are often found with rhizoids (Egunyomi (1984). Species with this type of diaspore include *Trachycarpidium tisseranti* (see Figure 75), *Archidium* sp. (Figure 76), *Bryum argenteum* (Figure 77), *B. coronatum* (Figure 78), *Bryum nitens*, and *Campylopus* (Figure 79) species. The latter two are strongly caducous.

Figure 81. *Jaegerina scariosa*, a species that produces protonemata and single-layered gemmae in leaf axils. Photo courtesy of Lucas Matheus da Rocha.

The second type is the **gemma** (Egunyomi 1984). In some, these are **uniseriate** (having only one cell layer) and produced from protonemata in leaf axils. This type includes *Splachnobryum gracile* (see Figure 80), *Jaegerina scariosa* (Figure 81), *Henicodium geniculatum* (Figure 82), and *Bryum argenteum* (Figure 77). Production of rhizoidal gemmae in *Splachnobryum gracile* and *B. argenteum* seems to be related to the high humidity where they were collected. Another type of gemma is borne on **excurrent** (extending beyond leaf tip) **costae** (leaf rib) and is **clavate** (club-shaped, like a baseball bat). Species with these include *Calymperes erosum* (Figure 74), *C. afzelii* (Figure 73), *C. palisotii* (Figure 52), and *C. rabenhorstii*. *Calymperopsis martinicensis* produces filamentous gemmae that occur in splash cups at the shoot apex. In *Octoblepharum albidum* (Figure 13), the gemmae occur at leaf apices and along the margins. Multiseriate gemmae occur in *Semibarbula lambareneis* and *Hyophila crenulata* (see Figure 61). *Gemmabryum apiculatum* (see Figure 83-Figure 85), and *Anoetangium spathulatum* (see Figure 86) produce **tubers** (Figure 85). These tubers are present on rhizoids in the soil and can germinate when the soil is disturbed. This can occur when wet season rains first disturb the soil. Tubers are able to remain viable 9-12 months after collection.

In Australia, Ramsay (1987) reported a variety of asexual reproductive types from the tropical north Queensland mosses. These include plantlets on leaf tips (*Octoblepharum albidum*), fragile leaf apices (*Groutiella tomentosa*), gemmae on leaf surfaces (*Macromitrium brevicaulis*, *Syrrhopodon* sp., *Calymperes tenerum*, *Clastobryella*), gemmae on leafless stem apices (*Trachyloma diversinerve*), or axillary toward stem apex (*Trachyloma watsii*), Flagellate julaceous shoots (*Taxithelium watsii*, *Wijkia extenuata*); shedding of whole leaves (*Arthrocnemum* sp.).

Fragments

In many cases throughout the world, fragments of bryophytes are important in producing new colonies [see, for example, *Octoblepharum albidum* (Figure 13) Egunyomi *et al.* 1980]. Nadkarni *et al.* (2000) tested the interception and retention of bryophyte fragments on branches in a tropical montane cloud forest in Costa Rica. They found that for canopy-dwelling tracheophytes, establishment of bryophytes frequently occurs first. Most fragments don't succeed in becoming established, but about 1% do adhere and become established when dropped from above. On the other hand, 24% were retained among undisturbed bryophytic epiphytes during the 6-month study and 5% were retained on stripped branches.

One of the more uncommon means of dispersal is through specialized branches that can break off easily. In the epiphytic, dioicous *Meteoriopsis undulata* (Figure 87), a recent addition to the Australian Wet Tropics flora, Meagher and Cairns (2016) found flagellate branches that break off when dry. Sexual reproduction is unknown in *M. undulata*. *Floribundaria walkeri* (Figure 88) is a relatively uncommon species in these Wet Tropics and also has flagellate branches. But in this case, the branches are not specialized, but rather are extensions of normal branches.

Figure 88. *Floribundaria walkeri*, a species that produces flagelliform ends on its branches. Photo by Manju Nair, through Creative Commons.

Spore Size

Richards (1984a) found that sun epiphytic mosses usually have larger spores than do shade epiphytes. This would provide a better energy source for establishment of sun mosses, whereas shade mosses would more opportunity for dispersal. Spore size seemed to be unimportant among liverworts, but van Zanten and Gradstein (1988) determined that some shade liverwort epiphytes had spores with much less drought resistance, failing germination after only a few days of desiccation. This lack of drought resistance greatly limits dispersal range.

Diaspore Banks

Diaspore (structure that functions in plant dispersal; propagule) banks provide temporary refuge for spores, gemmae, and sometimes fragments, particularly in habitats that are frequently dry (During & Moyo 1999).

Egunyomi (1979b) tested longevity of spores from Nigeria by keeping them at room temperature and humidity for 1-3.5 years. Subsequent germination ranged from 0 to 92%. Fifteen of 21 species had no germination after that time. Only four species [*Weisiopsis nigeriana*, *Microcampylopus nanus* (see Figure 89), *Mittenothamnium overlaetii* (see Figure 90), *Weissia*

papillosa (see Figure 91)] had at least 50% germination after two years. *Calymperes erosum* (Figure 74) survived at least 1 year with 71% germination. *Microcampylopus nanus* and *Weissia papillosa* had 75 and 76% survival, respectively, of alternate wetting and air drying every 24 hours for four weeks following two years of desiccation. None of the four species with 50% germination listed above survived 4 weeks at -2° following 2 years of desiccation. All four species had at least 43% survival for 4 weeks at 8°C following 2 years of desiccation, with *Microcampylopus nanus* having 80% and *Weissia papillosa* having 81%. Continuous submersion in water was as detrimental as freezing, with none of the four species surviving up to 3 weeks and the highest survival after one week was only 31% (*Weissia papillosa*). Egunyomi suggested that the submersion led to deterioration of the spores due to fungal attack.

Zander and During (1999) noted that diaspore banks often harbor the small species with a short life cycle that make them difficult to find above ground. They found *Uleobryum occultum* (Figure 92) (new to Africa, a moss species formerly known only from Brazil and Australia) and *Bryocephospora aethiopica* (Figure 93) (new to Zimbabwe). They also described a new species of the moss family Pottiaceae – *Neophoenix matoposensis* (Figure 94) from the diaspore bank of an experimental fire plot in Zimbabwe.

Figure 92. *Uleobryum occultum*, a species known from diaspore banks in Zimbabwe. Photo by Claudio Delgadillo Moya, with permission.

Figure 93. *Bryocephospora aethiopica* with capsules, a species known from diaspore banks in Zimbabwe. Photo by Claudio Delgadillo Moya, with permission.

Figure 94. *Neophoenix matoposensis*, a new species discovered from a diaspore bank in Zimbabwe. Image modified from drawing by Patricia Eckel in Zander & During 1999.

Maciel-Silva *et al.* (2012b) examined the properties of diaspore species in diaspore banks in the tropical rainforests. They compared species from the Atlantic rain forest (montane and sea level) in Brazil. Of the species identified, 68 were from bark, 55 from decaying wood, and 22 from soil. These species numbers differed little between sites. Mosses predominated, and monoicous species were more numerous than dioicous species. There was little pH effect on shoot emergence. The extant vegetation was well represented, with gemmae and spores making a high contribution. The researchers postulated that the diaspore banks contribute to fast establishment of species after disturbance of the tropical rainforests, as well as contributing to succession there. This is particularly true for species that produce lots of gemmae or monoicous mosses with a large commitment to sexual reproduction.

Bisang *et al.* (2003) germinated diaspores from Malaysian soil. Many of the germinated plants could not be identified and lived only a short time. Two moss species germinated from stem fragments – *Isopterygium* (Figure 95) and possibly *Ectropothecium* (Figure 96). The diaspore origin of the third identifiable moss, *Calymperes* (Figure 52), could not be determined.

Figure 95. *Isopterygium tenerum*; the genus *Isopterygium* was among those that germinated from diaspore banks in the Malaysian mountain rainforest. Photo by Scott Zona, with online permission.

Figure 96. *Ectropothecium* sp., a genus tentatively identified among those that germinated from diaspore banks in the Malaysian mountain rainforest. Photo by Niels Klazenga, with permission.

Diaspore banks can be especially important after a major disturbance such as a fire (During 1998, 2007). In his study in southern Zimbabwe, During found emergence of 2 hornworts, 10 liverworts, and 22 mosses from surface soil samples of the savannah Matopos Sandveld Fire Plots. Annual burning did not seem to harm the diaspores hidden in the soil.

Conditions are not good for sexual reproduction in the tropics. Even if the plant has successful fertilization, sporophyte maturation and dispersal might not be successful. For example, in *Bryum coronatum* (Figure 78), sporophytes are common in Nigeria (Egunyomi 1982). Nevertheless, Egunyomi found 42% of the capsules remained undehiscent even in the dry season. Furthermore, 41% of the setae had no capsules. On the other hand, spore germination was successful 65-88% of the time, but the protonemata exhibited abnormal growth. Egunyomi suggested that the numerous axillary propagules were important in dispersal in this species.

Prolonged Protonemal Stage

One adaptation to the short growth period is to prolong the duration of the protonema. As Gradstein and Wilson (2009) put it, this can be interpreted as a short-cut in the life cycle that permits rapid maturation and reproduction,

both providing benefits in unstable, impermanent habitats. In this extreme, it is known as **neoteny**. The most extreme of these are in bryophytes that produce capsules directly on the protonema. The thalloid type occurs only among epiphyllous bryophytes. In the tropics, the epiphytic moss *Ephemeropsis* (Figure 97-Figure 98) produces persistent thalloid protonemata.

Figure 98. *Ephemeropsis tjibodensis* protonematal mat on palm in Fiji. Photo by Tamás Pócs, with permission.

Liverworts

Liverworts in general produce gemmae more commonly than do mosses. And many of them are more sensitive to desiccation and low humidity. This leads to some differences in their adaptations to living in the tropics.

Monoicous vs Dioicous

Schuster (1988) surmised that sexuality of liverworts shifts to **monoicous** (both sexes on same plant) in the tropics, with *Plagiochila* (Figure 99) being a notable exception as entirely **dioicous** (sexes on separate plants). Schuster considers the ability of monoicous taxa to easily achieve fertilization to be an advantage on impermanent substrata such as leaf surfaces, twigs, and even tree trunks.

Figure 99. *Plagiochila* sp., a dioicous tropical leafy liverwort. Photo by Lin Kyan, with permission.

Neoteny

The monoicous property is further enhanced by multiple examples of **neoteny** (ability of juvenile plants to reproduce, *e.g.* species of *Cololejeunea* (Figure 100-Figure 102), a condition known for liverworts only in the tropics (Schuster 1988; Gradstein *et al.* 2006). Gradstein and Wilson (2009) note that botanists have interpreted neoteny as a short-cut in the life cycle because it permits rapid maturation and reproduction, an advantage in unstable, impermanent habitats. This is especially important for those species, like *Cololejeunea* species, that live on such temporary substrata as leaves (Schuster 1988; Gradstein *et al.* 2006). The high level of reproduction, especially sexual reproduction, coupled with the high diversity of niches in tropical forests, has resulted in a large number of liverwort taxa. In some cases, the leafy liverwort gametophyte is replaced by a large and persistent protonema (Figure 102) (Gradstein & Wilson 2009).

Figure 100. *Cololejeunea cardiocarpa* archegonium and antheridia exhibiting neoteny. Photo by Paul Davison, with permission.

Figure 101. *Cololejeunea minutissima*; members of *Cololejeunea* exhibit neoteny in the tropics. Photo by Michael Lüth, with permission.

Figure 102. *Cololejeunea borhidiana* dwarf male, an extreme case of neoteny. Image by Tamás Pócs, slightly modified, with permission.

Reduced Numbers of Antheridia and Archegonia

Many temperate liverwort taxa produce numerous antheridia (5-16) and archegonia (12-25) (Schuster 1988). This is wasteful since only one archegonium on a branch can successfully produce a sporophyte. In tropical liverworts, these numbers are reduced to a more typical 1-4 archegonia and 1-2 antheridia per set of bracts (Figure 100). Furthermore, the size of gametangial branches is reduced (Figure 102) in many tropical taxa. Since gametes are typically released during the wet season, the danger of their drying out without achieving fertilization is reduced.

One rather unusual tropical leafy liverwort is *Colura irrorata* (Figure 103), a **rheophilous** (thrives in running water) member of **Lejeuneaceae** that grows part of the year submerged in torrential water (Figure 103). It was long known only from the banks of the Rio Topo in the Pastaza province of Ecuador (Thiers 1988) where it was discovered by Richard Spruce in 1857. It was long considered extinct until it was rediscovered there by Gradstein *et al.* (2004). A second locality of the rare species, in the same type of habitat, was recently found several hundreds of km further to the south in Ecuador (Gradstein & Benitez 2014). The species is more robust and has a more complex structure than other members of the **Lejeuneaceae**, but its most outstanding feature is its reproduction. Thiers (1988) estimated that a 2-cm section of stem could produce as many as 1600 **gynoeceia** (archegonia and surrounding bracts, *i.e.* female reproductive structures).

Figure 103. *Colura irrorata*, a species that produces up to 800 gynoeceia per cm. Photo by Lou Jost, through Robbert Gradstein.

Short Life Cycles

These tropical liverworts enjoy short life cycles (spore to spore), with epiphyllous species completing a full cycle in one year and those on other substrata in 2-3 years (Schuster 1988; Piippo 1992). This is enhanced by green spores (Figure 104) that are able to germinate immediately, and that predominantly germinate within the capsule (Schuster 1988). Despite these indicators that long-distance dispersals are unlikely, there is ample evidence that at least some of them are successful.

One example of the spore germination for a common tropical species is that of the leafy liverwort *Frullania ericoides* (Figure 104-Figure 105) (Silva-e-Costa *et al.*

2017). This species is **endosporic** (spores divide within spore wall), producing a globular protonema within the spore wall. By the fourth week, the protonema breaks through the spore wall and produces tightly concave primordial leaves. This germination occurs at 1/4, 1/2, full, and 1 1/2 strength Knop's nutrient solution, but fails to occur at double strength solution. This suggests nutrient requirements for successful germination are relatively low (compared to that of tracheophytes) and that nutrient-rich substrates would be detrimental to these liverworts.

Alfayate *et al.* (2013) examined the spores of four pleurocarpous mosses in the Canary Islands, islands with a subtropical climate. They found that two of these were **isosporic** (all spores same size), but *Leucodon canariensis* (Figure 106) had two size classes of spores: medium-sized 1-celled spores and large multicellular spores. Furthermore, *Cryptoleptodon longisetus* (see Figure 107-Figure 108) has two sizes of spores, small spores and medium-sized spores. Spores germinate within the capsules in three of these species: *Leucodon canariensis*, *Cryptoleptodon longisetus*, and *Neckera intermedia* (Figure 109). *Neckera cephalonica* (Figure 110) spores do not germinate in the capsule. The perine wall of the spores of these species is papillose, an uncommon character for spores. The spores contain abundant lipid-like structures and chloroplasts with well-developed thylakoids.

Short Spore Longevity

Tropical liverwort spores have a short longevity and are unable to survive desiccation (Schuster 1988). Rather, they have several adaptations for rapid germination. They are typically **endosporic** (germinating and beginning development within spore wall; Figure 104), spores germinate within the capsule, and spores have elastic walls to facilitate development.

Prolonged Protonemal Stage

Several liverworts have remarkably prolonged protonemal stages, as in *Radula yanoella* (Figure 111) from the Amazonian rainforest (Thiers 1988; Gradstein & Wilson 2009). This species has since been found in French Guyana, Ecuador, and Costa Rica (Gradstein & Ilkiu-Borges 2009). In *Protocephalozia ephemeroides* (Figure 112) and *Cololejeunea metzgeriopsis* (Figure 113-Figure 114; syn.=*Metzgeriopsis pusilla*), the protonemal stage

replaces the leafy gametophyte except in association with the reproductive structures (Gradstein *et al.* 2006). *Metzgeriopsis pusilla* was formerly considered the only species in its genus, but has since been placed in *Cololejeunea* as *C. metzgeriopsis* (Gradstein & Wilson 2009). It lives in humid montane forests of tropical southeast Asia, growing as an epiphyll on living leaves. Its thallus is unistratose with minute, leafy sexual branches arising from the margins. *Protocephalozia ephemeroides* is a very rare liverwort, known only from two localities in southern Venezuela, near the border with Brazil, where it was collected by Richard Spruce. There it was growing on moist earth in shade and on little mounds "thrown up by mud worms." Thiers (1988) suggests that the normally short-lived liverwort protonemal stage has been lost in these taxa, replaced by a long one, because of the always abundant moisture. The protonemal stage of most bryophytes is typically subject to damage from rapid drying. This protonema can be thalloid, as in the liverworts *Cololejeunea metzgeriopsis* (Figure 114) and *Radula yanoella* (Figure 111), or filamentous, as in the leafy liverwort *Protocephalozia* (Figure 112) (Gradstein & Wilson 2009).

Types of Gemmae

Even gemmae differ between the tropics and temperate zones (Schuster 1988). In temperate zones, the commonest types of gemmae are 1-2 cells and occur in branching chains (Figure 115). As such, they are easily dispersed, much like spores. These small gemmae occur in the **Jungermanniales** [*e.g.* **Cephaloziaceae** (Figure 116), **Calypogeiaceae** (Figure 117-Figure 118), **Scapaniaceae** (Figure 119-Figure 121), **Lophoziaceae** (Figure 122-Figure 124), **Cephaloziellaceae** (Figure 125-Figure 126)]. A single shoot can produce thousands of gemmae in a single growing season. This type of gemma is not so common in the tropics, where the more common **Porellales** (including **Lejeuneaceae**; Figure 127-Figure 128) have large gemmae. Instead, many tropical species tend to have discoid and single-layered gemmae, permitting easy dispersal to "considerable distances." The number of types is more limited, including discoid gemmae (Figure 128) and **caducous** (deciduous) branches (Figure 129). Even fragmenting branches are rare in the tropics. Gemmae are in general less common and less important among sexually reproducing tropical liverworts, even though many liverworts may produce both gemmae and sexual organs.

Another anomaly among tropical liverworts is that gemmae and sexual organs can be produced at the same time, as in many species of *Cololejeunea* (Figure 127-Figure 128, Figure 130-Figure 131) (Schuster 1988). By contrast, in temperate regions many species of *Lophoziaceae* and *Scapaniaceae* (Figure 132) may

produce gemmae and sex organs at the same time. Their gemmae are typically produced in response to submarginal growth conditions that would often suppress production of sex organs.

Van Zanten and Gradstein (1987) found that spores of endemic liverwort species had less resistance to drying and freezing than did the transoceanic species of Colombian liverworts. When subjected to intercontinental transport on the wing tips of a jet airplane, spores of 60 out of 61 species became inviable, presumably due to high UV levels

at jet stream levels. Only spores of two species growing at high elevation (ca. 4000 m) were able to germinate after the flight. Probably they were well-adapted to UV radiation. On the other hand, van Zanten and Gradstein found that wet freezing permitted survival. They suggested that liverworts from high altitudes had a "good possibility" for aerial long-distance dispersal through hurricanes and tropical storms.

Diaspore Banks

Bisang *et al.* (2003) cultured diaspores from three Malaysian mountain rainforests. They found that more liverworts than mosses germinated in the samples, especially those from lower altitudes. Samples from higher elevations produced twice the species diversity compared to those from lower elevations. They were able to identify the liverworts *Calypogeia arguta* (Figure 133), *C. fusca*, *Lepidozia wallichiana* (Figure 134), and *Zoopsis liukuensis* (Figure 135), all common taxa in the collection area. The diaspore origin of the liverworts could not be determined.

Rheophilic Adaptations

River banks present problems unique to that habitat. The leafy liverwort *Cololejeunea stotleriana* (Figure 136) from Ecuador presents a highly specialized morphology and represents adaptations to that habitat (Figure 137) where little study has occurred (Gradstein *et al.* 2011). This species is both rheophilous and epiphyllous. Its adaptations include a robust stem, flatness, triangular lobules, large rhizoid fields not produced near each leaf base, super fertility, and clustered gynoecia. It was growing with the rare mosses *Fissidens hydropogon* (Figure 138) and *Lepidopilum caviusculum* (Figure 139).

Dispersal

Norhazrina *et al.* (2016) considered bryophytes to be very good dispersers, especially in contrast to flowering plants. This superior dispersal of bryophytes may lead to similar species richness patterns among the tropical regions, although tropical Africa has significantly fewer species than tropical America and tropical Asia. They found a slight but significantly higher beta diversity within tropical regions than among them. For many locations, oceans act as a barrier to "routine" dispersal, causing large-scale floristic patterns.

Suitable dispersal differs among regions and habitats. The tropics is in some places remote, separated from propagule sources by a wide expanse of ocean, and in others a mountain-valley topography likewise provides an expanse of unsuitable habitats. Thus, in discussing an area as expansive as the tropics, dispersal considerations are important for both biogeography and ecology.

With no experimental evidence but with vast ecological experience in the tropics and other regions, Richards (1988) ventured to apply his experience to hypothesize about dispersal of bryophytes in the tropics. First, he noted the impermanent nature of tropical substrates and suggested that these conditions would require efficient short-distance dispersal. He furthermore noted that each microhabitat has a distinct synusia of bryophytes that are characterized by particular life forms and life strategies. The swampy or oft-flooded sites are usually richer in species than sites that are well drained. The undergrowth probably has less effective wind dispersal than does the canopy.

For various asexual diaspores, splash is probably important (Richards 1988). For example, *Calymperopsis* species in Africa, as noted above, have their gemmae in splash cups. And discoid *Lejeuneaceae* (Figure 130-Figure 131) gemmae are probably dispersed by splashing rainfall. Richards also considered it likely that birds disperse fragments, particularly of *Meteoriaceae* (Figure 32-Figure 33), when they gather the mosses for nest building.

Baas-Becking (1934) introduced the concept that "everything is everywhere" for small things that can be dispersed by wind. The tropics seem like a good place to test this concept for bryophytes. Shaw *et al.* (2005) considered global patterns of moss diversity, patterns that must to some degree reflect dispersal patterns. Based on 86 globally distributed taxonomic checklists, they concluded that mosses are not more species-rich in the tropics than elsewhere. On the other hand, analysis of only North, Central, and South American samples demonstrate that a latitudinal gradient is apparent. Molecular diversity suggests that moss diversity is highest in the Southern Hemisphere, thus lowest in the Northern Hemisphere. The tropics are intermediate. These differences, however, are small, and essentially all moss lineages are represented in all three latitudinal zones. Hence, their data support the "everything is everywhere" hypothesis (Baas-Becking 1934) that is evident among many organisms with small

propagules. (See Chapter 4-8 for more information on the topic of "everything is everywhere.")

But liverworts seem to exhibit a somewhat different pattern, more closely mimicking the distribution patterns of the tracheophytes (Schuster 1969). Schuster cites as evidence their patterns of endemism and disjunction, as well as their having highly specific, restricted ranges. He cites further support from the high number of species of liverworts in the Arctic. Nevertheless, some taxa, especially the **monoicous** (both sexes on same plant) ones, seem to have wide spore dispersal, as suggested by their presence on islands in the Mid-Atlantic and Indian Ocean ridges. Interpretation is complicated by our inability to distinguish between ancient "overland" dispersal and more recent dispersal by spores. But in 1969, tropical liverworts were poorly known. Can we still support Schuster's (1969) distributional conclusions today?

Based on analysis of a large, world-wide data set of species distributions, Wang *et al.* (2016) found a clearcut latitudinal diversity gradient in liverworts and hornworts. The highest species richness was found in the tropics, which they explained by the explosive diversification of some of the most speciose liverwort lineages, such as **Lejeuneaceae** (Figure 36-Figure 39, Figure 65, Figure 101-Figure 103, Figure 113-Figure 114, Figure 127-Figure 131, Figure 136), **Plagiochilaceae** (Figure 99), and **Frullaniaceae** (Figure 14, Figure 105) in the humid tropical forests. But they also noted that there is much evidence to suggest that dispersal is not limiting, and that long-distance dispersal is common among bryophytes. In fact, bryophytes exhibit a much lower global turnover of **beta diversity** (ratio between regional and local species diversity) than do flowering plants and maintain relatively constant levels of **alpha diversity** (local species richness) on a gradient of geographical isolation (Patiño *et al.* 2015).

New ideas are emerging suggesting that islands, including tropical islands, are sources of diversity instead of the previously thought evolutionary dead ends and diversity sinks (Patiño *et al.* 2015). The dead end concept was based on "perceived low levels of genetic diversity, poor interspecific competitive and defensive ability, and loss of dispersal capacities." But bryophytes do not fit well into this model. They have high dispersal capabilities compared to most tracheophytes, and when genetic diversity was examined, it proved to be higher in island populations than in continental populations. Patiño and coworkers suggest that rather than being evolutionary dead ends for such organisms as bryophytes, islands become sources of diversity for bryophytes that subsequently disperse to continents. They also found that species richness of islands correlates by habitat diversity, not by size or age of the islands or distance to the continent, hence is not driven by dispersal.

Karlin *et al.* (2012) examined genetic diversity on the remote Hawaiian Islands in the Neotropics. Because of this remoteness, the popular opinion was that long-distance dispersal to the islands was rare. In

their investigation into the population genetic diversity, the researchers concluded that the peat moss *Sphagnum palustre* (Figure 140) most likely arrived with a single dispersal event. This species lacks sporophytes on the Hawaiian Islands and most likely lacks sexual reproduction. Further evidence to support a single dispersal event is that all samples share a rare genetic trait. They concluded that the original Hawaiian dispersal event was from vegetative propagation.

Figure 140. *Sphagnum palustre*, a species that apparently arrived on the Hawaiian Islands as a single dispersal event. Photo by Bernd Haynold, through Creative Commons.

Bryophytes exhibit a high capacity for transoceanic dispersal (Lewis *et al.* 2014) when compared to flowering plants (Patiño *et al.* 2014). This thinking is further supported by the low levels of competition among bryophytes compared to that among flowering plants (Rydin *et al.* 2009). This low competition suggests that the niche preemption hypothesis (Whittaker & Fernández-Palacios 2007) does not apply to bryophytes and thus makes it easier for them to succeed when they arrive on an island or subsequently on a new continent. The clonal nature of bryophytes (Cronberg *et al.* 2006; Hutsemékers *et al.* 2010, 2013; Karlin *et al.* 2011; Patiño *et al.* 2013), and their ability to disperse viable fragments means that the minimum population size is quite small (Bengtsson & Cronberg 2009) and further enables them to succeed when they colonize. Thus, as indicated by a compilation of data, island populations of bryophytes are not necessarily genetically depauperate (Fernández-Mazuecos & Vargas 2011; Laenen *et al.* 2011; Désamóré *et al.* 2012; García-Verdugo *et al.* 2015). Even seed plants can have a larger genetic diversity on islands than in associated continents (Désamóré *et al.* 2012). Based on these studies, and particularly that of Patiño *et al.* (2015), it is likely that the Macaronesian archipelagos, including the tropical portion, have provided a stepping stone for trans-continental bryophyte immigration to other tropical regions in new continental locations. Hence, islands may help to explain the **pantropical** (distribution covers tropical regions of both hemispheres) distribution of many bryophytes.

Another possibility, potentially as an additional scenario rather than a preferred one, is that islands can serve as refugia during times when the continent becomes uninhabitable. Such seems to be the case for the leafy

liverwort *Radula lindenbergiana* (Figure 141) in Macaronesia (Laenen *et al.* 2011). It appears that a number of European plants, including *R. lindenbergiana*, share a Macaronesian common ancestor and that these species may have back-colonized Europe. The widespread (including tropical Africa and tropical America) aquatic moss *Platyhypnidium riparioides* (Figure 142-Figure 143) likewise supports the concept that oceanic islands serve as major sources of biodiversity for recolonization of continents following glaciation (Hutsemékers *et al.* 2011). The lack of morphological diversity among the bryophytes, but presence of high genetic diversity, reflects the simple structure of the bryophytes.

Figure 141. *Radula lindenbergiana*, a species that seems to have used Macaronesia as a refugium. Photo by Dick Haaksma, with permission.

Figure 142. *Platyhypnidium riparioides* in its usual habitat. Photo by Hermann Schachner, through Creative Commons.

Figure 143. *Platyhypnidium riparioides*, a species that exhibits some genetic variation along its river course, using mostly fragments as dispersal units. Photo by Hermann Schachner, through Creative Commons.

For the moss *Platyhypnidium riparioides* (Figure 142-Figure 143), Hutsemékers *et al.* (2013) found that some genetic variation occurs along the river basin and indicates that this widespread aquatic moss has weaker dispersal than that expected for pollen or wind-dispersed seeds. Rather, it appears that fragments are more important than spores for local dispersal of this moss, thus explaining the low levels of genetic diversity.

Even the dispersal-limited dung moss *Tetraplodon* (Figure 144) has **amphitropical** (distributed on both sides of the tropics) and bipolar (distributed in cold temperate regions) disjunctions that seem to require long-distance dispersal (Lewis *et al.* 2014). Lewis and coworkers suggested that the disjunct distribution in the Western Hemisphere may have been accomplished through stepwise migration along the Neotropical Andes. But *Tetraplodon* is typically dispersed by flies that provide only short dispersal ranges. Furthermore, experiments indicate that the spores of *Tetraplodon* cannot survive long-distance dispersal by wind. The researchers suggest that instead, birds might provide the dispersal vector necessary to account for the widespread but disjunctive distribution of the species in South America.

Figure 144. *Tetraplodon mnioides*, an amphitropical moss, with the toad *Nannophryne variegata* in South America. Photo by Filipe Osorio, with permission.

In examining bryophytes on oceanic islands, Patiño *et al.* (2013) concluded that even bryophytes exhibit an island syndrome. They exhibit genetic drift, indicating relatively slow migration rates between the oceanic islands and continents. This suggests that the ocean does impede migration. This period of isolation seems to lead to an increase in production of specialized asexual diaspores and a decrease in sporophyte production on the oceanic islands.

To demonstrate the relatively large number of Afro-American distributions in bryophytes, Gradstein (2013) examined records of liverworts in tropical regions of both Old World and New World tropics. Based on the disjunctions of 74 liverworts in 13 genera with Afro-American ranges, he estimated that about 5% of the

Neotropical and 8% of the African liverwort species had Afro-American disjunct distributions. This number is doubled when pantropical species are included. Gradstein cited spore dispersal experiments and molecular-phylogenetic studies to conclude that for the majority of these genera, long-distance dispersal was the reason for the disjunction.

Ah-Peng *et al.* (2010) demonstrated the high bryophyte diversity on the small, oceanic La Reunion Island. In only 2512 km², 776 taxa are known. This island is near East Africa and Madagascar. The high diversity is fostered by its subtropical climate, a high altitudinal range (to 3070 m asl), and high rainfall.

Much of our understanding of long-range dispersal comes from van Zanten (1978; van Zanten & Pócs 1981; van Zanten and Gradstein 1987). In their laboratory experiments using 86 Colombian liverwort species, van Zanten & Gradstein (1987) found that spores of transoceanic species were more durable than those of endemic species. Survival was also greater in wet air-currents at high altitudes than in dry air currents. When they placed the spores on airplane wing tips during flights at jet stream elevation from Amsterdam to Los Angeles and back, however, only two species, the endemic *Marchantia chenopoda* (Figure 145) and the transoceanic *Gymnocoleopsis cylindriformis*, could survive. All others were dead, probably due to exposure to UV radiation. Presumably *G. multiflora* spores survive because this species grows in the high Andes above 4000 m, where UV radiation is high. Van Zanten and Pócs (1981) concluded that tropical lowland moss species are much less drought tolerant than are temperate species. These tropical species are, however, resistant to wet-freezing and can be dispersed over short distances by rain showers and typhoons. They concluded that north-south dispersal across the equator was the most difficult and occurred rarely, if at all.

Figure 145. *Marchantia chenopoda* archegoniophores, a species whose spores can survive flight on the wings of a jet plane. Photo by Janice Glime.

Dispersal by wind is considered limited in forests, except in the canopy (Richards 1988). Some species, such as African moss species of *Syrrhopodon* (Figure 146) subsect. *Calymperopsis*, produce gemmae in splash cups similar to those of the moss *Tetraphis pellucida* (Figure 147). Although experimental dispersal studies are lacking for tropical species, but Richards suggests that the discoid

gemmae (Figure 128) of many of the **Lejeuneaceae** (Figure 130-Figure 131) are probably dispersed by splashing rain. Hanging mosses get dispersed by birds through dropped fragments when they are collected for nest making.

Figure 146. *Syrrhopodon albobaginatatus*; some species of this genus produce gemmae in cups in the tropics. Photo from Natural History Museum, London, through Creative Commons.

Figure 147. *Tetraphis pellucida* with gemmae cup and discoid gemmae – similar to those of African species of *Syrrhopodon*. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Dispersal adaptations reflect moisture relationships. The secretion of sticky mucilage (Thiers 1988) can aid in the attachment to vertical surfaces and prevent being washed away during rainstorms. Gemmae and the precocious development of spores permit more rapid development and thus greater chance for establishment. The prolongation of the protonemal stage may also aid in insuring attachment, whereas the **neotenus life cycle** (see under Liverworts above) permits early maturity, providing greater likelihood of completion of the life cycle before host leaves are shed during the rainy season.

I must re-emphasize the strategies of the **Lejeuneaceae** (Figure 36-Figure 39, Figure 130-Figure 131), a large pantropical family of considerable importance among the liverworts. This family has many monoicous species, and many species have intercontinental ranges, but all have large, multicellular spores – an atypical character for taxa with transoceanic distributions (Gradstein *et al.*

1983; Gradstein & Pócs 1989). Nevertheless, the multicellular large spores should permit the species to become established more easily once they arrive because of greater food reserves to permit a quick start. And the monoicous character facilitates sexual reproduction.

Although I have discussed the flying fox in volume 1, a discussion of dispersal in the tropics cannot be complete without the recalling this unique mechanism for some bryophytes in the Wet Tropics of northeastern Australia. Parsons *et al.* (2007) found that the spectacled flying fox *Pteropus conspicillatus* (Figure 148) spreads bryophyte fragments in its feces (Figure 149). When the researchers cultured the feces, they found that the fragments were viable (Figure 150). Not only were there bryophyte fragments, but also live invertebrates and other organisms.

Sampling

Sampling in the tropics can present problems that are less important elsewhere – such difficulties as canopy height and excessive moisture. Mountainous areas may be remote, with some available only by foot paths. Tall trees make small branches of the canopy almost impossible to sample; methods to overcome this obstacle are in the subchapter on epiphytes. Several researchers have addressed the problems unique to bryological collecting in the tropics (Mori & Holm-Nielson 1981; Edwards 1986; Delgadillo 1987; O'Shea 1989; see Frahm *et al.* 2003 for a comprehensive review).

One important consideration when collecting in tropical countries is that researchers there are often struggling with inadequate herbarium materials, particularly ones that can be used for checking their own collections. Duplicate specimens should always be provided to an accessible herbarium in the country – one that has a curator and can loan specimens. And of course one should be aware of local collection laws, obtain proper collecting permits, and determine in advance what restrictions there might be by customs and plant control in both the country of collection and in the receiving country.

Delgadillo (1987) and Frahm *et al.* (2003) detail many things to consider before departing for the tropical country, behavior during the visit, and how to treat specimens from another country upon return home. He suggests researching the geography, customs, and language of the country and contacting one or more resident bryologists for suggestions on places to stay and places to sample. Obtain collecting permits in advance for each country you plan to visit. Be sure you have health insurance to cover you in the places you will visit. Follow the routines of the local herbaria and institutions you visit and take their advice on food, roads, and other items of local knowledge. Remember that appointment times are not as rigid in some countries, so be patient, especially with local natives who might help you. Be sure you provide the local herbaria or national herbarium with a set of identified specimens. If possible, use their herbarium specimens in their herbarium so you don't have to borrow from their typically small number of specimens. To get both loans and your own specimens back to your own country, use registered mail.

Be sure you understand the quarantine regulations in both countries. Avoid travelling in the field alone; taking a local student along can benefit both of you. Carry a first-aid kit and a letter of introduction from the local university or herbarium in case it is needed to satisfy local authorities. Upon returning home, return loaned specimens as soon as possible, being sure to meet quarantine requirements. Send a set of duplicate specimens from your own identified collections for any species you have not already deposited in a herbarium in the country visited.

Braun-Blanquet Sampling Method

While sampling may be more difficult in a tropical jungle, methods used elsewhere often work well. A common method of sampling vegetation, particularly in Europe, is the **Braun-Blanquet method**. This method uses a cover-abundance scale to describe the vegetation. These levels are divided into cover classes, typically using 5-7 categories:

- 1 <1
- 2 1-5
- 3 5-10
- 4 10-25
- 5 25-50
- 6 50-75

The levels are estimated through the use of **relevés**. This system has been applied originally to tracheophytes, but many bryologists have adapted it for a more efficient means of quantitative sampling. Poore (1955) criticized the system, but Moore (1962) countered those criticisms, stating that Poore had misapplied the method. Damgaard (2014) determined that despite its bias to over-estimate abundance, the Braun-Blanquet method gave results comparable to those of other methods of estimating plant cover. It has the added advantage of providing comparisons to the many studies that have used it, permitting data comparisons over time.

Wikum and Shanholtzer (1978) noted that most methods of measuring vegetation density are time-consuming and costly. The Braun-Blanquet method requires only about one-third to one-fifth the amount of field time, giving comparable results. I am unaware of any studies comparing the Braun-Blanquet system with other cover estimates for bryophytes, but it has been used in tropical studies and provides a relatively rapid method that is helpful when time is often quite limited.

A discussion of the unique methods for sampling epiphytes is in the subchapters on epiphytes and epiphylls in this chapter.

Drying Specimens

Because of periods of daily rain, there isn't enough time for anything to get dry, and that includes your clothes and your bryophytes. And both damp clothing and bryophytes can soon become a garden for molds. Molds make the bryophytes difficult to identify, and certainly make them unsightly, not to mention a health hazard. They introduce molds to the herbarium, and their spores can cause allergic reactions and asthma. They will also make it more difficult to get the bryophytes through plant protection agencies when you enter another country.

Frahm and Gradstein (1986) note these difficulties in the tropics, making several suggestions to overcome them.

One method that is used is to place the bryophytes in paper bags on a dry floor of a tent with open flaps (Frahm & Gradstein 1986). The opening is covered with mosquito netting to permit air movement. But during the rainy season, the dry periods are often insufficient for the bryophytes to dry. Some bryologists have resorted to putting a professional plant dryer in the back of a truck, using butane to provide the heat. But this method is not practical when only foot paths are available to the campsite. And most budgets can't afford such equipment. A less expensive approach is to suspend the bryophytes near a campfire, but the fire might get too hot and thus requires close watching. It can heat the bryophytes too much and thus damage them, particularly for those who might later want to use them for chemical analysis.

Frahm and Gradstein (1986) suggest an inexpensive, lightweight apparatus for drying bryophytes (Figure 151). It is constructed of L-shaped aluminum pieces with a frame that supports a wire mesh. Nylon should not be used because of its flammability. The heat source is two kerosene camping stoves (see also Croat 1979). The structure should then be surrounded with cotton cloth, as shown in the inset, again avoiding the more flammable nylon. The frames are about 1 m high, but the level of the screen can be adjusted to change the heat level. The apparatus should be monitored until you learn how much flame you need to avoid toasting the bryophytes or causing a forest fire. Once the ideal flame size is determined, the apparatus can be left unguarded overnight.

Figure 151. Light-weight drying apparatus for bryophytes in the field. From Frahm & Gradstein 1986.

Greene (1986) used chicken wire instead of wire screening. He suggested a method for keeping the specimens dry once getting them that way. They should immediately be put into large, heavy-duty plastic bags with silica gel to absorb moisture and sealed. [The plastic bags can be sealed by folding in the top corners, then folding down the top several times and fastening it with several large paper clips. – JG.] The specimens themselves can be kept in paper bags or packets. Greene transported the silica gel containers to the site in cotton bags. When they were needed, the silica gel containers were put into paper specimen bags and heated along with the specimens so that they were dry and ready when the specimens were stored.

Summary

Bryophytes in the tropics undoubtedly have a crucial role in water and nutrient retention, releasing nutrients during re-wetting, but filtering them from the lower branches and ground during rain events. Because of their sponge-like behavior, they can maintain moisture and nutrients for other members of the ecosystem. Nutrients can be released slowly, providing nutrients to the forest floor at critical times.

The primary environmental drivers determining the types of bryophyte communities are moisture, temperature, and light intensity. Life and growth forms differ among the habitats, with such forms as **pendants**, **fans**, and **tails** in moist habitats and **mats** and short acrocarpous mosses in dry conditions. Likewise, productivity differs with habitat, with dense growths in wet cloud forests and little biomass on the rainforest floor where there is little light penetration. Furthermore, growth periods and reproduction coincide with rainy periods, whereas the bryophytes are typically dormant in dry seasons.

Moss reproduction varies with habitat, but antheridia and archegonia are typically produced during the rainy season. **Monoicous** species have the most sexual reproduction. Many species lack sexual reproduction and spread through gemmae and regrowth. Sun species typically have larger spores than do shade species. Protonemal development is often prolonged.

Some liverworts and a few mosses may exhibit **neoteny**. Liverworts often have shortened life cycles, fewer antheridia and archegonia, longer spore lives, longer protonemal stages, and few types of gemmae in the tropics. Both mosses and liverworts can survive as spores, vegetative propagules, or fragments in diaspore banks, but liverwort spores typically have short longevity in the tropics. Liverworts have a limited number of propagule types, whereas the mosses have many.

Dispersal is mostly by wind and occurs in most cases in the dry season. Long distance dispersal is often important between mountains, and some species exhibit disjunct distributions between Africa and the Neotropics.

Rheophilic species probably have similar adaptations to the stream habitat, but few tropical studies have occurred.

Sampling brings special problems of getting mosses dry in the cloud forest or in the rainy season, often necessitating drying racks and a heat source. Investigators need to gain permission and should leave a set of herbarium specimens with a notable herbarium in the host country.

the chapter. Without his input this chapter would be far less complete. Tatiany Oliveira da Silva provided a critical reading for clarity, provided additional references, and shared her knowledge of the Amazon. Andi Cairns helped me add information on the Australian tropics to the appropriate subchapters and reviewed those chapters for the November 2019 version.

CHAPTER 8-2

TROPICS: GEOGRAPHIC DIVERSITY DIFFERENCES

Figure 1. Rainforest in Borneo. Photo by Duke Abruzzi, through Creative Commons.

Diversity – Geographic Differences

Only in the 21st century are we seeing publications with keys that cover broad areas or a wide range of taxa in the tropics, especially the Neotropics. This lack of taxonomic understanding has hindered our understanding of diversity and geographic differences.

Among these recent publications, the publication by Gradstein *et al.* (2001) dealing with all bryophytes of the Neotropics (mosses, liverworts, hornworts) is notable. In addition, there is a large series of floras dealing with Neotropical mosses (for a list see Gradstein *et al.* 2001), fewer on liverworts (Gradstein & Costa 2003; Gradstein & Ilkiu-Borges 2009). For Africa, a broad spectrum moss key has been translated from 1978, lacking modern familial

classifications, but is somewhat comprehensive (Petit 1992). More recent treatments on liverworts and hornworts was published for West Africa by Jones *et al.* (2004), based on an unpublished flora manuscript of the specialist of African liverworts E. W. Jones, and for Rwanda by Fischer (2013), including keys to genera and species and many color photos. For the southwestern part of Asia (Arabia) one can use the treatise by Kürschner and Frey (2011), for Singapore mosses by Tan *et al.* (2008) and for liverworts and hornworts of Java by Gradstein (2011). Other treatments are available for China and Japan, where bryology has long been studied, but publications were mostly in the native languages until recently. Recent publications include dozens of good floristic papers by young bryologists from the tropical countries, for example

from Brazil, Bolivia, Venezuela, Costa Rica, Puerto Rico, Guadeloupe, but also West Africa, Reunion, Madagascar and Malaysia.

Hedenäs (2007) used checklists from 78 countries to determine the global diversity patterns of pleurocarpous mosses. He found that most of this moss diversity occurred outside the Holarctic area. Rather, the tropics have an especially diverse pleurocarpous moss flora. Furthermore, species turnover among pleurocarpous mosses is higher in the tropics than in the temperate zone.

It is not surprising that the greatest number of bryophyte species occurs in the tropics, with one-third of the Earth's flora occurring in the tropical Americas alone (Gradstein 1995a, b; Gradstein *et al.* 2001). Nevertheless, there are fewer species of mosses in the tropics than in the temperate zone; it is the liverworts and hornworts that reach their peak of species here. Delgadillo (1998) reported 3,900 species of mosses recorded from the Neotropics but considered that the real number, taking into account taxonomic revisions, might be considerably lower. Gradstein *et al.* (2001) accepted about 2,600 species of mosses, 1,350 of liverworts, and 30 of hornworts in the region, and this number may further fluctuate due to synonymy and new discoveries. This number is commensurate with the high diversity of flowering plants (90,000) in the Neotropics, compared to 250,000 species of flowering plants worldwide (Churchill *et al.* 1995a). Frahm (1995) compared the European, tropical African, and Neotropical moss floras, a task that provides the knowledge base for many kinds of ecological studies.

On the other hand, estimates of the number of bryophyte species in the tropics is compromised by the large number of synonyms in the literature. For example, *Frullania atrata* (Figure 2) has been widely misinterpreted in the literature and has been confused with other *Frullania* species, whereas the true *F. atrata* is rare (Uribe & Gradstein 2003; Gradstein, pers. comm. 9 September 2018). The common Neotropical *Marchantia chenopoda* (Figure 3-Figure 4) has 15 synonyms (Bischler 1984) and the common pantropical moss *Leucomium strumosum* (Figure 5) has almost 30 synonyms from all over the tropics (Allen 1987). Such synonymy is mostly the result of researchers in different parts of the world naming a species as new because of inadequate knowledge of or access to bryophytes in other locations.

Figure 5. *Leucomium strumosum*, a tropical species with almost 30 synonyms. Photo by Claudio Delgadillo Moya, with permission.

Tropical liverworts in the families *Lejeuneaceae* (Figure 6), *Frullaniaceae* (Figure 7-Figure 8), *Radulaceae* (Figure 9-Figure 10), *Plagiochilaceae* (Figure 11), and *Lepidoziaceae* (Figure 12) predominate among the liverworts, with lesser numbers in *Metzgeriaceae* (Figure 13) and *Aneuraceae* (Figure 14) (Schuster 1988). Gradstein (1995a) suggests that the liverwort genus *Plagiochila* (Figure 11), with hundreds of species in tropical montane forests, is generally considered the most

diverse liverwort genus. Pendent taxa are common on branches and tree trunks of the montane forests.

Despite all these cautions about conspecific taxa that have been given multiple names in multiple locations, DNA genetics may once again expand the species number. For example, Dong *et al.* (2012) analyzed molecular data from the epiphyllous liverwort *Diplasiolejeunea* (Figure 15-Figure 16). This is a pantropical genus that occurs from lowlands to more than 4,000 m altitude. This indicated that the evolutionary diversity of the genus based on morphology alone has been underestimated. The molecular data indicate a distinct split between the Neotropical and

Palaeotropical (Old World) clade, with two predominantly Neotropical subgenera [*Austrolejeuneopsis* and *Diplasiolejeunea* (Figure 15) with the former containing mainly epiphytic species, the latter mainly epiphylls] and one predominantly Palaeotropical subgenus, *Physolejeunea* (Figure 16), an epiphytic montane subgenus.

Checklists of the tropics are listed in Frahm *et al.* (2003). For the geographic areas treated in this chapter, the number of references given are probably less than representative, but are listed to help researchers get started on the areas. More recent references have been included only as I have discovered them, with much help from Robert Gradstein.

Frahm *et al.* (2003) estimated that about 8,000 species of bryophytes occur in the tropics, comprising half to two-thirds of all the bryophyte species in the world. The European flora has only about 1,600 species that one can find in 32 floras. For the tropics, as of 2003, only 16 floras existed. As will be seen in the following subchapters, the liverworts and hornworts are much more abundant and occupy a much higher percentage of the bryophyte flora in the tropics compared to other regions of the world. Nevertheless, many areas remain unexplored or poorly explored, so numbers of species and numbers of **endemics**

(known only from a limited area) should be compared with caution.

Norhazrina *et al.* (2016) considered the **beta diversity** [ratio between gamma (regional) and alpha (local) diversities] of bryophytes in the tropics. They examined the beta diversity of 7485 tropical moss species and 3276 tropical liverwort and hornwort species in 164 and 154 operational geographical units, respectively. They found a "slight but significantly higher beta diversity among than within tropical regions." They concluded that oceans provide a significant barrier to the routine dispersal, even for the easily dispersed bryophytes, causing large-scale floristic patterns.

The following sections on diversity and endemism are mostly historic. Hence, numbers are likely to be out-dated. They are designed to provide the background and explain why ecological studies in the tropics are occurring only recently.

Africa

Africa is a continent with a wide range of tropical habitats, from dry desert of the Sahara to the 5,895 m summit of Mt. Kilimanjaro. The climate ranges from tropical to subarctic, but much of the land is desert, particularly the northern half.

One of the earliest recorded observations relating to ecology of the African desert is that of Mungo Park. As quoted in Crum (1983), Park was crossing 3220 km of unknown land and African desert when he reported "I considered my fate as certain, and that I had no alternative but to lie down and perish... At this moment, painful as my reflections were, the extraordinary beauty of a small moss in fructification irresistibly caught my eye." Stark (1860) captured the story in this poem (author not specified):

*Sad, faint, and weary on the sand
Our traveller sat him down; his hand
Cover'd his burning head.
Above, beneath, behind, around,
No resting for the eye he found;
All nature see'd as dead.*

*One tiny tuft of moss alone
Mantling with freshest green a stone
Fix'd his delighted gaze;
Through bursting tears of joy he smiled
And while he raised the tendril wild
His lips o'erflowed with praise*

*O! shall not He who keeps thee green,
Here in the waste, unknown, unseen,
Thy fellow-exile save?
He who commands the dew to feed
Thy gentle flower, can surely lead
Me from a scorching grave.*

Mungo Park lived to tell the tale and a specimen of this lowly moss was later identified as a species of *Fissidens* in

the *F. bryoides* (Figure 17) group. This genus is particularly common in Africa, with ~90 known species out of 450 worldwide (Bruggeman-Nannenga, 2013a, b), with a new one soon to be published from termite mounds (Bruggeman-Nannenga in press; Ezukanma *et al.* in prep.).

Figure 17. *Fissidens bryoides*, possibly the moss found by Mungo Park, or one of its close relatives. Photo by Hermann Schachner, through Creative Commons.

O'Shea (1995) provided an early checklist of the mosses of sub-Saharan Africa (Figure 18), listing 2939 species, based on the literature, and indicating distribution by country. While he updated some of the nomenclature, naming new combinations, much remained to straighten out the duplication in names around the continent.

Figure 18. Sub-Sahara Africa. Photo from CIFOR, through Creative Commons.

Ros *et al.* (1999) provided a checklist of northern Africa. It is striking that only 171 liverwort species were known, compared to 706 of mosses. It is likewise remarkable that only 4 taxa were known from the Republic of Mali or Niger. Wigginton (2001b) noted that *Eucladium verticillatum* is widespread in Mali, where it is encrusted with **tufa** (variety of limestone formed when carbonate minerals precipitate out of ambient temperature water).

Pócs, with his coworkers, has been a lifelong contributor to the bryophyte flora of Africa. Among his earlier contributions was a joint paper (Bizot & Pócs 1974) on bryophytes of East Africa, based on collections from a number of bryologists, himself included. This included 441 species, of which 115 were new for East Africa and 4

for all of tropical Africa and 30 were new for all of continental Africa. Other studies reporting on African bryophytes include Arnell (1956 – East African Mountains – liverworts), Bizot & Pócs (1974, 1979, 1982 – East Africa), Pócs (1990, 2011 – East Africa), Kürschner & Onraedt (1990 – Republic of Djibouti), Grolle [1993 – Zaire and Rwanda – **Pallaviciniaceae** (Figure 19), **Haplomitriaceae** (Figure 20)], and Miehe & Miehe (1994 – Ethiopia).

Figure 19. *Symphogyna brasiliensis* female from the Neotropics. This family **Pallaviciniaceae** also occurs in Africa. Photo by George Shepherd, through Creative Commons.

Figure 20. *Haplomitrium hookeri*; **Haplomitriaceae** are among the liverworts known from Zaire and Rwanda. Photo by Des Callaghan, with permission.

In an update of his earlier checklist, O'Shea (1997a, b) reported 3,048 taxa from sub-Saharan Africa (Figure 18), but suggested that it will probably be reduced to ~1300 species by revisions. Based on an expedition of the British Bryological Society to the Mulanje Mountain (Figure 21), Wigginton (2001a) reported 64 taxa in the single leafy liverwort family of **Lejeuneaceae** (Figure 6, Figure 15-Figure 16). This report acknowledged 47 species new to Malawi, emphasizing how poorly we knew the bryophyte flora in so many tropical areas. Frahm (2003) bemoaned the lack of studies in Africa and the likely number of synonyms. Such taxonomic and floristic studies and

compilations as these laid the foundation that permitted ecological work to begin.

Figure 21. Mount Mulanje, Africa. Photo by David Davies, through Creative Commons.

Not all of the African tropics have a high bryophyte diversity. In three locations in the Ekiti State, Nigeria (Figure 22), 69 samples yielded only 8 species of mosses (Adebiyi & Oyeyemi (2013), two of which were among those studied by Odu (1981, 1982) in Nigeria for their reproductive phenology: ***Pelekium gratum*** (syn.=*Thuidium gratum*; Figure 23) and ***Racopilum africanum*** (Figure 24). A study of bryophytes in the Eastern Nigerian Highlands yielded only 27 bryophyte taxa – 22 mosses, 5 liverworts (Ezukanma *et al.* 2017).

Oyesiku (2012) reviewed the Nigerian bryophytes, including a discussion of uses. His was one of the few attempts to assess the importance of bryophytes to agriculture and the effects that agriculture is having on the bryophytes. He expressed concern that so few people are working on Nigerian bryophytes.

Few studies seem to be available from Ghana. Hodgetts *et al.* (2016) reported on the bryophytes of the Atewa Forest in eastern Ghana. The region is highly threatened by farming, hunting, and illegal mining. Hodgetts and coworkers explored the swamp forest and upland evergreen forest where they expected the greatest bryophyte richness. They identified 164 species, 58 of which were new to Ghana.

The cover of bryophytes differs markedly, dependent on light availability, litter cover, and climate. Petit and Symons (1974) found that in the planted woods of *Cupressus* (Figure 25) and *Acacia* (Figure 26) in Burundi (an east African country with an equatorial climate), the ground surface is mostly covered with bryophytes. Nevertheless, in 17 woods, only 28 species were found, and only 15 of these were typical for that habitat.

Figure 26. *Acacia*; forest floors of *Acacia* are covered by bryophytes in Burundi. Photo from pxhere, through Creative Commons.

To demonstrate just how poorly some African floras are known (Hylander *et al.* 2010), we need only look at the new records from the biosphere reserve of Kafa in Ethiopia (Figure 27). A team of 29 experts, but no bryologists, spent 10 days collecting plants (Müller & Flügel 2016). They did, however, bring some bryophyte specimens back. While this yielded only 13 liverwort and 24 moss species, it revealed 5 mosses not previously known from Ethiopia!

Hylander *et al.* (2010) found 89 species of liverworts, of which 41 were new to Ethiopia (Figure 27), further emphasizing that bryological explorations have been inadequate there. Among these are many epiphyllous species that are typically sensitive to drought. These are mostly along streams where humidity remains higher. The family **Lejeuneaceae** (Figure 6, Figure 15-Figure 16) is the most common family, with several representatives in other families, including **Frullaniaceae** (Figure 2, Figure 7-Figure 8), **Plagiochilaceae** (Figure 11), and **Radulaceae** (Figure 9-Figure 10).

In a more recent study, Hylander *et al.* (2017) found 139 moss species in montane forests of Ethiopia (Figure 28), of which 53 are newly reported for the country. *Meteoriopsis reclinata* (Figure 29) is a new record for Africa.

Figure 27. Forest with native carrying firewood in Kafa, Ethiopia. Photo by Rod Waddington, through Creative Commons.

Figure 28. Semien Mountains, Ethiopia. Photo by Hulivili, through Creative Commons.

Hedderson *et al.* (2015) added to the list of bryophytes from Mabu Mountain in Mozambique, based on collections from non-bryologists. They were able to identify 56 species, of which 43 were new records for the country. The authors considered this small sampling of the country to be indicative of its bryophyte diversity and the need for more study.

Marline *et al.* (2012) provided an updated checklist of Madagascar bryophytes. This updated list revealed 751 moss, 390 liverwort, and 3 hornwort taxa. Of these, ~29% are endemic.

Reunion Island provides an interesting ecological site. It has diverse habitats of lava flows and large topographic relief. Ah-Peng *et al.* (2010) brought the total number of

species and infraspecific taxa to 776 in 2010 with the addition of 123 taxa. They considered the presence of a high altitudinal gradient and high rainfall regime, coupled with relatively short distance to East Africa, to account for the large number of species on an island with only 2512 km².

Figure 29. *Meteoriopsis reclinata* was a new record for Africa in 2017. Photo by Niels Klazenga, with permission.

Several studies have compared the bryophyte floras of parts of Africa with other parts of the tropics (Frahm 1995), including Asia (Pócs 1976), and Madagascar (Pócs 1975). Oyesiku (2012) noted the "moribund" state of bryology in Africa.

Asia

The earliest studies on tropical Asian bryophytes are those in Java. Dozy and Molkenboer produced *Bryologia Javanica* (1856 – vol. 1, 1867 – vol. 2) on the Java mosses. Later Max Fleischer produced a three volume set, the *Moss Flora of Java* (1900-1922). For liverworts, Reinwardt *et al.* (1824) and Nees von Esenbeck (1830) provided the first species lists. These were followed later by the floras of vander Sande Lacoste (1857, 1864) and Schiffner (1900) (in Gradstein 2011). The latter work remained unfinished. Most recently, Gradstein (2011) has presented the Guide to the Liverworts and Hornworts of Java, covering nearly 200 years of bryological studies in Java. Approximately 1000 species of bryophytes are now known from Java (Robbert Gradstein, pers. comm. 9 September 2018). The presence of a biological research station at Cibodas (Figure 30) in Indonesia, founded by the Dutch around 1890 in the montane rainforest belt, has been of enormous help in accomplishing these bryological studies, including also work by Schiffner, Goebel, Giesenhagen, Verdoorn, and others.

Figure 30. Botanical garden in Cibodas, Indonesia. Photo by Hullie, through Creative Commons.

One of the early Asian studies was that of Dixon (1935) who reported on the moss flora of Borneo (Figure 1). Other studies on Asian tropics in China and Japan have been unavailable to people from other countries because they were published in the native languages and not understood by others. In some cases political boundaries and cultural differences complicated the ability of bryophyte ecologists to conduct studies. Redfearn (1990) points out that many of the early studies in China have been lost during the Cultural Revolution. And isolationism led to much synonymy, even within China. At that time he noted that much study was needed. Now there are many bryologists in China, but work is still needed on the many diverse habitats that define the country.

Asia has the most generic and familial diversity in the tropics, with many taxa that occur only in the Asian tropics. Africa, on the other hand, has few taxa of its own and little liverwort diversity, as we currently understand the flora. In the Americas, there are fewer unique moss taxa, but the liverworts are more diverse, with cover of liverworts in montane forests exceeding that of the mosses.

Asia is the center for distribution of a number of tropical taxa in a variety of families and is home to the **epiphyllous** (living on leaves) moss *Ephemeropsis* (Figure 31) and liverwort *Metzgeriopsis* (Figure 32) (Gradstein & Pócs 1989). Again, members of **Lejeuneaceae** (Figure 6, Figure 15-Figure 16) dominate liverworts, but with a number of different genera. The African flora is less rich and has few elements of its own. Typical mosses in the Asian rainforest (Figure 33) are *Leucoloma* (**Dicranaceae**; Figure 34), **Cryphaeaceae** (Figure 35), **Rutenbergiaceae**, *Hildebrandtiella* (Figure 36) and *Renauldia* (**Pterobryaceae** – see Figure 183), and in both lowlands and montane regions, *Fissidens* (Figure 37). Among liverworts, *Lepidozia* (Figure 12; subgen *Sprucella*) is

most common (vanden Berghen 1983; Gradstein & Pócs 1989).

Gradstein (1991) summarized the known Asian **Ptychanthoideae** (Figure 38) in the leafy liverwort family **Lejeuneaceae** (Figure 6, Figure 15-Figure 16). This group was represented by 88 species in 17 genera, having fewer genera but more species than this group in the Neotropics. Gradstein suggested that the greater number of species in Asia might be the result of the greater latitudinal extension of the rainforest in the Far East. That region has 22% non-tropical species of **Ptychanthoideae** compared to less than 2% in the Neotropics. It could also represent greater early exploration.

In Malaysia (Figure 39-Figure 40), the diverse vegetation consists of swampy mangroves, extensive river floodplains, dipterocarp forests, and montane forests (Chuah-Petiot 2011). **Altimontane** (montane grasslands, shrublands, and woodlands; Figure 40) communities occur on Mt. Kinabalu in Sabah above 3300 m asl, with average temperatures from 6° to 10°C. The tropical climate of Malaysia ranges in temperature from 21° to 32°C; annual rainfall is from 2000 mm to 3500 mm.

Malaysian (Figure 41) liverwort studies can be traced to the year 1838 (Lee *et al.* 2018). Most of the collections have been made from 1950 to 2000, with many new taxa described. In a recent paper, Chuah-Petiot (2011) published a checklist of liverwort and hornwort species and infra-specific taxa, citing 758 liverworts and 6 hornworts. The **Lejeuneaceae** (Figure 6, Figure 15-Figure 16) far outnumber the other liverwort families (282 taxa), as found also in the study by Pócs and Chantanaorrapint (2016) in Thailand, where 30 out of 38 liverworts were in the **Lejeuneaceae**. In Malaysia, Chuah-Petiot found that species richness of the **Lejeuneaceae** was followed by **Lepidoziaceae** (110, Figure 12), **Frullaniaceae** (67; Figure 2, Figure 7-Figure 8), **Plagiochilaceae** (52; Figure 11), **Geocalycaceae** (36; Figure 42), **Lophoziaceae** (35; Figure 43), and **Radulaceae** (35; Figure 9-Figure 10). As in many areas of the tropics, the genera with the most Malaysian species are **Cololejeunea** (84; Figure 44), **Frullania** (67; Figure 2, Figure 7-Figure 8), **Bazzania** (53; Figure 45, Figure 149), **Plagiochila** (47; Figure 11), and **Radula** (35, Figure 9-Figure 10). More recently, Lee *et al.* (2018) reported 747 liverwort species from Malaysia, occupying nearly 15% of the liverwort diversity in the world.

Among the older studies including mosses of Malaysia (Figure 41) are those of Tixier (1980), Mohamed and Tan (1988), Frahm *et al.* (1990), Inoue (1989), and Akiyama *et al.* (2001). Mohamed and Tan (1988) reported 475 taxa of mosses, a number that has changed with further studies and nomenclatural synonymies. More recently, Suleiman *et al.* (2006) enumerated 582 moss taxa from Sabah, Borneo. Tan and Iwatsuki (1999) considered Mt. Kinabalu (Figure 40, Figure 46) to be one of four diversity hotspots for mosses in Malesia, an area that includes the Malay Peninsula, the Malay Archipelago, New Guinea, and the Bismarck Archipelago. Vitt *et al.* (1995) characterized the **Orthotrichaceae** flora of the Huon Peninsula of Papua New Guinea. Higuchi *et al.* (2008) found 97 species of mosses, exclusive of pleurocarpous species, on Mt. Kinabalu. Among the rare species there is the moss *Takakia lepidozoides* (Figure 47) near Paka Cave. Higuchi and Lin (2005) found that the size and life form of *Takakia lepidozoides* in Taiwan differ between sheltered and exposed sites. Higuchi and coworkers (2008) found that plants in their open sites on Mt. Kinabalu were larger, forming loose mats, compared to those from sheltered places.

Figure 46. Mount Kinabalu, Borneo. Photo by Nep Grower, through Creative Commons.

Figure 47. *Takakia lepidozoides*, a rare species of moss that occurs on Mt. Kinabalu. Photo through Creative Commons.

In 2019, Pócs *et al.* added a number of new records to the known liverwort (**Lejeuneaceae**) flora of the Huon Peninsula, Papua New Guinea. They brought the number of *Cheilolejeunea* (Figure 48-Figure 49) species to 21 and the number of *Drepanolejeunea* (Figure 50) to 26. In this publication they summarized altitudinal ranges for the Peninsula, noting that most of the species are in the wet montane rainforests at 1000-3000 m asl. Most of these liverworts were epiphyllous on trees and shrubs with few on tree trunks, twigs, or logs.

Kürschner (2003a) is among the more recent of the Asian researchers. He studied epiphytes in the Asir Mountains of Saudi Arabia and Yemen (see Tropics subchapters on epiphytes). In a second study (Kürschner 2003b), he examined the xeric bryophyte community in Yemen. He described a new association of *Riccia jövet-astiae* with *R. argenteolimbata* and *Barbula unguiculata* (Figure 51). This association occurs typically on the shallow soils overlying volcanic rock outcrops in the *Sterculia africana* (Figure 54) woodland. This area is beset with monsoons. It supports a number of **Ricciaceae** (Figure 52-Figure 53) and **Marchantiaceae** (Figure 3-Figure 4) that are typical or xerotropical Africa. *Riccia atromarginata* var. *jövet-astiae* (see Figure 52) and *R. albolimbata* (Figure 53) are characteristic of this habitat. The life strategies are characterized by shuttle species with large spores, providing for a good diaspore bank.

Sukkharak and Chantanaorrapint (2014) summarized the bryophyte studies that have occurred in Thailand (Figure 55). They indicated two periods in bryological studies. In the first period (1899-1977), foreign bryologists were the contributors. In the second period (1977 to present), bryologists from Thailand conducted the studies. These studies resulted in 2 new species of hornworts, 20 of liverworts, and 63 of mosses. Based on studies elsewhere, 48 remain unique to Thailand and may therefore be considered endemic.

Figure 55. Thai rainforest. Photo by Michael Cory, through Creative Commons.

Many areas of the Asian tropics remain poorly explored for bryophytes. Sulawesi, Indonesia (Figure 56), is among such locations. Steep mountains with dense vegetation make exploration difficult (Rowe *et al.* 2016). In their exploration of the island, Gradstein *et al.* (2005) found 476 species of bryophytes. Four moss species and one liverwort species appear to be **endemic** to the island. But several large genera are unknown from Sulawesi, suggesting that sufficient exploration may be lacking.

Figure 56. South Sulawesi, Indonesia, Mountains. Photo by Achmad Rabin Taim, through Creative Commons.

Few studies seem to be available on Viet Nam (Figure 57) bryophytes. Pócs (1969) surveyed the leafy liverwort genus *Bazzania* (Figure 45, Figure 149). A more comprehensive study by Ninh (1993) recorded 178 taxa. Much more comprehensive work is needed in that country, and ecological work seems to be absent.

Sri Lanka (Figure 58) is likewise an understudied country bryologically. Rubasinghe and Long (2014) reviewed the history of bryological work in the country and remarked on the goal to produce a comprehensive bryophyte flora for Sri Lanka, the first of its kind for the country.

Australia

Scott (1985) provided a basis for bryophyte studies in the late 20th century. While the nomenclature is largely out-dated now, one can still use the reference for its keys and figures, keeping a good modern checklist or database at hand.

There are around 13 different rainforest types in northeastern Australia (Figure 59), including inland "dry rainforest" (Andi Cairns, pers. comm. 23 October 2019). Among the somewhat earlier studies on Australian tropics, Fensham and Streimann (1997) described the moss flora from the inland dry rainforest in north Queensland. They found that moss species richness correlated strongly with several parameters: patch area, mean annual rainfall, and tracheophyte species richness. Volcanic craters create areas with increased moisture, supporting greater species richness. Their analyses suggested that large closed canopy patches create a humid microclimate where more species are preserved. What seems to be most unusual is that a high proportion of rare species were associated with the soil – a substrate that in most tropical forests has few species due to low light and heavy litter.

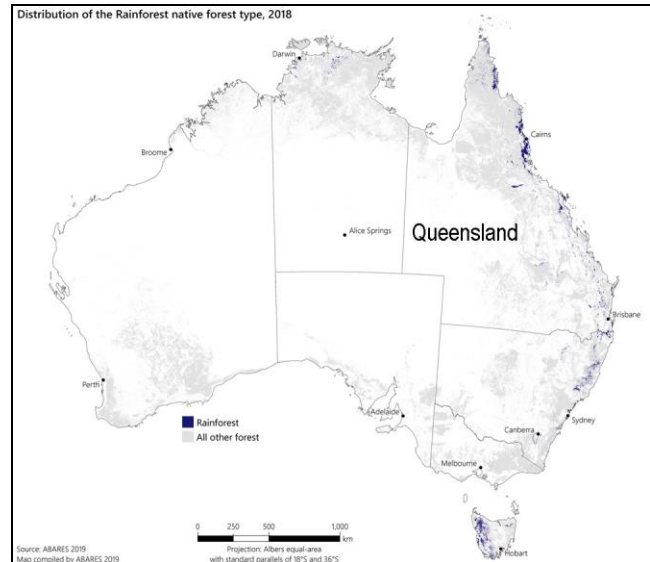

Figure 59. Australian rainforest locations. Image from Department of Agriculture, Australian Government (ABARES), with permission.

The Wet Tropics bioregion of Australia exists along the seaboard of northeastern Queensland for about 500 km (Goosem *et al.* 1999). The Wet Tropics climate usually has two seasons, a wet season in December-April, with a summer monsoon season and occasional tropical cyclones, and then a nearly dry season in May-November when there are occasional showers. Mean annual temperatures range from 30°C in the lowland to less than 10°C in the montane areas (Webb 1968). The rainfall is highly variable, being strongly influenced by the local topography, and declining both northward and southward (Adam 1994).

Monographic studies on genera and families contributed to the possibilities for more accurate floristic studies [e.g. Reese & Stone 1995 – **Calymperaceae** (Figure 64-Figure 65); Streimann 1991 – **Meteoriaceae** (Figure 60); 1997, 2000 – **Hookeriaceae** *s.l.* (Figure 61)]. Other studies have specifically compared the rainforests, of which many are not in tropical parts of Australia (Ramsay *et al.* 1987).

Figure 60. *Papillaria crocea* (Meteoriaceae), a tropical epiphyte. Photo courtesy of Andi Cairns.

Figure 61. *Achrophyllum dentatum* (Hookeriaceae), a species known from the Wet Tropics of Australia. Photo by Niels Klazenga, with permission.

Even now, studies in the Wet Tropics of Queensland are revealing new records and range extensions (Cairns & Meagher 2017). Both *Pleuridium nervosum* (Figure 62) and *Pseudotaxiphyllum pohliaecarpum* (Figure 63) were new to this region, among a number of other new records.

Figure 62. *Pleuridium nervosum* growing with *Wilsoniella karsteniana* in the Wet Tropics of Australia. Photo from Cairns & Meagher 2017, with permission.

Ramsay and Cairns (2004) found the greatest species richness in the rainforests of high mountain peaks and on the Atherton Tableland of the Wet Tropics bioregion. They found that the **mats**, **cushions**, and **pendents** are able to harvest water on their surfaces. These droplets of water can store nutrient exudates and insect droppings, releasing them slowly over time as leachates. The bryophytes are able to reduce runoff and maintain forest humidity.

The mangroves, in contrast to the high diversity in other parts of the Wet Tropics, have very little diversity, with only *Calymperes* (Figure 64-Figure 65) species present on the mangrove trees (Ramsay & Cairns 2004). The terrestrial *Taxithelium leptosigmatum* (Figure 66-Figure 67) forms extensive mats on mud and exposed mangrove roots, especially if there is a high input of fresh water.

Figure 63. *Pseudotaxiphyllum pohliaecarpum* in the Wet Tropics of Australia. Photo from Cairns & Meagher 2017, with permission.

On the forest floor one can find *Pogonatum* (Figure 68) and *Dawsonia* (Figure 84-Figure 85) where they gain more exposure from road cuts (Ramsay & Cairns 2004). *Dicranella* (Figure 69) and the rarer *Garckea* (Figure 70) occur in more protected cuttings. Shaded earth banks and forest tracks typically have colonizing species of *Fissidens* such as *F. crispulus* (Figure 71) and *F. perobtusius* in coastal areas or *F. dietrichiae* and *F. pallidus* (Figure 72) at higher altitudes. The tiny earth mosses [*Archidium* (Figure 73), *Erpodium* [now in *Solmsiella* (Figure 74) and *Venturiella* (Figure 75)], and *Gigaspermum* (Figure 76) are frequent, but difficult to locate. No specific study has addressed epiphytes or epiphylls, but one can find *Distichophyllum mittenii* (Figure 77) on leaves of filmy ferns. *Calypstrochaeta brassii* (see Figure 78) is present on Mt. Finnigan and *Clastobryum cuculligerun* var. *dimorphum* (see Figure 79) on many high peaks in the Australian Wet Tropics.

We once thought that the larger mosses (e.g. *Dawsonia*) in **Polytrichaceae** (Figure 80), **Garovagliaceae** (Figure 81), **Hypnodendraceae** (Figure 82), and **Spiridentaceae** (Figure 83) were unique to Asia (Gradstein & Pócs 1989). However, we now know that most of these families also occur in the Australian tropics. *Dawsonia longiseta* (Figure 84) and *D. polytrichoides* (Figure 85) occur in the Wet Tropics (Cairns *et al.* 2019)]. In the **Hypnodendraceae**, *Hypnodendron vitiense* (Figure 87) subsp. *australe* and *H. vitiense* subsp. *vitiense* both occur in tropical Australia, as does *H. spininervium* (Figure 86). Also in the Wet Tropics of Australia we find *Ephemeropsis tjbodensis* (Figure 88), an epiphyllous moss. *Garovaglia* (Figure 81) has since been moved to the **Pterobryaceae** (see TROPICOS) and along with several other species in this family or closely related ones occurs in the Wet Tropics of Australia: *Euptychium setigerum* subsp. *setigerum*, *Garovaglia elegans* (Figure 81) subsp. *diétrichiae*, *Garovaglia powellii* (Figure 89) var. *muelleri*. *Hampeella concavifolia* (Figure 90), *Hampeella pallens* (Figure 91-Figure 92), and *Ptychomnion aciculare* (Figure 93) are also in the Australian Wet Tropics. *Spiridens* (Figure 94), considered by Bell *et al.* (2007; Catcheside & Meagher 2016) to be in the **Hypnodendraceae**, is only known in Australia from Lord Howe Island. It is still unknown in the Australian tropics, although it occurs elsewhere in Eastern Hemisphere tropics.

Dixon (1938) considered the bryophyte flora of tropical Queensland as one of special interest to botanists, considering both what had already been found and what was yet to be discovered. It is currently considered a hotspot for bryophyte diversity (Cairns *et al.* 2019).

More than 80 years later, new records of bryophyte species are still being added regularly to the tropical Queensland flora (Cairns *et al.* 2019). For example, family or generic treatments of the Australian tropical moss flora include the **Brachytheciaceae** – especially *Rhynchostegium* / *Platyhypnidium* (Figure 95) (Huttunen & Ignatov 2010), **Stereophyllaceae** – *Entodontopsis* (Figure 96) (Meagher & Cairns 2014), **Sematophyllaceae** – *Clastobryophilum balansaeum* (Figure 97), a species previously known only in New Caledonia, on bark with the leafy liverwort *Heteroscyphus aselliformis* (Figure 97) (Cairns & Meagher 2014) and *Entodontopsis pygmaea* (Figure 96), a paroicous epiphytic species (Meagher & Cairns 2014), **Meteoriaceae** (Figure 98) (Meagher & Cairns 2016), and **Orthotrichaceae** – especially *Macromitrium* (Figure 99) (Vitt & Ramsay 1985). Comprehensive treatments of the liverwort flora include the **Lejeuneaceae** (Figure 100) (Renner 2011), **Radulaceae** (Figure 101) (Renner 2014, Renner *et al.* 2014), and **Lepidoziaceae** (Figure 102) (Brown & Renner 2014; Renner & Wilson 2018). Meagher (2019 reports 28 species of *Bazzania* (**Lepidoziaceae**; Figure 103) in the Australian Wet Tropics bioregion, representing the highest species richness of the genus in Australia. These Wet Tropics *Bazzania* species occur on trees, tree ferns, logs, soil, rocks, rocks on stream banks, but are not epiphyllous (Meagher 2019). In the **Plagiochilaceae** 8 species were newly named from the Wet Tropics (Figure 104), occupying the diverse substrates of forest floor saturated humic soil, granite boulders, decaying wood, tree trunks, branches, and twigs (Renner 2018).

Australia appears to have received much more attention (at least in English publications) than many of the Asian countries. This has permitted ecological and physiological studies to take place. Nevertheless, as already noted, the tropical regions remain under-explored. In 2004, Ramsay and Cairns contributed a checklist for the Wet Tropics bioregion in northeastern Queensland (Figure 105), listing 397 species. This permitted them to determine the families represented by the most species (Table 1). They elaborated on habitat, distribution, and bryogeographical affinities for the Wet Tropics. These areas of study have been possible due to the strong taxonomic background that is available online via the Australian Mosses Online website. In 2019, Cairns *et al.* released a new checklist that updated the nomenclature and included new finds, bringing the total number of species of mosses to 410, including 170 genera in 60 families. This number is somewhat misleading because some families decreased in number of species due to realization of synonymy, while others increased (Table 1); the total of new moss species was 55. Nevertheless, most of the bryological studies in Australia have been in the southern part where bryophyte-friendly habitats are more common and accessible, but not tropical. The epiphytes and epiphylls in the Australian tropical forests remain unexplored in any comprehensive way.

Table 1. Families of mosses exhibiting the highest species richness in the Wet Tropics of Australia. The first line of each family is based on Ramsay and Cairns 2004. The second line is based on Cairns *et al.* 2019.

Family	Number of genera	Number of species
Bryaceae	5	23
	9	32
Calymperaceae	7	47
	7	48
Dicranaceae	7	29
	8	19
Meteoriaceae	8	13
	9	16
Sematophyllaceae	16	32
Sematophyllaceae	11	23
Pylaisiadelphaceae	7	13
Additional Species-Rich Families		
Orthotrichaceae	4	24
Fissidentaceae	1	44

This history is representative of the background necessary to carry out ecological studies on species dominance, community structure, comparative diversity, biomass comparisons, and many other aspects of ecology. It demonstrates the long process needed before ecologists can begin many kinds of studies and it helps to explain the paucity of ecological studies in many parts of the tropics, especially in Australia.

Neotropics

The **Neotropics** (Figure 106) is synonymous with New World Tropics. It includes areas of Mexico, Central America, the West Indies, Chocó, Northern Andes, Central Andes, Amazonia, Guyana Highland, Planalto, and Southeastern Brazil (Gradstein *et al.* 2001).

Until relatively recently, any comprehensive guide to the bryophytes of the Neotropics was lacking. Researchers had to find the scattered treatments among individual papers, making comprehensive ecological studies,

especially community studies, difficult to impossible. The publication by Gradstein *et al.* (2001) made it possible to expand the types of ecological studies that are feasible.

Most studies have been exclusive to either mosses or liverworts. Various studies contributing to these records include, for mosses, Steere 1948 – Ecuador, Pursell 1973 – Venezuela, Bowers 1974 – Costa Rica, Hermann 1976 – Bolivia, Yano 1981, 2011 – Brazil, Florschütz Waard 1990 – Guianas, Menzel 1992 – El Salvador, Moreno 1992a, b – Venezuela, Sharp *et al.* 1994 – Mexico, and Churchill & Linares 1995 – Colombia. For liverworts, these include Gradstein & Hekking 1989 – Guianas and Bolivia; Gradstein 2006 – French Guiana, Gradstein *et al.* 2007 – Ecuador, Gradstein 2016 – Colombia, Gradstein & León-Yáñez 2018 – Ecuador, Gradstein *et al.* 2018 – Colombia. But these provided primarily checklists and descriptions. Those publishing the lists of species often did not have access to specimens collected elsewhere. Hence, many species from multiple countries were named more than once, creating synonyms and inaccurate estimates of species numbers and distributions. It was not until keys became available that an ecologist had the tools needed to conduct ecological studies that included species information.

To illustrate the problems caused by synonyms among the bryophytes of the Neotropics, we need only examine a few studies. Delgadillo *et al.* (1995) indicated 4,103 species and varieties of mosses recorded from the Neotropics. Within five years, subsequent taxonomic revisions reduced the number to 3,869 species and varieties (Delgadillo 2000). Only one year later, Gradstein *et al.* (2001, Table 2, page 3) estimated 3,980 species of all bryophytes in the Neotropics, including only 2,600 mosses, 1,350 liverworts, and 30 hornworts, based on systematic studies that found many synonyms.

Based on the 1996 expedition in the Chagos Archipelago (Neotropics; Figure 107), Seaward *et al.* (2006) found a good correlation of bryophyte diversity with island size. But only 19 taxa were recorded on the 25 islands (out of 55) that they explored. They attributed the low diversity to the remoteness and young age of the islands, as well as their small size. Nevertheless, where the bryophytes are found on these islands, they tend to be in abundance and play "significant" ecological roles. They found no evidence of host specificity of epiphytes and no epiphyllous species were found by the expedition.

Bryophytes are advantageous as indicators of biodiversity and can be useful in broader conservation efforts in the Neotropics (Salazar Allen *et al.* 1996). Hence, the presentation of the treatise of Gradstein *et al.* (2001) is of tremendous value to all Neotropical bryophyte researchers. The two volumes present 200 genera of liverworts and 400 of mosses. They provide not only taxonomic aids, but also ecological attributes such as habitat indicators.

The rainforest of the Americas (**Neotropics**) is quite different from that in the African or Asian tropics (Gradstein & Pócs 1989). The New World Americas are characterized by **Pilotrichaceae** (Figure 108), **Phyllogoniaceae** (Figure 109), **Porotrichodendron** (Figure 110; **Lembophyllaceae**), **Chorisodontium** (Figure 111; **Dicranaceae**), **Octoblepharum** (Figure 112; **lowland; Octoblepharaceae**), and **Phyllocladophyllum** (Figure 113; **Phyllocladophyllaceae**) among the mosses, and **Monocleaceae** (Figure 114) and numerous **Lejeuneaceae** (Figure 6, Figure 15-Figure 16) among the liverworts. In the Asian **Lejeuneaceae**, the subfamily **Ptychanthoideae** (Figure 38) predominates, whereas in the Neotropics the **Brachiolejeuneae** (Figure 115-Figure 116) predominate (Gradstein 1991, 1994).

Nevertheless, disjunctions among the liverworts between the **Neotropics** (American tropics) and Africa are well known (Pócs 1976, 1992; Gradstein *et al.* 1983; Delgadillo 1993; Frahm 1995). Records in 1983 indicate 35 Afro-American shared species (see examples in Figure 117-Figure 118) (Gradstein *et al.* 1983). Most of these liverwort disjuncts are in the **Jungermanniales** (leafy liverworts) (Gradstein *et al.* 1983). By 1993, records indicated the Neotropics shared 334 bryophyte species and infraspecific taxa with the African tropics (Delgadillo 1993). This might be the result of an ancient land connection or long-distance dispersal. These are just hypotheses as experimental data on longevity of liverwort spores is greatly lacking (Gradstein *et al.* 1983). Another possibility is dispersal from Gondwanaland.

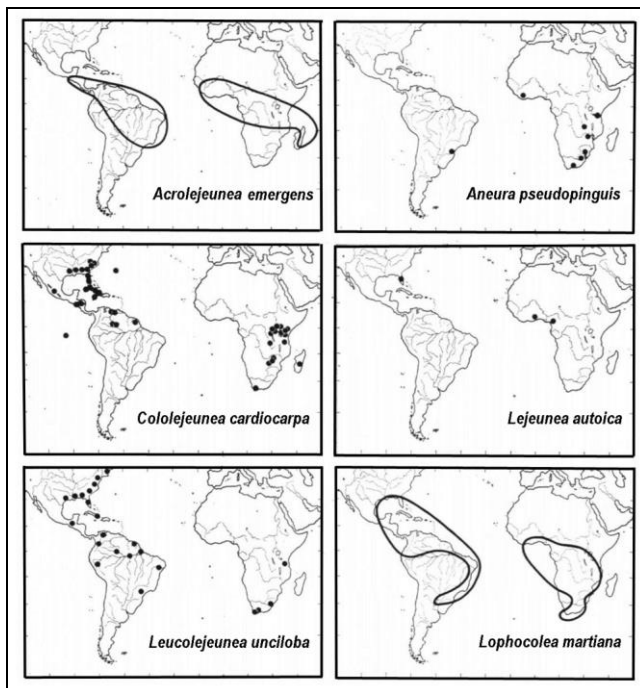

Figure 117. New and old tropical lowland disjunct species between Africa and the Americas. Modified from Gradstein *et al.* 1983.

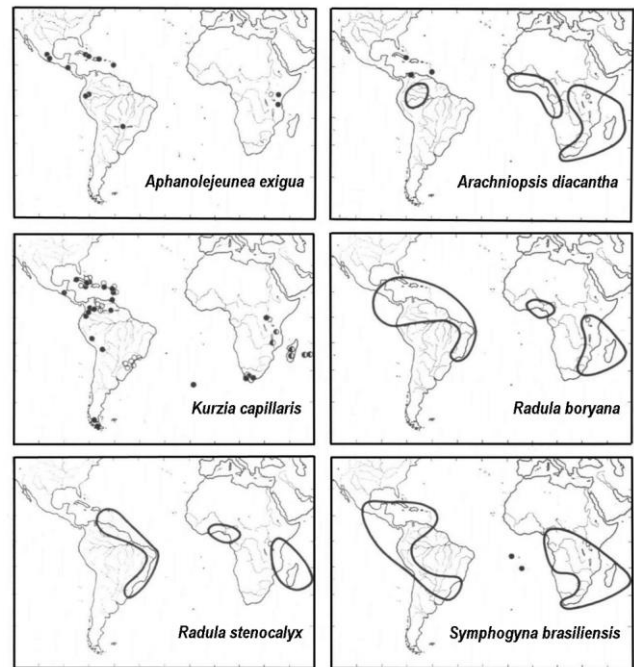

Figure 118. New and old tropical montane disjunct species between Africa and the Americas. Modified from Gradstein *et al.* 1983.

North and South America seem to have more species in common, sharing about 675 species (Delgadillo 1992, 1995). These include those with a continuous range and those with a disjunct distribution. Migration seems to have been stepwise, but some of these occurrences may have resulted from the breakup of previous distributions. Others arrived by long-distance dispersal. Other connections of the bryophyte flora to other parts of the Americas is through elevational distributions (Delgadillo & Cárdenas 1989). For example, the highlands of Chiapas, Mexico (Figure 119), are suitable for growth of species that may be found at lower elevations farther from the equator. The Chiapas have 155 taxa of mosses that fit into five phytogeographical elements. Mexico and Colombia alone share 371 moss species (Delgadillo 1992). Of these, 25 have a disjunct distribution that suggests long-distance dispersal. The Central American bridge facilitates the exchange of species, but the northern Andes in Colombia and the Neovolcanic Belt of Mexico form barriers that limit that exchange.

Figure 119. Sumidero Canyon, Chiapas, Mexico. Photo by Srplattano, through Creative Commons.

Delgadillo (1984) reported on mosses of the Mexican part of the Yucatan Peninsula (Figure 120). He identified 69 moss species and varieties and noted the similarities to the flora of the West Indies. There are virtually no endemics, perhaps due to the close connections with the Mexico mainland and the West Indies.

Figure 120. Yucatan moist forest, Mexico. Photo by Carlos Delgado, through Creative Commons.

In the *Liquidambar* forest (Figure 121) of Mexico, 194 species of mosses were known in 1979 (Delgadillo 1979). Of these, 70% are strictly American. This flora exhibits both a wide altitudinal and latitudinal range in Mexico and represents both tropical and temperate species.

Figure 121. *Liquidambar* forest canopy, through Creative Commons.

Herrera-Paniagua *et al.* (2008) reported 212 moss species for the Mexican state of Querétaro. As indicated by endemism, this state has three distinct regions: the conifer-cloud-temperate forests in the northeast (Sierra Madre Oriental), the more xeric parts in the center and southeast (Mexican Plateau and ecotone areas of the Transmexican Volcanic Belt), and the almost temperate areas in the south (Transmexican Volcanic Belt). The Sierra Madre Oriental province has the highest species richness.

The Trans-Mexican Volcanic Belt spans Central-Southern Mexico from the Pacific Ocean to the Gulf of Mexico between 18°30'N and 21°30'N. Villaseñor *et al.*

(2006) reported diversity hotspots for mosses in this tropical region, finding 596 moss species out of 980 known for Mexico at the time. The tropical region of Oaxaca had 459 recorded species in 2011 (Delgadillo & Cárdenas 2011).

It seems that almost any expedition even now is likely to reveal new records for the region. In 2001, Equihua *et al.* reported nine new moss records for Mexico from the Lacandona rainforest. The authors noted that these and other records continue to corroborate the continuity of bryophytes from North America to South America through the Central American bridge.

In a study of only 6 hectares (about 6 rugby fields or 10 American football fields) in a Costa Rican upper montane *Quercus* (oak) forest (Figure 122), Holz *et al.* (2002) found 100 species of mosses, 105 of liverworts, and 1 hornwort. In the oak forests and páramo of the Cordillera de Talamanca, Costa Rica, Holz and Gradstein (2005) found 401 species of bryophytes. In both studies, the number of mosses and liverworts was almost equal, with Holz and Gradstein finding 209 mosses, 191 liverworts, and 1 hornwort. To illustrate the limitations that early ground-based studies imposed, studies in the lowland rainforest found 50% of the bryophyte species only in the crowns and upper trunks, >10 m above the ground (Cornelissen & Gradstein 1990).

Figure 122. *Quercus* (oak) tropical montane forest. Photo by Cody Hinchliff, through Creative Commons.

Acebey *et al.* (2003) found similar high numbers of species in Bolivia (Figure 123). In a submontane rainforest there, they found 80 species on just six trees, 48 liverwort and 32 moss species. But they are quick to point out that finding nearly all the species in the forest requires only a small sample size. They estimate that these six trees had floras that represented 95% of the total bryophyte flora of the forest. Churchill *et al.* (2010) published a catalog of the bryophytes of Bolivia with discussions of diversity, distribution, and ecology.

In Cuba (Figure 124), an island in the Greater Antilles, 383 taxa were reported, mainly from mountain areas (Motito *et al.* 1992). However, more recent studies seem to be lacking, preventing an evaluation of Cuban species compared to those of other localities.

Figure 123. Santa Cruz, Bolivia. Photo by Vincent Raalvia, through Creative Commons.

Figure 124. Montane moist forest on the slopes of Pico Turquino, Santiago de Cuba, Cuba. Photo by Male Gringo, through Creative Commons.

The tropical Andes (Figure 125) has by far the highest bryophyte diversity in the tropical Americas. For a general review on liverwort diversity in the Andes see Gradstein (1995b). Gradstein *et al.* (1977) compared oil body structures and examined the ecological distributions of selected species of the leafy liverworts in the Andes of Colombia. Churchill and co-workers listed 2,058 moss species names but suggested the actual number was probably closer to 1,500-1,700 because of likely synonyms (Churchill *et al.* 1995b).

The extraordinary biological richness of the Andean region is due to the great climatic and elevational variation of the area as well as historical factors. The authors concluded that an "increase in species diversity from the poles to the equator does not apply to mosses" (Churchill *et al.* 1995b). The latitudinal gradient has recently been studied by Shaw *et al.* (2005) for mosses and by Wang *et al.* (2016) for liverworts. These papers indicate that moss diversity is highest in the Southern Hemisphere and lowest in the Northern Hemisphere, with the tropics having an intermediate level. Liverwort diversity, in contrast, is highest in the tropics.

Figure 125. Andes, Ausangate hillside, Peru. Photo by Marturius, through Creative Commons.

In the El Sira Communal Reserve of the Peruvian Andes, Graham *et al.* (2016) found 171 liverwort species, representing 51 genera and 18 families. This flora flourishes in the high humidity, with sometimes more than 7500 mm in a year. Climate, soils, and microhabitat delineated diverse distributional patterns along the 2000-m elevational range.

An example of the high diversity is the San Francisco Biological Reserve in the Andes of southern Ecuador (Figure 126) (Gradstein *et al.* 2007). The reserve ranges from 1,800 to 3,100 m asl and consists of about 1,000 ha of pristine montane forest and páramo. Almost 570 species of bryophytes (357 liverworts, 206 mosses, 3 hornworts), including more than half the total number of liverwort species known from Ecuador, have been recorded from the reserve and the number is still rising (Schäfer-Verwimp *et al.* 2013; Gradstein & Benitez 2017). One reason for the high number of species recorded is probably the large number of bryologists who conducted fieldwork in the reserve and studied the collections. As Churchill *et al.* (2009) remarked: "One could readily predict similar diversity numbers throughout the montane forest of the tropical Andes employing such expertise. This study provides a basis for comparing other localities of similar vegetation and elevational range."

Figure 126. Reserva Biológica San Francisco, southern Ecuador. Photo courtesy of Robbert Gradstein.

In contrast, lowland habitats are usually less rich in bryophytes and do not provide for the same diversity seen by the rest of the flora and fauna (Churchill *et al.* 2009). While the number of niches in the multi-layered rainforest is relatively high, much of the tropical lowland is inhospitable to bryophytes, being too dry, too hot, or too dark. Whereas Churchill (1991) suggested that there is no strong latitudinal gradient of species richness from the temperate zone to the tropics, Hallingbäck (1992) further asserted that the temperate regions have a much higher diversity of mosses than is known in the tropics.

But "known" may be the operative word. On the one hand, many species have been described as different species multiple times; Ireland (1992) reduced the number of Latin American species of *Isopterygium* (Figure 127) from 92 to 8, Edwards (1980) accepted only 6 of the 93 species of *Calymperes* (Figure 128) from West Africa, and Bischler (1984) only 9 of 69 previously described New World *Marchantia* (Figure 3) species. Many taxa have been viewed as different simply because they were from a new place (O'Shea 2002). On the other hand, we are just beginning to explore the bryophytes high in the canopy through the use of a number of somewhat recent techniques (McClure 1966; Grison 1978; Perry 1978; Whitacre 1981; Parker *et al.* 1992; Gradstein 1996; Zotz & Vollrath 2003). Cornelissen and Gradstein (1990) report that about 50% of the lowland rainforest bryophyte species of Guyana occur in the crowns and upper bole, typically missed by early bryological studies. Bryologists are beginning to find that the canopy of these primary forests may support many more species than the more-readily studied understory (Cornelissen & ter Steege 1989; Wolf 1993a, b). Bryophytes in the tropics find their dominance in different places from those in the temperate forests.

Figure 127. *Isopterygium tenerum*; the genus *Isopterygium* has had many of the same species named by different names in the tropics, creating many synonyms. Photo by John Bradford, with permission.

Figure 128. *Calymperes* sp. (Calymperaceae), one of the families that dominate in tropical Guyana. Photo by Niels Klazenga, with permission.

In the lowland rainforests of Mabura Hill, Guyana (Figure 129), South America, Cornelissen and Gradstein (1990) found 134 bryophyte species. The dominant bryophyte family is the leafy liverwort family **Lejeuneaceae** (Figure 6, Figure 15-Figure 16), comprising about 30% of the cryptogamic flora (including bryophytes and lichens). As seems to be typical, the canopy accounted for 50% of the species. The humid mixed forest on loamy soil sports the richest liverwort flora.

Figure 129. Rainforest in Guyana. Photo through Creative Commons.

In Guyana (Figure 129), **Calymperaceae** (Figure 128), **Hookeriaceae** (Figure 182), **Hypnaceae** (Figure 130), **Orthotrichaceae** (Figure 99), and **Sematophyllaceae** (Figure 131) dominate the mosses. **Lepidoziaceae** (Figure 12), **Plagiochilaceae** (Figure 11), and **Frullaniaceae** (Figure 2, Figure 7-Figure 8), in addition to the species-rich **Lejeuneaceae** (Figure 6, Figure 15-Figure 16), are the predominant liverworts (Gradstein 1992). As will be discussed in another subchapter of this chapter, **epiphylls** (those algae, plants, and fungi living on leaves of other

plants) are common in the lowland and lower montane rainforests.

Figure 130. *Mittenothamnium reptans*, in the family **Hypnaceae**, one of the dominant families from Guyana. Photo by Michael Lüth, with permission.

Montfoort and Ek (1990) have provided us with a detailed study in French Guiana (Figure 132), reporting 154 bryophyte species from only 28 mature trees (22 species) in a lowland rainforest by sampling from tree base to top of the canopy. Of these, 88 were liverworts, with 71 of these in the **Lejeuneaceae** (Figure 6, Figure 15-Figure 16).

Figure 131. *Sematophyllum* sp. (**Sematophyllaceae**), one of the families that dominates in tropical Guyana. Photo by Michael Lüth, with permission.

Figure 132. Cataratas de Kaieteur, Guiana. Photo through Creative Commons.

In Kartabo, Co-operative Republic of Guiana (Figure 132), Graham (1933) also found the most diverse family to be the leafy liverwort family **Lejeuneaceae** (Figure 6, Figure 15-Figure 16). The most abundant moss here, by far, is *Rhaphidorrhynchium subsimplex* (see Figure 133), a species that is likewise abundant in Trinidad. Gradstein and Ilkiu-Borges (2009) compiled a guide to the liverworts and hornworts of Central French Guiana, including descriptions of habitats, especially the lowland cloud forest. This guide included 175 species of liverworts and 2 of hornworts, with the **Lejeuneaceae** again being the most species rich with 117 species. This guide recognized new combinations, providing updated nomenclature.

Figure 133. *Rhaphidorrhynchium callidum*; *R. subsimplex* is abundant in Kartabo in the Co-operative Republic of Guiana and in Trinidad. Photo by Juan Larrain, with permission.

In Moraballi Creek rainforest in the Co-operative Republic of Guyana (Figure 132), few species are very frequent (Richards 1954). *Calymperes lonchophyllum* (see Figure 134) and *Octoblepharum albidum* (Figure 135) occur in all synusiae (high canopy epiphytes, shade epiphytes, dead wood) except epiphyllous ones. Like most of the moist rainforests, the stream area is characterized by absence of ground-dwelling bryophytes, abundance of epiphyllous bryophytes, and dominance of the leafy liverwort family *Lejeuneaceae* (Figure 6, Figure 15-Figure 16).

Figure 134. *Calymperes tenerum* showing gemmae on leaf tips. *Calymperes lonchophyllum* is a frequent species, occurring in all synusiae except epiphylls at Moraballi Creek, Guyana. Photo by P. J. de Lange, through Creative Commons.

The Chocó region (Figure 136) of Colombia has the highest precipitation level in the Neotropical rainforests (Frahm 2012) and one of the wettest rainforests in the

world (Frahm 1994), with an annual rainfall up to 12,000 mm, in some places even up to 15,000 mm. As a result, the bryophyte flora differs from elsewhere and the mosses do not serve as adequate indicators of the vegetational zones. Rather, this location permits us to observe the effects of high humidity on bryophytes.

Figure 136. Everwet lowland rainforest of the Chocó, Pacific coast of Colombia. Photo by Jan-Peter Frahm, with permission.

Frahm (1994, 2012) worked on the moss flora of the Chocó region. Although it has a high level of endemism in flowering plants, birds, and butterflies, the moss flora was too poorly known to assess endemism. Frahm found 125 species of mosses on a transect from sea level to 1600 m elevation, using 10-hectare plots and different altitudes. In contrast, liverwort diversity in the same area was much higher, more than 200 species were reported, including 13 endemic taxa (Gradstein & Reiner-Drehwald 2017). In fact, Frahm (2012) found that mosses comprise only ~10% of the bryophyte cover, whereas elsewhere at the same elevational vegetation zone in the rainforest they comprise 40-50%. Gradstein (pers. comm.) commented that Frahm was able to finish his moss identifications quickly and get them published because there were rather few species only, whereas it took years to complete the many more liverwort identifications.

Some of the endemic liverworts of the Chocó region (Figure 136), such as *Fulfordianthus pterobryoides* (Figure 137), *Luteolejeunea herzogii*, and *Symbiezidium dentatum*, all members of *Lejeuneaceae* (Figure 6, Figure 15-Figure 16), are surprisingly common and widespread in the Chocó despite their absence elsewhere (Frahm 1994).

The higher liverwort diversity in the Chocó is probably due to the exceedingly high humidity in the area.

Figure 137. The endemic *Fulfordianthus pterobryoides* on a twig in Chocó, Colombia. Photo by Jan-Peter Frahm, with permission.

When Vital and Visnadi (1994) surveyed the bryophyte flora of the Rio Branco Municipality in Brazil, they found only 76 species of bryophytes; 66 of these were new records for the State of Acre and 2 were new records for Brazil. The only hornwort was *Notothylas vitalii* (Figure 138). We now know that there are at least 12 species of hornworts in Brazil (Felipe *et al.* 2016).

Figure 138. *Notothylas* sp.; *N. vitalii* was the only hornwort known to Vital and Visnadi from Rio Branco Municipality in Brazil in 1994. Photo by Blanka Aguero, with permission.

Costa (2003) studied the Amazonian rainforest bryophytes in Acre, Brazil. She revealed 514 species, with two field trips increasing the known bryoflora by 50%. She concluded that the diversity is still poorly known for the Brazilian Amazon.

In their study in the Chapada Diamantina region of Brazil, Valente *et al.* (2013) identified 400 bryophyte taxa, with the forests and **campos rupestres** (Figure 139; dry, rocky grasslands) accounting for 51% and 40%, respectively. The **caatinga** (Figure 140; shrub and thorn desert vegetation in interior northeastern Brazil) and **cerrado** (Figure 141; savanna) accounted for only 5% and 4%, respectively.

Figure 141. Cerrado, Campo Sujo, Brazil. Photo by Andreza Oliveira Borges, through Creative Commons.

Recent studies mostly support the earlier ones, but changes in nomenclature are reducing the numbers of endemic species. Costa and Peralta (2015) reported 1,524 species of bryophytes in Brazil, including 11 hornwort, 733 liverwort, and 880 moss species. As has been typical, the **Lejeuneaceae** (Figure 6, Figure 15-Figure 16) are the most abundant (285 species!). Following that record high are **Lepidoziaceae** (Figure 12) (48), **Frullaniaceae** (Figure 7-Figure 8) (37), **Ricciaceae** (Figure 52-Figure 53) (36), **Plagiochilaceae** (Figure 11) (27), **Radulaceae** (Figure 9-Figure 10) and **Metzgeriaceae** (Figure 13) (26 each), **Lophocoleaceae** (Figure 142) (18), **Aneuraceae** (Figure 14) (15), and **Calypogeiaceae** (Figure 143) (13). Surprisingly, **Sphagnaceae** (Figure 144) sets the record for mosses with 83 species, followed by **Fissidentaceae** (Figure 145) (65), **Pottiaceae** (Figure 146) (63), **Dicranaceae** (Figure 34, Figure 111) (54), **Bryaceae** (Figure 147) and **Sematophyllaceae** (Figure 131, Figure 184) (53 each), **Orthotrichaceae** (Figure 99) and **Pilotrichaceae** (Figure 148, Figure 182) (51 each), **Calymperaceae** (Figure 128, Figure 134) (48), and **Hypnaceae** (Figure 130) (28). Together, these account for 71% of the known bryophyte species in Brazil.

Other new records include those of Oliveira and Alves (2007) for the State of Ceará, Brazil. Even at this recent date, 35 of the 81 species they identified were new for the state, and one was new for Brazil. In the Parque Ecológico de Gunma, Pará, Brazil, Fagundes *et al.* (2016) found 103 species, with the liverworts exhibiting the greater diversity (59). Of course the **Lejeuneaceae** again had the predominant representation of species (42). The rare species predominated with 62 species, whereas generalists were represented with only 47 species. Five new records were uncovered.

Oliveira and Bastos (2009) contributed to the knowledge of **Anthocerotophyta** and **Marchantiophyta** from Chapada da Ibiapaba, Ceará, Brazil. Of the 10 thallose liverwort species found, this study revealed 3 species of thallose liverworts for the first time in northeastern Brazil.

Florschütz-de Waard and Bekker (1987) compared the bryophyte flora in different forest types in West Suriname. They found the highest species richness in the marsh forest and the lowest in the savannah and **xeromorphic** (having structural adaptations to dry conditions) scrub forests. Based on their microclimatic data, they considered liverworts to have a greater ecological amplitude in these forests than that of mosses, a conclusion different from that in many ecosystems.

Although the Neotropics have not been studied to the degree of the temperate systems, most areas have had at least some studies. Spruce (1884-1885), Fulford (1963, 1966, 1968, 1976) and Gradstein (numerous papers, *e.g.* Liverwort Flora of Brazil by Gradstein & Costa 2003 and Liverwort Flora of French Guiana by Gradstein & Ilkiu-Borges 2009) studied liverworts. Very little work, however, has been done on the hornworts, a problem that Villarreal (2007) and others are attempting to rectify.

A number of additional general Neotropical floristic studies are available, but nomenclature should be reviewed to find more recent revisions: Delgadillo (1976) on bryophyte ecology in Veracruz, Mexico, Mägdefrau (1983 – forests and páramos of Venezuela and Colombia), van Reenen and Gradstein (1983, 1984), Timme (1985 – Peru), Buck & Thiers (1989), Gradstein *et al.* (1990 – Guianas, especially lowland forest), Richards (1991 – Co-operative Republic of Guiana and West Indies), Sastre de Jesus & Santiago-Valentín [1996 – Puerto Rico, managed forests of **Cupressus** (Figure 25) and **Acacia** (Figure 26)], Churchill (1996 – Andes), Gradstein (1998 – páramos), Benavides *et al.* (2006) in the Colombian Amazon, Gradstein *et al.* (2016) on bryophytes of Sierra Nevada de Santa Marta, Colombia among others.

More recently, Delgadillo-Moya *et al.* 2017) have studied mosses in the cloud forests of Veracruz, Mexico. They suggested that the terminology of **Humid Mountain Forest** provided the broadest conceptual and geographical term. Nevertheless, using the most restrictive definition of the cloud forest, they found 323 species and varieties through literature searches, field, and herbarium records.

A few have ventured into ecological studies such as the vegetative variability of liverworts as demonstrated by *Bazzania* (Figure 149) (Bernecker 1990) or the differences among physiognomies in species richness and distribution (Valente *et al.* 2013). Others have sought to make broader statements regarding the ecology and biogeography

(Gradstein & Pócs 1989). More recent studies, particularly on epiphytes, epiphylls, altitude, and rock outcrops, will be covered in more detail in subsequent subchapters of this chapter. These studies point to the need for more studies in order to gain a clear understanding of tropical bryophyte ecology.

Endemism

Endemism (condition of species being unique to defined geographic location) has in the past been considered high in the tropics. In 1994 Delgadillo reported 48% endemism for mosses in the Neotropics. He suggested that endemism for mosses is higher in Bolivia, Costa Rica, and Ecuador than in other Neotropical areas. But he also considered that low numbers in some areas may be due to insufficient study. In others, low numbers result from strong connections with adjacent land masses having suitable habitat. I would also caution that high numbers may be the result of synonymy.

Frahm (2003) concluded that the rate of endemism is much higher in the tropics than outside the tropics but it is always much lower than that of tracheophytes (Table 2). Furthermore, we must consider these earlier numbers of endemics with skepticism. Throughout the tropics, many researchers worked independently of each other. They encountered bryophytes that were new to them and gave them new names. But researchers in other locations encountered these same bryophytes and gave them different names. There were no comprehensive keys to species from the tropics, and it was difficult to know that a species had already been named by someone else in a different location.

Schuster (1982) explained the high degree of endemism in the liverwort flora of Gondwanaland (Figure 150) as a result of the break up and dispersal of Gondwanaland. The resulting isolation permitted speciation that led to endemism. This was further enhanced by extinctions in the Antarctic, leaving behind an isolated flora in New Zealand. Schuster attributes the current degree of endemism seen in the Antipodes (Australia and New Zealand) to the climate changes and breakup of Gondwanaland.

Table 2. Percent of endemism in tracheophytes and bryophytes in tropical countries. From Frahm 2003.

	Tracheophytes	Bryophytes
Galapagos Islands	50%	10%
Cuba	50%	12%
Kilimanjaro		6%
Usambara Mtns.		3%
Réunion		9%
Mauritius		6%

Figure 150. Gondwana Box Log Falls; Gondwanaland has a high degree of liverwort endemism. Photo by Malcolm Jacobson, through Creative Commons.

In Australia (Figure 105), endemism in the Wet Tropics is among the highest in the country (Stevenson *et al.* 2012). That area likewise had the highest number of species. Areas having high numbers of species were not necessarily the areas with endemism.

Schuster (1982) contended that only two areas had high levels of endemic genera: Australasia and South America. India (Figure 151) has few endemic groups, most likely reflecting wide-spread extinction of cool-adapted taxa. By contrast, Schuster listed 39 genera and 11 subgenera of leafy liverworts that were endemic to tropical America. All but two of these endemic genera are in the families **Acrobolbaceae** (Figure 152), **Cephaloziellaceae** (Figure 151, Figure 155-Figure 156), **Gymnomitriaceae** (Figure 153), **Jungermanniaceae** (Figure 154), and **Plagiochilaceae** (Figure 11), or the very specialized **Lejeuneaceae** (Figure 6, Figure 15-Figure 16). (Note that family classification may be different now.) The endemic

species, furthermore, are usually highly specialized. One common feature of the liverwort genera *Pteropsiella* and *Protocephalozia* in the **Lepidoziaceae** (Figure 12) and *Phycolepidozia* (Figure 151, Figure 155-Figure 156) in the **Cephaloziellaceae** is that they develop either a thalloid or **confervoid** (loosely interwoven) gametophyte (Figure 156).

In Australia (Figure 105), at least four endemic species of the moss *Macromitrium* (Figure 99) occur in higher elevation rainforests dominated by *Nothofagus moorei* (Figure 157; not tropical) (Ramsay *et al.* 1987). Of these, the tropical rainforests have three endemic *Macromitrium* species: *M. erythrocomum* (Figure 99), *M. dielsii*, and *M. funiforme* (Andi Cairns, pers. comm. 7 October 2019).

Figure 157. *Nothofagus moorei* forest. Photo by David, through Creative Commons.

Karlin *et al.* (2012) used *Sphagnum palustre* (Figure 158) in Hawaii to explore the viability of a species from a single propagule. They concluded that this species currently has significant genetic diversity in Hawaii and that vegetative propagation does not preclude evolutionary success. This species is not known to produce sporophytes in Hawaii, although it does in other parts of the world (Figure 159).

Figure 159. *Sphagnum palustre* with capsules in Sweden. Photo by Oskar Gran, through Creative Commons.

Africa

In sub-Saharan Africa (Figure 160), O'Shea (1997b) reported 77% of the 3,000 taxa to be endemic. However, he warned that this figure may be misleading because the bryophyte flora of Africa was (and still is) so poorly known (and many may turn out to be synonyms).

Figure 160. Sub-Saharan Ruwenzori moss. Photo by Albert Backer, through Creative Commons.

Pócs (1998) found a high species diversity (~700 species known in 1998) along the Eastern Arc Mountains of Africa (Kenya and Tanzania; Figure 161), with only 32 (4.5%) endemic species, a low number even when compared to that of tracheophytes in the area.

Figure 161. Usambara Mountains, Eastern Arc Mountains, Tanzania. Photo by Joachim Huber, through Creative Commons.

Asia

In 2003, O'Shea reported 11% bryophyte endemism in Sri Lanka. The bryophyte flora of Sri Lanka is relatively rich, with 561 taxa. In fact, Gunawardene *et al.* (2007) considered the Western Ghats and Sri Lanka to be biodiversity hotspots.

In the Azores (Figure 162), of the 89 epiphyllous bryophyte species, 14 were considered endemic to the Azores or to Macaronesia (Sjögren 1997). These are somewhat frequent members of the endemic epiphyllous (Figure 163) association, the *Cololejeuneo-Colurion: Cololejeuneetum azoricae* (see Figure 44, Figure 163, Figure 164).

Figure 162. Island of Ponta Delgada, Azores. Photo by Larageast, through public domain.

The Asian endemics of the **Ptychanthoideae** (Figure 38) in the **Lejeuneaceae** (Figure 6, Figure 15-Figure 16) tend to be restricted to subtropical and temperate regions, with the majority also known from Eocene fossils (Gradstein 1991). They are largely **relicts** (something that has survived from earlier period). The **Lejeuneoideae** (Figure 165-Figure 166) are mainly in the tropical rainforests of the Malesian archipelago, are frequently highly specialized, and have no fossil records.

In 1987 Piippo *et al.* reported 48% endemism among the liverworts of New Guinea; 23% of the moss species seemed to be endemic. Most of these occur between 1500 and 3500 m elevation. The researchers found a high degree of endemism in the Frieda River Area and concluded that this is due to the high levels of metals in the area. The leafy liverworts *Bazzania* (Figure 149), *Frullania* (Figure 2, Figure 7-Figure 8), *Plagiochila* (Figure 11), and *Radula* (Figure 9-Figure 10) have a high degree of species endemism. The highest percentages of endemics among liverworts were in the **Plagiochilaceae** (Figure 11) (78%) and **Schistochilaceae** (Figure 167) (74%). Among the mosses, the number of species is much smaller, so the percentages may not be meaningful. The most notable may be the **Bryaceae** (Figure 168) with 35 species, 12 of which were considered endemic. The researchers cautioned that many of the families had not been studied well, so these numbers for both mosses and liverworts should be considered preliminary. All of these numbers will need revision after eliminating synonymy.

Figure 167. *Schistochila* sp., in the family **Schistochilaceae**, a family with many endemics in New Guinea. Photo by Li Zhang, with permission.

Figure 168. *Bryum billardieri*; *Bryum* is a genus with 12 endemic species in New Guinea. Photo by Jan-Peter Frahm, with permission.

Piippo (1994a) reported 38.2% endemism in Western Melanesia among the 440 species there. The highest reported endemism occurs in **Frullaniaceae** (Figure 2,

Figure 7-Figure 8) and **Plagiochilaceae** (Figure 11). Although this is a slightly more recent study, synonyms again create a problem in determining endemism.

Piippo (1994b) also studied the liverwort family **Lejeuneaceae** (Figure 6, Figure 15-Figure 16) of Western Melanesia and reported that only 20.5% of these species were endemic. She attributed this to the large number of epiphyllous species in the family, a group that is widespread throughout the tropics.

Australia

Ramsay *et al.* (1987) considered about 50-60 of the mosses to be endemic to the Wet Tropics bioregion in northeast Queensland (Ramsay & Cairns 2004). This number is most likely no longer accurate due to new discoveries and synonymy of old ones. One might expect a high number here; the next closest known population is 5400 km away (Figure 169) from the Australian populations (Meagher & Cairns 2016).

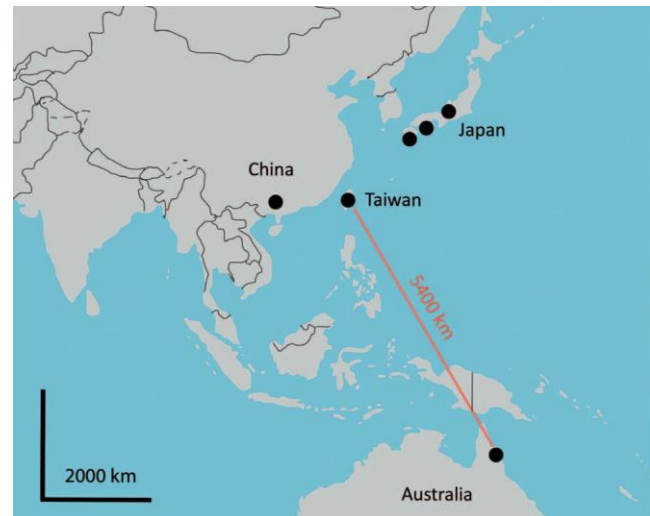

Figure 169. Australian tropical distance map. From Meagher & Cairns 2016.

In his report to the IUCN on areas and bryophytes to be protected, Streimann (2000) noted that "a reasonable number of endemics and restricted species are generally found in higher, more moist ranges in north Queensland." This area includes several high peaks with high levels of rainfall and cloud cover. Such endemics as *Calypstrochaeta brassii* (see Figure 78) (Streimann 2001) and *Dicranoloma braunii* (Figure 170) occur on Mt. Finnigan. On the Bellenden-Ker Range, *Clastobryum dimorphum*, once considered an endemic to the Wet Tropics, has been reduced to a variety of the more widespread *Clastobryum cuculligerum* (see Figure 79), now as var. *dimorphum* (Cairns *et al.* 2019). *Mniodendron comatulum* (Figure 171; treated as *Hypnodendron comatulum* in TROPICOS) is another endemic to the Australian tropics. Because of many nomenclatural changes and synonymies, the number of endemics is most likely different from that suggested by Ramsay *et al.* (1987), and it is likely that more endemics will be discovered in the future in this relatively underexplored part of Australia.

Figure 170. *Dicranoloma billardierii*, a species common in southern Australia; *D. braunii* is known only from Mt Finnigan in the Wet Tropics of Australia, but is widespread in continental SE Asia, Malesia and Oceania (Klazenga 2012). Photo by Niels Klazenga, with permission.

Neotropics

Holz and Gradstein (2005) found more endemics in the oak (*Quercus*) forests of Central America than in the páramo. They considered that the high percentages of endemic bryophytes in oak forests in Central America reflected the importance of climatic changes associated with Pleistocene glaciations. In an older publication, Delgadillo (1998) likewise reported a high endemic element, with *ca.* 47% endemics. At that time, he reported 2,900 species of mosses, a number that decreases when systematic studies uncover synonymy. He considered isolation as the major contributor to endemism.

Delgadillo *et al.* (2003) compared endemism in the mosses, grasses, and Asteraceae. Of the 2,373 endemic taxa known among these groups, 86 are mosses; 2030 are Asteraceae. In an earlier study, Delgadillo and Cárdenas (2002) reported no endemic taxa from the Monies Azules Biosphere Reserve, where they identified 136 species and varieties, plus 8 more from published records. In the Chiapas, Mexico, Delgadillo and Cárdenas (2002) found that endemic taxa are "virtually absent." Nevertheless, they

considered the area to be unique in harboring life-forms and structural diversity of mosses that have been lost in other tropical areas of Mexico.

As suggested by earlier studies, when Delgadillo-Moya *et al.* reported on moss endemism in the entire Mexican flora, they were only able to verify 77 endemic species out of the nearly 1000 species. They identified three main areas of endemism in Mexico: lowland areas in various states, the mountain area along 19020°N lat., and the highlands in Oaxaca and Chiapas. Their data suggest that the highest numbers of endemic species occur in the Trans-Mexican Volcanic Belt, Sierra Madre Oriental, Chihuahuan Desert, and Sierra Madre del Sur. Although many areas have not been explored, they do not anticipate many additions to the endemic list. It is likely that more species will reveal a wider distribution as other areas of the Neotropics are explored.

Fortunately, there are now good Neotropical bryologists who are increasing our knowledge of that bryoflora. Costa *et al.* (2015) examined the species richness and floristic composition on an elevation gradient in the Itatiaia National Park in Brazil. They reported 519 taxa, representing 10 elevations, using literature, herbarium samples, and data banks. These represented 34% of the total Brazilian bryoflora.

In southeastern Brazil, the endemic *Bromeliophila natans* (Figure 172) is difficult to distinguish from *Lejeunea* (Figure 173) (Gradstein 1997). It was so-named because it lives in the basins of bromeliads (Figure 174) (Heinrichs *et al.* 2014). The Neotropical moss *Philophyllum tenuifolium* (Leucomiaceae; Figure 175) is also restricted to this unusual habitat.

Figure 172. *Bromeliophila natans*, an endemic species that lives in bromeliad basins. Drawing from Heinrichs *et al.* 2014, slightly modified, through Robbert Gradstein.

It is interesting that *Spruceanthus theobromae* (Figure 176) is endemic to the *Cacao* (source of cocoa) plantations (Figure 177) of western Ecuador (Gradstein 1999). Kautz and Gradstein (2001) concluded that because of its host specificity on *Cacao* and its exclusive occurrence in plantations, it should be removed from the World Red List of Bryophytes and its status changed to that of a near threatened species. Its survival depends on the low management intensity of plantations such as those in western Ecuador.

Due to the efforts of a number of bryologists, the flora of Brazil is reasonably well known. Endemism in the Atlantic rainforest of Brazil reaches 242 endemic species out of the 1,337 species present (Costa & Peralta 2015). The dense **ombrophilous** (tolerant of wet conditions) forest here has 73% of these species represented, 62% of which are endemic. The southeastern region, with 1,228 species in total, has 219 endemic species. But the Atlantic rainforest in southeastern Brazil has most of the endangered species. Further monographic, worldwide or continent-wide studies may reduce the number of endemic species, but numbers are starting to approach reality.

Pócs (2019) recently reported a large number of liverworts new to Peru, two of which are endemic: *Colura ochyrana* (Figure 178) and *Drepanolejeunea halinae* (Figure 179), both restricted to the Andes.

Figure 178. *Colura ochyrana*, a new endemic species from the Peruvian Andes. Photo modified from Pócs (2019), with permission.

Figure 179. *Drepanolejeunea halinae*, a new endemic species from the Peruvian Andes. Photo modified from Pócs (2019), with permission.

Visnadi (2015) likewise reported on the Atlantic Forest of southeastern Brazil, at Mata Atlântica. This research revealed 199 species newly known for the area, bringing the total for the area to 220 species. This added two new records for Brazil and revealed locations of 13 Brazilian endemic species.

Causes of Endemism

Merckx *et al.* (2015) surmise that tropical mountains are diversity hot spots, but also exhibit a high degree of endemism. They point out that researchers have debated whether these mountain endemics originate more from local lowland taxa or from long-range dispersal from cool localities elsewhere. The latter could be similar to the separation of many frog species on different mountain tops, as discussed in the interaction chapter on amphibians in volume 2. This would presume that the species arrived, but was separated from interbreeding with the original species

for a long enough period of time that a new species evolved. On the other hand, if the population originated from lower elevations, it might have become a new species through the **founder principle** (loss of genetic variation that occurs when new population is established by very small number of individuals from larger population), followed by natural selection for characters that suited their mountain habitat.

To try to answer this question, Merckx *et al.* (2015) examined the species on Mount Kinabalu, a 4,095 m high mountain in Sabah, East Malaysia. They found that most of the unique species of the mountain are younger than the mountain (6 million years). This mountain exhibits a mix of pre-adapted immigrant lineages and descendants from local lowland ancestors, suggesting that the species did not arrive by long distance. Nevertheless, substantial shifts from lower to higher vegetation zones in these lowland groups were rare. The presence of sibling pairs of *Frullania* (Figure 2, Figure 7-Figure 8) with each member of the pair at a different elevation range of the same mountain (Figure 180) would tend to support the latter (Glime *et al.* 1990). Is there any reason to think that both processes could not occur? Is one of them the dominant cause?

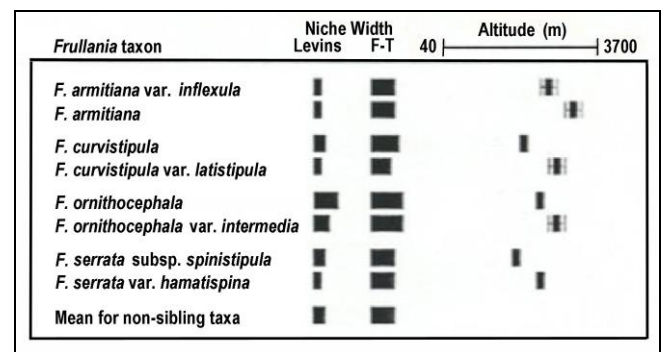

Figure 180. Levins and Freeman-Tukey niche width and elevational range of sibling pairs of *Frullania* on Mount Albert Edward, Papua New Guinea. Redrawn from Glime *et al.* 1990.

Patiño *et al.* (2014) attempted to explain the emergence of endemism by questioning why some genera diversify and others do not. Speciation on islands through gradual change from a founder population has been termed **anagenetic speciation**. They challenge this approach, saying that this process does not lead to "rapid and extensive speciation within lineages." Using surveys of the endemic bryophyte, fern, and seed plant floras of nine oceanic archipelagos, they showed that **anagenesis** (species formation without branching of evolutionary line of descent) was highest in bryophytes (73%), as measured by the proportion of genera with a single endemic species. Ferns had 65% and seed plants 55%. They concluded that "the dominance of anagenesis in island bryophytes and pteridophytes [ferns] is a result of a mixture of intrinsic factors, notably their strong preference for (sub)tropical forest environments, and extrinsic factors, including the long-term macro-ecological stability of these habitats and the associated strong phylogenetic niche conservatism of their floras."

Dangers to Endemics

Silva *et al.* (2014) raised concerns about conserving key species of bryophytes. They created potential distribution models for ten species that had been classified as bio-indicators of environmental quality and/or were endemic to the Atlantic Forest or to Brazil. Distributions of nine of the species could be explained by the Mean Diurnal Temperature Range. They raised concern that these species were not known in all the potentially suitable areas and that only 27% of the potentially suitable areas overlapped with Conservation Units. While these species were not specifically endemic, this approach could be used for determining the need for areas to protect endemic species.

Like Silva and coworkers (2014), Raxworthy *et al.* (2008) found that temperature was important in shifting altitudinal distributions of plants and animals, with increasing temperature likely to surpass a warming threshold for some species. Of three endemic species in the tropical montane of Madagascar, two could not be relocated after 10 years. In addition, out of nine species analyzed, seven species had shifted their distributions to higher elevational means. In the 10 years of study, the mean lower elevation limit had shifted upward 29-114 m.

Tropical Rainforests

Whitmore (1998) provided an introduction to the tropical rainforest. These forests are evergreen, and the precipitation occurs more or less equally throughout the year, exceeding *ca.* 2000 mm per year. Under the umbrella of **rainforests** (Figure 181), Frahm and Gradstein (1991) recognized elevational rainforest types (see Chapter 8-1). The elevations of the different types of rain forest are lower on islands than on the continent. In areas with prolonged dry periods (>3 months), these forests are replaced with deciduous forests, seasonal forests, and savannahs. These types of forests will be discussed more specifically in the subchapters on Altitude.

Figure 181. Hawaiian tropical rainforest. Photo from Photoeverywhere, through Creative Commons.

Early researchers in the tropics considered the tropics to be an "inexhaustible" source of new bryophyte species (Pócs 1982). Richards (1954) bemoaned the scantiness of studies on the species and their ecology in tropical rainforests.

As one moves from the temperate zone into the tropics, there will be an increase in members of the moss families

Calymperaceae (Figure 128, Figure 134) and **Sematophyllaceae** (Figure 131, Figure 184), in particular, as well as **Fissidentaceae** (Figure 17, Figure 37), **Leucobryaceae** (including ***Octoblepharum***; Figure 112), **Pilotrichaceae** (Figure 182), and **Pterobryaceae** (Figure 183) (Pócs 1982). The **Calymperaceae** are distributed primarily in the humid lowland tropical and subtropical forests (Reese 1993). These primarily epiphytic taxa are usually dioicous but produce numerous gemmae at their leaf tips, facilitating short-distance dispersal (Gradstein & Pócs 1989). Whereas ***Calymperes*** (Figure 128) is restricted to the lowlands, another tropical member of **Calymperaceae**, ***Syrrhopodon*** (Figure 185), extends up to more than 2,000 m elevation. Both are primarily **corticolous** (growing on bark), but occur also on logs in the first stages of decomposition. In the **Sematophyllaceae**, ***Taxithelium planum*** (Figure 184) is abundant enough to be termed a weed in the lowland tropical forests of the Americas (Buck 1985; Churchill & Salazar Allen 2001).

Figure 185. *Syrrhopodon gaudichaudi* from the Neotropics, where the genus is known up to 2000 m asl. Photo by Michael Lüth, with permission.

Ramsay *et al.* (1987) stressed the importance of learning the role of bryophytes in the rainforest ecosystem in order to encourage more study of rainforest bryophytes. Jordan *et al.* (1980) could only hypothesize on the role of epiphytes in scavenging nutrients and moderating the flux of nutrients in the throughfall. Since then, Nadkarni and her students have greatly increased our knowledge of the role of bryophytes in nutrient relationships in the tropics (see Nutrient Relations in Chapter 8-1 of this volume).

Elevation and waterways are major contributors in determining the flora. Dixon (1935) described that below the Borneo ridgetop, cushions of the moss family **Dicranaceae** (Figure 34, Figure 111) are relatively common on both the ground and on logs, but liverworts remain more abundant. Near the stream, the large, pendent moss *Spiridens reinwardtii* (Figure 83) might be found on tall tree ferns. Dixon also reported abundant *Macromitrium ochraceum* (Figure 99) under the thin cover of *Dacrydium* (Figure 186; Podocarpaceae) and *Leptospermum* (Figure 187; Myrtaceae).

Several additional studies are helpful in understanding the rainforest bryophyte communities. Giesenhagen (1910) described moss species of the rainforest. Pócs (1987) reported the changes in the biomass and productivity of bryophytes in east African rainforests. Gradstein and Pócs (1989) discussed tropical rainforest ecosystems and biogeography. Equihua and Gradstein (1995) compared the bryophyte communities of a rainforest with those of an old field. A more recent comprehensive study is that of Gradstein and Sporn (2010) on land use gradients.

Pantropical Distributions

Although liverworts seem to reach particularly high diversity in the tropics, moss richness estimates, based on 86 taxonomic checklists, do not support the hypothesis of a richer moss flora in the tropics compared to that of other latitudes (Shaw *et al.* 2005). Nevertheless, the latitudinal gradient for just North, Central, and South America was significant. Molecular data suggest that the Southern Hemisphere exhibits a higher diversity than does the Northern Hemisphere. The tropics are intermediate. Furthermore, virtually all the moss lineages are represented in all three latitudinal zones. Hence, it should be no

surprise that mosses have travelled long distances and that many tropical mosses, particularly above the species level, are pantropical. This reasoning fits the Baas-Becking Hypothesis that everything is everywhere, a principle that seems to apply well to organism with small, resistant propagules such as spores (see Volume 2, Chapter 2-6; Pisa *et al.* 2013).

By examining tropical bryophyte communities in both Old World and New World tropics, Kürschner and Parolly (1999) could compare the differences. They concluded that although communities may be similar among the Americas, Africa, and Asia, there is not a **pantropical** (in tropics of both Eastern and Western Hemispheres) bryophyte flora. Could this be a result of too many bryologists giving different names to the same species in different places? In any case, there are clear similarities among the bryophyte communities of the three continents and a pantropical class of epiphyte communities can be recognized. Earlier, similarities and differences among the bryofloras of the tropical Americas, Africa, and Asia have been described by Theodor Herzog (1926) in his classical treatise *Geographie der Moose*. Recent studies such as that of Dauphin L. and Grayum (2005) support the relatively large number of pantropical species, with 16% of their 55 collected species of bryophytes from the dry lowland forests and moist montane forests of the Santa Elena Peninsula and Islas Murciélagos, Guanacaste Province, Costa Rica, being pantropical.

While most of the species are not pantropical, many families and genera are, and certain general community characters are present. For example, Germano and Pôrto (2006) examined bryophytes in Pernambuco, Brazil (Figure 188), and found that the community distribution patterns and growth forms were similar to those of other humid tropical forests, but in Pernambuco the richness was somewhat less. In their study, the most diverse bryophyte flora was that of **corticolous** (living on bark) bryophytes (33% of species). **Epixylic** (growing on wood, *i.e.*, trunks without bark, mostly logs) bryophytes were next (23%). With this high diversity, it is somewhat surprising that communities share 75% of the species. Liverwort diversity is higher than that of mosses, with a ratio of 23:1 among the **epiphyllous** (living on leaves) and 2:1 among corticolous species. However, **terricolous** (living on ground) species exhibited a 1:3 ratio of liverworts to mosses. The researchers also found that epixylic species were not specific for degree of decomposition, nor did richness vary with degree of decomposition.

The mangroves, in contrast to the high diversity in other parts of the Wet Tropics, have very little diversity, with only *Calymperes* (Figure 64-Figure 65) species present on the mangrove trees (Ramsay & Cairns 2004). The terrestrial *Taxithelium leptosigmatum* (Figure 66-Figure 67) forms extensive mats on mud and exposed mangrove roots, especially if there is a high input of fresh water.

Substrate Specificity

Usable substrates in the understory of mature lowland forests are somewhat limited. The forest floor is typically covered with leaf litter that buries bryophytes. Rock surfaces may be available, especially vertical surfaces, if there is sufficient light. The forest itself provides trunk, branches, and leaf surfaces as substrates. At higher elevations, the soil and rock surfaces provide suitable surfaces. Soil in disturbed areas and other areas with sufficient light provides an available substrate. Bien (1982) examined substrate specificity of the leafy liverworts in a rainforest in Costa Rica. A later subchapter will be devoted to the leaf as a substrate for epiphyllous liverworts.

In a study in the Ecological Reserve of Gurjaú, Pernambuco, Brazil, Germano and Pôrto (2005) found few species that have substrate specificity. Rather, they typically occurred on two or three types of substrates. Some, however, were exclusively **corticolous** (bark-dwelling): *Archilejeunea fuscescens* (see Figure 189), *Cheilolejeunea rigidula* (see Figure 190), *Lejeunea monimiae* (Figure 191), some species of *Frullania* (Figure 2, Figure 7-Figure 8), and additional members of the **Lejeuneaceae** (Figure 6, Figure 15-Figure 16, Figure 191-Figure 192). Few epiphyllous species were restricted to leaves, including several species of *Cololejeunea* (Figure 163) and *Leptolejeunea elliptica* (Figure 192). Only *Neckeropsis disticha* (Figure 193) was restricted to rocks (**rupicolous**). On the ground the typical bryophytes were **Fissidentaceae** (Figure 17, Figure 37), thallose liverworts, and the hornwort *Notothylas vitalii* (see Figure 194).

Forest Floor

The forest floor of the lowland rainforest is nearly devoid of bryophytes, suffering from the same leaf burial found in temperate deciduous forests (Richards 1954), but also suffering from the multi-layered canopy that blocks a large percentage of the sunlight.

But decaying logs, stumps, and branches here can host a number of taxa. It is here, in the low light and high humidity, that one finds *Leucobryum* (Figure 195) and mosses in the **Hookeriaceae** (Figure 182), **Hypnaceae** (Figure 130), and **Sematophyllaceae** (Figure 131, Figure 184) (Gradstein & Pócs 1989). Liverworts of the **Lepidoziaceae** and **Lophocoleaceae** (Figure 196), rather than the seemingly ever-present **Lejeuneaceae** (Figure 6, Figure 15-Figure 16, Figure 191-Figure 192), thrive here. Generally, only on road cuts, termite mounds, and other disturbed soil can one find bryophytes, including many *Fissidens* (Figure 17, Figure 37) species.

Rockhouses

Outside the tropics, **rockhouses** can mimic the conditions prevailing in some tropical habitats. These rockhouse cliffs, occurring as geologic formations in the eastern United States, are sufficiently deep holes among the rocks to buffer both temperature and moisture extremes. Added to this are very low light conditions, thus in several ways mimicking conditions deep under the tropical rainforest canopy. These caves house a group of endemic species whose closest relatives are tropical, as well as disjunct species with a primarily tropical range (Farrar 1998). Although the ferns are the most conspicuous of these plants, the bryophytes are the most numerous (Figure 197). Farrar suggests that their vegetative reproduction and adaptation to net photosynthetic gain in very low light makes their existence in these unusual habitats possible. Evidence of morphology, physiology, genetics, and geology suggest that they have persisted in these relict habitats since the pre-Pleistocene when the eastern U.S. experienced tropical and subtropical climates.

Summary

Although some bryophytes are pantropical or have disjunct distributions on both sides of the Atlantic, their specialized habitats often restrict their distributions. This is indicated by a higher **beta diversity** among than within tropical regions. Nonetheless, the greatest number of bryophyte species occurs in the tropics. But many publications represent synonyms and many areas remain to be explored. Furthermore, it appears that increase in species diversity from the poles to the equator does not apply to mosses.

Tropical liverwort families are dominated by **Lejeuneaceae**, **Frullaniaceae**, **Radulaceae**, **Plagiochilaceae**, and **Lepidoziaceae**, with lesser numbers in **Metzgeriaceae** and **Aneuraceae**. The moss *Fissidens* has ~90 species in Africa. In tropical Asia and Australia, common mosses include the large species in **Dawsoniaceae**, **Pterobryaceae**, **Ptychomniaceae**, and **Hypnodendraceae**. The liverwort family **Lejeuneaceae** is particularly species-rich in Asian tropics.

In the Australian Wet Tropics, moss species richness correlates strongly with patch area, mean annual rainfall, and tracheophyte species richness. The greatest species richness occurs in the rainforests of high mountain peaks and on the Atherton Tableland of the Wet Tropics bioregion. The tropical mangroves have little diversity, with only *Calymperes* species as epiphytes. Road cuts and downed forests permit the growth of such large mosses as those in **Polytrichaceae**. Several liverwort families are very species rich.

In the **Neotropics**, typical moss families are **Pilotrichaceae**, **Phyllogoniaceae**, **Lembophyllaceae**, **Dicranaceae**, **Octoblepharaceae**, and **Phyllorepniaceae**. Dominant liverwort families include **Monocleaceae** and **Lejeuneaceae**, with the subfamily **Ptychantheae** mainly in Asia and subfamily **Brachiolejeuneae** mainly in the Neotropics.

An inordinate number of endemic species has been reported from the tropics, but this number has been

steadily decreasing as synonyms are determined. Furthermore, the rate of bryophytic endemism is much lower than that of tracheophytes. O'Shea reported that 77% of the sub-Saharan bryophyte flora was endemic, but warned that this large number probably represented many synonyms. Some of the liverwort families in Asia reach such high numbers, but mostly the endemism reported there is notably lower. Records in the Neotropics are similar to those of Asia. Tropical mountains are often diversity hot spots, and distance from similar habitats can lead to endemism, but these also are a source of many synonyms. Nevertheless, differences in selection pressures with elevation can cause speciation. But endemic species, by their very nature of having a restricted distribution, increase their probability of extinction. Only 27% of the areas deemed suitable for them occur in protected areas. Much exploration is still needed in areas of little or no collecting, hinting at more new species and endemic species on the horizon. The Australian Wet Tropics are still underexplored. There is a greater chance for discovery of new endemic species there because of the distance from other tropical areas of the world.

The tropical rainforest provides a wide range of niches due to its multiple levels of vegetation heights. To the usual substrata of rocks, logs, trunks, and branches, the tree and shrub leaves add a highly diverse assemblage of liverworts. The soil, however, typically has too many leaves and not enough light penetration for bryophytes to survive. As one goes from the temperate zone to the tropics, the moss families **Calymperaceae**, **Sematophyllaceae**, **Fissidentaceae**, **Leucobryaceae/Octoblepharaceae**, **Pilotrichaceae**, and **Pterobryaceae** increase in representation. Liverworts are typically more species-rich than mosses.

In the eastern United States, **rockhouses** created on mountainsides and slopes provide a tempered environment where a number of tropical species are able to survive.

Acknowledgments

My appreciation goes to Noris Salazar Allen for her efforts to make a very early version of this chapter reliable. Her helpful discussions kept me going on this part of the world I know so little about. S. Robbert Gradstein has been very helpful in discussions, obtaining images and references, and in providing a critical review of the chapter. Without his input this chapter would be far less complete. Tatiany Oliveira da Silva provided a critical reading for clarity, provided additional references, and shared her knowledge of the Amazon. Andi Cairns was a huge help in providing me with literature and images for the Australian tropics. Claudio Delgadillo-Moya provided me with more current references to update the treatment of Mexican tropics.

CHAPTER 8-3

TROPICS: EPIPHYTE ECOLOGY, PART 1

Figure 1. Celaque cloud forest in tropical Honduras. Photo by Josiah Townsend, with permission.

Barkman (1958) has contributed the definitive work on cryptogamic epiphytes (bryophytes, lichens) in 628 pages. It provides an account of the ecology and adaptations as they were known at the time and is the "bible" on cryptogamic epiphyte ecology. The work is restricted to temperate regions and does not treat tropical epiphytic bryophytes, which were very little known at the time. Nevertheless, much of the ecological information provided in this book is also valid for the tropics.

I was surprised to learn that approximately 10% of the tracheophytes are epiphytes (Prosperi & Michaloud 2001). It was not a surprise to learn that these are almost exclusively tropical, where they represent up to 25% of the tracheophytes. Overall, bryophytes comprised 40% of the epiphytic biomass in a neotropical cloud forest in Costa Rica (Nadkarni 1984) compared to 6% in the leeward cloud forest (Ingram & Nadkarni 1993). In both forests, bryophytes were most abundant among the smallest branches. The gnarled, windblown trees and the frequent mist in the elfin forest provide extremely favorable conditions for bryophytic growth (see Lawton & Dryer 1980).

The epiphytic habitat (Figure 1) is the most diverse one for tropical rainforest bryophytes, with 14 of the 15 main bryophyte families being predominantly epiphytic (Figure 1) (Gradstein & Pócs 1989). This is where the greatest bryophytic biomass of the rainforests occurs (Hofstede *et al.* 1993). Not surprisingly, the dry weight of epiphytes in the tropics is generally less than that shown in a New Zealand study (Hofstede *et al.* 2001), where lower temperatures and shorter dry periods are more favorable for bryophytes. In a New Zealand lowland, a single tree supported 61 tracheophyte species compared to 94 non-tracheophytes (lichens included). Pócs (1980) found a positive correlation between the amount of "surplus" rainfall (rainfall above 100 mm/month) and the epiphytic biomass in rainforest climates.

Among the early studies on bryophytic epiphytes, one must note the Japanese studies (Horikawa 1932, 1939, 1948, 1950; Kamimura 1939; Horikawa & Nakanishi 1954; Hattori & Noguchi 1954; Hattori & Kanno 1956; Hattori *et al.* 1956; Hattori 1966; Hattori & Iwatsuki 1970; Iwatsuki 1960, 1961, 1962, 1963a, b; Iwatsuki & Hattori 1955, 1956a, b, c, d, e, f, 1957, 1959a, b, 1965a, 1965b, 1966,

1968, 1970, 1987; Mizutani 1966). Hosokawa (1950, 1951, 1953, 1954) and coworkers (Hosokawa & Kubota 1957; Hosokawa & Odani 1957; Hosokawa & Omura 1959; Hosokawa *et al.* 1954, 1957, 1964) pioneered in describing epiphytic communities. Another important early study from Asia is the work by Tixier (1966) on epiphytic communities in Vietnam. Went (1940) discussed the sociology of tracheophytic epiphytes of Java.

Gradstein *et al.* (2007) compared the species richness on various substrates in southern Ecuador. This study demonstrated the preponderance of epiphytes there (Figure 2).

Figure 2. Substrate types of liverworts and hornworts at Reserva Biológica San Francisco, southern Ecuador. Number above each bar is number of species on that substrate type; e = epiphytic (bark); s = soil (incl. humus); r = rock; el = epiphyllous (living leaves); d = decaying wood. From Gradstein *et al.* 2007.

Frahm (1990a, 1994) found that in Borneo lowland and montane rainforests, even bark texture (smooth, fissured, flaky, or striped) made a difference in the epiphytic communities that developed. All bryophytes were considered to be acidophilic, with epiphytic bryophytes having no significant correlation with pH. On the other hand, rich concentrations of Na, K, and Mg seemed to be important in the substrate.

Akiyama *et al.* (2001) contributed to the knowledge of the Borneo bryophyte flora through two expeditions to the Kinabalu National Park in Malaysia. They reported 203 moss species and 31 liverwort species, with 25 species added to the checklist for the park and 17 new to Borneo.

Kürschner and Parolly (1998a) examined **pantropical** (tropical regions of both Eastern & Western Hemispheres) features that determined distribution of the epiphytic bryophytes. They found that distribution is correlated with structural parameters of the tree stands and with temperature zone intervals. Using only **supraspecific** taxa (*i.e.*, above the species level) they concluded that communities at low altitudes and those at high altitudes, respectively, resemble each other more pantropically than do lowland and montane communities on the same continent. Kürschner and coworkers were instrumental in elucidating epiphytic bryophyte communities in Africa (Kürschner 1995a, b).

Kürschner and Parolly (1999) sought to derive a consistent system for classifying the tropical epiphytes on a pantropical basis. Instead of using species, they used higher classification levels. For the lowland and submontane tropics they recognized the **Coeno-Ptychanthetalia** (Figure 3), whereas in the montane zones they recognized the **Coeno-Bazzanio-Herbertetalia**

(Figure 4-Figure 5). Using this thinking, they found that the low-altitudinal and high-altitudinal communities are more similar to each other pantropically than the communities of lowland and montane vegetation units occurring on the same continent.

Much remains to be found among the tropical bryophytes. Lee and Pócs (2018) have recently added to our knowledge of the distribution of the large genus *Lejeunea* (Figure 6), describing the new species *Lejeunea konratii* from Fiji.

Figure 6. *Lejeunea flava*; *L. konratii* was a new species in Java in 2018. Photo by Jia-dong Yang, through Creative Commons.

Some epiphytic bryophytes are **facultative**, growing on other types of substrate. Ando (1969) reported that the epiphytic bryophytes on *Buxus microphylla* var. *insularis* (= *B. sinica* var. *insularis*; Figure 7) also grew on limestone ridges in Taishaku.

Figure 7. *Buxus microphylla*. Epiphytic mosses of this species also grow on limestone ridges. Photo by Sage Ross, through Creative Commons.

Frahm and Kürschner (1989) investigated factors related to bryophyte success on trees. Rhoades (1995) provided an extensive review on the nontracheophyte epiphytes of the canopy, including distribution, abundance, and ecological roles, but this paper mainly focuses on temperate forests.

Water Relations

The distribution of epiphytic bryophytes in the tropics seems to be all about water. The bryophytes in the crowns of the trees generally are more desiccation-resistant than are those at the tree base (Hosokawa & Kubota 1957; Hosokawa *et al.* 1964).

Water is always a primary limiting factor for epiphytes, and in the tropics the daily change from wet to dry can be particularly problematic (Johnson & Kokila 1970). For some species in the saturated rainforests, as little as 4 hours of exposure to a relative humidity of 63% or less can result in damage. Thus, such sensitive species often live on the wettest sides of the trees. Within a range of 10-76% humidity for four hours, two groups of mosses emerged. One group had low resistance, but the other had a high resistance to desiccation. This latter group of species grew in microhabitats of the forest with low humidity.

Löbs *et al.* (2019) opined that our understanding of the role of the extensive epiphytic bryophyte cover was largely unknown, noting their potential importance in biosphere-atmosphere exchange, climate processes, and nutrient cycling. Their water content could have important impact on local, regional, and even global biogeochemical processes. The researchers measured a vertical gradient from the Amazon Tall Tower Observatory in the Amazonian rainforest and determined that only minor variations occurred in the monthly average ambient light intensity above the canopy, but that different patterns emerged at different heights. At 1.5 m, the values were extremely low, exceeding 5 $\mu\text{mol m}^{-2}$ photosynthetic photon flux density only 8% of the time. These values differed little throughout the year. The temperatures likewise showed only minor variation throughout the year, with larger values and more height dependence during the dry season. Water levels, on the other hand showed more variability. At higher levels they were affected by the frequency of wetting and drying; at low levels near the forest floor they retained water over a longer time period. They concluded that water content is the deciding factor for overall physiological activity, with light intensity determining whether net photosynthesis or dark respiration occurs. Temperature was of only minor importance. Light was limiting on the forest floor; in the canopy the bryophytes had to withstand a larger variation in microclimatic conditions.

Water Content

Klinge (1963) reported on the epiphyte humus from El Salvador. Their role in forest water and nutrient dynamics, however, seemed to attract little attention. Water content of bryophytic epiphytes in an old-growth forest in Costa Rican cloud forest reached maximum values of 418% of dry weight, with a minimum of 36% (Köhler *et al.* 2007). The epiphytic bryophytes experienced more dynamic wetting and drying cycles than did the canopy humus. The maximum water loss from bryophytes through evaporation was 251% (dry weight), whereas it was only 117% from the canopy humus, following three days of sunny weather with no intervening precipitation.

Pócs (1989) estimated that high altitude epiphytic bryophytes in Tanzania can absorb up to 30,000 L ha⁻¹ of water during one rainstorm. When high humidity and high

temperatures occur at the same time, as they often do, they cause respiratory losses that cannot be balanced by photosynthesis in these C₃ plants, thus limiting their productivity, especially in the lowland forests (Richards 1984, Frahm 1990b).

Karger *et al.* (2012) measured the relationship of bryophyte cover to air humidity at two elevation ranges in the tropics. When the highland site (1800-3500 m asl) was considered separately from the lowland site (<1800 m asl) there was a significant relationship between bryophyte cover and relative air humidity. Temperature related to cover in the lowlands only. They confirmed that bryophyte cover is a good proxy for relative air humidity along the elevational gradient in the tropics, proposed earlier by van Reenen and Gradstein (1983).

Müller and Frahm (1998) compared the water-holding capacity of epiphytes in a montane rainforest in the Andes of Ecuador. They found an average of 0.57 L m⁻² on the trunks, 19.51 L m⁻² on branches, and 4.16 L m⁻² on twigs. This is ten times the dry weight on branches, but only three times on twigs. Using a representative tree of 27 m height, which has an average of 65.4 kg dry weight of epiphytes, they calculated that the epiphytic bryophytes on one such tree could store 669 liters of water.

Growth Forms and Life Forms

Several life forms and their role in water relations have already been discussed in an earlier chapter. For definitions, illustrations, and examples, see Chapter 4-5 in the Physiology volume.

Kürschner (1990) looked at the distribution of life forms and water-bearing and water-storing structures in epiphytic moss communities on Mt. Kinabalu, North Borneo. Norris (1990) concluded that water relations must be understood along at least four dimensions: hydration/dehydration frequency; duration of hydration; duration of dehydration; degree of water loss. More recent studies of xerophytic bryophytes suggest that the rate of drying is also important (Greenwood & Stark 2014). Norris further concluded that **large colonies** generally maintain hydration longer than do smaller colonies. Water can be conducted laterally among contiguous clones. Separated **tufts** and **cushions**, on the other hand, may store more water, but they contribute little to transfer of water over the surface of the host tree. In the tropical rainforests, the mass of the bryophytic epiphytes is typically larger than that found in temperate forests. The biomass is reduced as a result of disturbance, probably due to increased opportunity for desiccation with increased isolation and wind movement. This further results in the loss of water transfer and reduction in both water and mineral retention. Norris cited the *Braunfelsia* (moss; Figure 8) community in Papua New Guinea as an example of sensitivity to deforestation and resulting increase in dehydration frequency of adult plants.

Working in the tropical montane oak-bamboo forest of Costa Rica, Romero *et al.* (2006) conducted investigations on four **pendent** bryophyte species, listed from most protected to most exposed: *Phyllogonium viscosum* (Figure 9), *Pilotrichella flexilis* (Figure 10), *Dendropogonella rufescens* (Figure 11), and *Frullania convoluta* (Figure 12). They found that the most exposed species had higher light saturation and compensation

points, higher dark respiration rates, more chlorophyll, higher chlorophyll *a:b* ratios, and higher N concentrations. Contrary to expectations, the most exposed species had the lowest water content at full saturation. Rate of water loss differed little among the species. The rather exposed moss *Dendropogonella rufescens* had a substantially higher moisture compensation point for carbon uptake than did the other three species. The researchers concluded that density, size, and arrangement of leaves, as well as clump architecture, defined the physiological patterns of water storage and transport they observed.

Kürschner and Parolly (1998b) discussed adaptations to water conduction and storing. The **mat** life form that is typical of lowland habitats correlates with such water-holding structures as leaf lobules (Figure 13) [especially **Lejeuneaceae** (Figure 6)] and water sacs as well as rhizoids that can act like sponges to hold and move water in capillary spaces. In addition to these, Frey *et al.* (1990) included **alar cells** (Figure 14), **vittae** (row of elongated cells down center of leaf, only one cell deep; Figure 15), and **ocelli** (darkened cells in row in leafy liverwort leaf; Figure 13, Figure 16) as characteristic of epiphytic

bryophytes in the lowland forest of Mt. Kinabalu, North Borneo. Rhizoid discs (Figure 17) maintain attachment. In areas with high humidity in the montane belt, the **mat** form is replaced by **fan** (Figure 21), **weft**, and **pendant** (Figure 9-Figure 12, Figure 34-Figure 35) life forms that are able to obtain water from fog and mist (**fog-stripping**). Fine leaves (Figure 10) or deeply divided leaves are able to capture this water.

Frey *et al.* (1990) suggested three principles of water conduction and storing mechanisms: draining surplus water, storing water in dry seasons, and condensing water vapor. They cited the "groovelike" arrangement of leaves as a mechanism to permit water support as well as drainage of water surplus. They found a significant correlation between water sacs (Figure 13), **mat** life form, and smooth bark in the epiphytic bryophyte communities of the lowland forest, facilitating water availability during short periods of dryness.

Parolly and Kürschner (2004) noted that the adaptive trends of functional types (life forms, life strategies, water conduction, and water storage) among the **oreal** (pertaining to mountains) trunk epiphytes at various elevations of southern Ecuador were distinct. They further concluded that these trends occur worldwide among tropical trunk epiphytes.

Kürschner (2003) conducted a phytosociological analysis on the epiphytic Afrotropical bryophytes of southwestern Arabia. These epiphytes are affected by monsoons, but at the same time must be drought-tolerant. *Orthotrichum diaphanum* (Figure 18) and *Syntrichia laevipila* (Figure 19) provide "character species" that define alliances. As in other studies, life forms and life strategies correlate with the ecological site conditions. The *Orthotricho* (Figure 18) – *Fabronietum socotranae* (see Figure 20) is a drought-tolerant, light-tolerant, and xerophytic alliance. It is dominated by cushions, short turfs, and mats of perennial stayers that regularly produce sporophytes. In contrast, the alliance in the shaded, subhumid habitats are described as the *Leptodonto* (Figure 21) – *Leucodontetum schweinfurthii* (see Figure 22) association. This association is comprised of **tail** or **fan**-forming **pleurocarpous perennial shuttles** that have large spores. This life strategy adapts them for short-range dispersal and moderately limited reproduction, with large spores more likely to survive and germinate than would smaller ones. Furthermore, this more humid atmosphere supports a much higher diversity in life forms and life strategies.

In a similar study on Socotra Island, Yemen, Kürschner (2004) described the epiphytic *Lejeuneo rhodesiae* (see Figure 23) – *Sematophylletum socotrensis* (see Figure 24) from the upper parts of Haghier Mountains. This association characterizes the evergreen Afromontane forests where heavy fogs and mists are typical. Kürschner identified three subassociations [*typicum*, *Hyophiletosum involutae* (drought-tolerant; Figure 25), and *Papillarietosum croceae* (shade-loving humid; Figure 26).

These subassociations are dependent on altitude, forest structure, life conditions, and humidity. Both the *typicum* and *Hyophiletosum involutae* subassociations are characterized by **perennial stayers** or **perennial shuttle** species that form **mats** and **short turfs**. They regularly produce sporophytes. The *Papillarietosum croceae* subassociation is likewise characterized by **perennial stayers** and **perennial shuttle** species that are **pendant** or **mat-forming**, but these have large spores with moderate-low reproductive rates. As seen in the more humid areas in the 2003 study, the *Papillarietosum croceae* subassociation has a much higher species richness with more diverse life forms and life strategies.

For a comparative discussion of life strategies in bryophytes as functional types, see Kürschner and Frey (2013). This treatise addresses vegetation types and their associated bryophyte life strategies for both temperate and tropical systems, based on more than 140 bryophyte communities and 1,300 taxa for corticolous, saxicolous, and terrestrial bryophytes. Sporn (2009) compared life

forms of bryophytes in various height zones in the forests of Central Sulawesi, Indonesia (Figure 27).

Figure 28. Epiphyte zones from Sporn 2009.

Osmotic Potential

Experimental studies on tropical bryophytes are still rare. However, several have looked at **osmotic potential**. This is the potential of water molecules to move from a **hypotonic** solution (more water, less solutes) to a **hypertonic** solution (less water, more solutes) across a semi permeable membrane. The osmotic potential becomes more negative as solutions become more concentrated.

Hosokawa and Kubota (1957) discussed the resistance to desiccation of epiphytic mosses from a beech forest in southwest Japan and related this to osmotic pressure. They found that the amount of time adult bryophytes could tolerate desiccation varied by species, but also by season of collection.

Akande (1984) looked at the use of **anhydrobiosis** (strategy that permits organisms to survive severe dry and/or extreme cold or hot conditions they often encounter) by corticolous tropical bryophytes as a means of surviving dry periods. Akande (1985b) also demonstrated the importance of **osmotic potential** (measure of tendency of solution with dissolved salts to withdraw water from pure water by osmosis, across differentially permeable membrane) as a factor in resistance to water stress in four Nigerian corticolous species. Using the mosses *Stereophyllum nitens* (see Figure 29-Figure 30) and *Calymperes palisotii* (Figure 31-Figure 32) and the leafy liverworts *Spruceanthus floreus* (syn. = *Mastigolejeunea florea*; see Figure 33) and *Frullania spongiosa* (see Figure 12) he found that the osmotic potentials of the corticolous mosses are higher than those of the tested liverworts. These osmotic potentials increase from wet to dry season. *Spruceanthus floreus* is less desiccation tolerant than the two mosses, but all three of these taxa could survive desiccation of 0%, 32%, and 54% relative humidities for six months at room temperature.

Proctor (2002) measured water relationships in two **pendent** mosses [*Pilotrichella ampullacea* (Figure 34), *Floribundaria floribunda* (Figure 35)] in Uganda. The estimated osmotic potential at full turgor in *P. ampullacea* was -1.82 MPa and in *F. floribunda* it was -1.43 MPa. Based on the definition above, net diffusion of water occurs from regions of less negative potential to ones of more negative (or lower) potential. Hence, in this case, more water would move into *P. ampullacea*. Both species are able to hold large quantities of external capillary water, up to *ca.* 12 in *P. ampullacea* and *ca.* 6 in *F. floribunda*. *Pilotrichella ampullacea* has a very rapid initial recovery (30-60 minutes after 20 h air drying at -37 MPa), but as desiccation time increased from 20 hours to 12 days recovery became less complete and full recovery time was slower. This osmotic relationship is well suited to its humid tropical forest environment. *Floribundaria floribunda* requires more continuously moist conditions.

Figure 34. *Pilotrichella ampullacea*, a species in Uganda that holds large quantities of external water. Photo by Jan-Peter Frahm, with permission.

Figure 35. *Floribundaria floribunda*, a species in Uganda that holds large quantities of external water, but requires nearly continuously moist conditions. Photo through Creative Commons.

Desiccation Recovery

One advantage that bryophytes have following desiccation is that liverworts and some mosses recover their full photosynthetic capacity within hours of rehydration, whereas resurrectable ferns such as *Polypodium* (Figure 36) need at least a full day (Peterson *et al.* 1994). On the other hand, liverworts and most mosses lose water very quickly, whereas orchids, bromeliads, and other succulent tracheophytes lose water slowly. But some mosses also are able to retain their water for a longer time, as, for example, *Leucobryum* (Figure 37). *Leucobryum* has several adaptations that facilitate its water storage. It has a tight, compact cushion life form (Figure 37); its leaves are several cells thick (Figure 38); and it has **hyaline** (colorless – lacking chloroplasts; Figure 38) cells that permit water storage. Peterson and co-workers found that plants in the understory and gaps dried more slowly than did plants in their box treatment that simulated the canopy. Those in the gap dried slightly faster than did those in the understory.

In French Guiana (Figure 39), 13 of 18 tested bryophyte species were able to maintain more than 75% of their photosynthetic capacity, as indicated by chlorophyll fluorescence, after 9 days of desiccation at 43% relative humidity (Pardow & Lakatos 2012). However, species from the understory required maintenance at 75% or higher relative humidity in order to recover. The researchers reactivated these bryophytes with water vapor only, a condition that is common in many tropical habitats, but which has been largely ignored in physiological ecology studies. The researchers concluded that tolerance to desiccation is of utmost importance as climatic changes occur (see also Wagner *et al.* 2013 and pertaining discussions in the subchapters on Tropics: Altitude).

Rainfall Interception

Frahm (2003a) compared the microhabitats of epiphytic bryophytes and lichens to determine why some trees were covered by lichens and others by bryophytes

(Figure 40) or others where lichens were in the crowns and bryophytes were on the trunks. Using humidity data loggers for one year, he used periods when the plants were wet and the relative humidity was at least 80%. He found that bryophytes typically thrive where there is a 20-30% longer duration of the wet period than where the lichens thrive. He cautioned that when doing pollution studies, such humidity differences should be considered.

Figure 40. Moss forest Mt. Ruwenzori Africa. Photo by G. Miehe, courtesy of Robbert Gradstein.

Pócs (1980) in the Uluguru Mountains, Tanzania (Figure 41), East Africa, examined the effect that epiphytic biomass (all kinds of epiphytes) had on the water balance of two rainforest types. With 2,130 kg ha⁻¹ dry matter in the submontane rainforest, the rain interception capacity was approximately 15,000 L ha⁻¹. By contrast, the mossy **elfin forest** (cloud forest; Figure 42) at 2,120 m altitude had approximately 14,000 kg ha⁻¹ with an interception capacity of 50,000 L ha⁻¹ during a single rainfall. Aerial humus accounts for a large portion of the interception capacity of the elfin forest, with ca 4,700 kg ha⁻¹ compared to ca 375 kg ha⁻¹ in the submontane rainforest.

Hölscher *et al.* (2004) examined the importance of epiphytes to rainfall interception in a tropical montane rainforest of Costa Rica. These canopy epiphyte masses are comprised mostly of mosses, liverworts, and lichens, all known for their ability to intercept rainfall. Biomass of all epiphytes was 1.9 t ha⁻¹ dry weight in the studied 35-m-tall old-growth oak (*Quercus*) forest. The monthly moss water contents measured *in situ* ranged 24-406% of moss dry weight. This contrasts with sums of observed throughfall, stemflow, and interception measurements of 70, 2, and 28%, respectively, of the associated 2,150 mm of rain. Cloud water was not a factor in this ecosystem. This study suggested that mosses contributed only about 6% to the interception total, making the bryophytes much less important than in many rainforest ecosystems.

In central Veracruz, Mexico, Holwerda *et al.* (2010) assessed rainfall and cloud-water interception in a mature forest (Figure 43) and a 19-year-old secondary lower montane cloud forest. The researchers used separate calculations for events with rainfall only. They estimated cloud-water interception at 6% of dry-season rainfall (640 mm on average) for the secondary forest and 8% for the mature forest. On the other hand, annual values of cloudwater interception were less than 2% of the total rainfall (3,180 mm). The researchers considered the higher

loss in the mature forest to be the result of a higher canopy storage capacity, reflected in the greater tree leaf area and more epiphyte biomass.

Figure 43. Cloud forest, Bosque Comaltepec, Mexico. Photo by Prsjl, through Creative Commons.

In Colombia, Veneklaas and van Ek (1990) found that rainfall interception was 262 mm (12.4%) of the 2,115 mm of annual precipitation at 2,550 m elevation and 265 mm (18.3%) of the 1,453 mm precipitation at 3,370 m elevation. They found no evidence of fog precipitation. Most of this rainfall interception was accomplished by the epiphytic bryophytes. They attributed the higher rainfall retention at 3,370 m to differences in rainfall distribution and canopy storage capacities. They considered epiphytes to have an important role in this retention. The total epiphyte mass was approximately 12 **tonnes** (metric ton = 1,000 kg) dry weight per hectare, with most of it consisting of bryophytes and dead organic matter. In experiments, Veneklaas *et al.* (1990) found that epiphyte-covered branches were efficient in capturing rainfall. Most of this capture was accomplished by bryophytes. Release of this rainwater was very gradual, as was loss by evaporation.

In southeast Queensland, Ford (1994) found that epiphytes could absorb water 6-7 times their dry weight. This absorption affects stemflow and throughfall. The increased weight can cause outer, thin branches to break.

Other sources may prove helpful in understanding the water relations of tropical bryophytes. Pócs (1976) elaborated on the role of epiphytic bryophytes and other plants in the water balance of rainforests in the Uluguru Mountains, East Africa. Thompson *et al.* (1994) described the water-holding capacity of subtropical epiphytic bryophytes. Bergstrom and Tweedie (1995) described the hydrologic properties of epiphytic bryophytes. Kürschner and Parolly (1998b) described life forms and adaptations to water conduction and storage in North Peruvian epiphytic bryophytes. Other studies that pertain to rainfall interception are those of Kürschner & Parolly (2004) and Fleischbein *et al.* (2002).

Fog Interception

Some areas that receive little rainfall do experience fog on a regular basis (Lakatos *et al.* 2012). Fine wires and thin leaves are able to collect this fog water (Figure 44). Lakatos and coworkers measured dew formation on bark and lichens to be 0.29-0.69 mm d⁻¹. This water aids in cooling and provides enough moisture to prolong photosynthetic activity.

Figure 44. Spider web with fog drops; a similar appearance of water drops occurs on spider webs, fine wires, bryophyte leaf awns, and other thin structures in fog. For mosses, this is a source of water. Photo by Janice Glime.

Fog is able to provide sufficient water to many kinds of bryophytes in areas with low rainfall. Santon and Horn (2013) demonstrated this in lichens in a shrubland of northern Chile. They compared the ability to harvest fog water to the biomechanical mechanisms of filter-feeding aquatic invertebrates. Greater branchiness, as measured by fractal dimensionality, indicates greater fog-harvesting ability. Fractal dimension of the foliose and fruticose lichens increased significantly as fog availability increased.

Fog (Figure 45) is an important contributor to the cloud forest (elfin forest) (Camilo *et al.* 2008). The abundant epiphytes in these forests benefit from this fog input, especially during periods of lower rainfall. Camilo and coworkers suggested that it is especially important when wind speed is high and leaf water content has intermediate values, but that at both low and high leaf water content the interception of fog water is constrained.

Figure 45. Cloud forest showing fog, Ella, Sri Lanka. Photo by Kenny OMG, through Creative Commons.

In a subtropical montane forest in northern Taiwan, Chang *et al.* (2002) estimated fog deposition rate on epiphytic bryophytes by measuring the increase in plant weight when exposed to fog. Fog duration in this forest averaged 4.7 hours per day in summer months and 11.0 hours per day in other months. The maximum duration was 14.9 hours per day in November. The bryophytes experienced an average fog deposition rate of $0.63 \text{ g water g}^{-1} \text{ dw h}^{-1}$.

Many bryophytes in the cloud forest and some tropical rainforests are **pendent** (Figure 34-Figure 35). Renner (1932) referred to these as dripping liquid water under various conditions in Javanese forests. León-Vargas *et al.* (2006) demonstrated the humidity stratification in the lowland Amazonian forest in upper Orioco (Figure 46). They found that all six species of **pendent** bryophytes in their Venezuelan cloud forests could survive at least a few days of desiccation. High humidities supported more recovery than low humidities. They considered droplets of cloudwater to be important sources of water for **pendant** and other bryophyte life forms, particularly during periods of low rainfall.

Figure 46. Relative humidity profile in meters above the ground in an Amazonian lowland forest of Surumoni, upper Orinoco. Modified from León-Vargas *et al.* 2006.

Pardow *et al.* (2012) described a recently discovered tropical lowland cloud forest type in the Guianas (Figure 47), originally discovered by Gradstein (2006) (see

Gradstein *et al.* 2010; Obregón *et al.* 2011; Gehrig-Downie *et al.* 2013). This habitat is created by frequent early morning fog events in the valleys, providing suitable habitat for a richer epiphytic species diversity compared to the common lowland rainforest. In the French Guiana (Figure 39) they compared the distribution of functional groups of epiphytes by height zone in the lowland cloud forest and lowland rainforest. These forests differed in composition of epiphytes in the canopy, especially in the mid and outer canopy, with the cloud forest exhibiting both a higher biomass and cover of both bryophytes and tracheophytes. Furthermore, the cloud forest had a richer bryophyte life-form composition. The cloud forest frequently exhibited tails, wefts, and pendants, life-forms that were nearly absent in the canopies of the common rainforest.

Microclimate

In any ecosystem, a diversity of microclimates can increase the diversity of species. These provide differences in substrate, temperature, light, and moisture availability. With their many layers of canopy, the tropical forests provide a wide range of microclimates and niches.

One might expect that gradients in light and humidity would affect species diversity and richness. In a Brazilian Atlantic Forest remnant, Silva and Pôrto (2013) found the highest diversity and richness in the trunk zone. But they found no significant difference of bryophyte total richness or diversity along edge distance or vertical zonation gradients. However, at the species level, they found that shade epiphytes decreased significantly along vertical gradients, while sun epiphytes increased. They concluded that the bryophyte distribution in the forest is more related

to the microenvironmental gradation than to such landscape characteristics as edge distance.

Early studies by Biebl (1964, 1967) attempted to relate success of the tropical species to water and temperature. Wolf (1993a) recognized that some species from the Colombian lower montane rainforest were able to occupy the more exposed habitats in the warmer lowland rainforest of Guyana where they could receive more radiant energy. Furthermore, the epiphytes in the northern Andes tropical montane rainforests were divided by height on the tree, occupying a gradation of microhabitats characterized by differences in moisture (Figure 46) and light (Figure 48).

Figure 48. Light gradation from ground to canopy in an Amazonian lowland forest. Modified from León-Vargas 2001.

Temperature is one of the important aspects of microclimate. As noted by Wagner *et al.* (2013), bryophyte biomass and diversity both decrease dramatically as one goes from high to low altitudes in the tropics. They surmise that high respiration rates at high temperatures may at least in part explain this decrease. They transplanted two bryophyte species from 1,200 and 500 m asl to 500 m and sea level, respectively, in Panama and studied the short-term temperature acclimation of CO₂ exchange for 2.5 months. They also compared survival and growth for 21 months. Mortality was highest and growth lowest in transplanted samples, with no evidence of short-term acclimation.

Whereas the Wagner *et al.* (2013) study implies that temperature is important in altitudinal distribution of species, Wolf (1993c) suggests that it is a moisture gradient that accounts for epiphyte community differences in the northern Andes. Nevertheless, in a study in Panama, Zotz *et al.* (1997) found a strong diurnal variation in water content of tropical bryophytes in a lower montane rainforest. Both low and high water content limited carbon gain. More than half of the daily carbon gain was lost during the night as respiration, suggesting that temperature also was important.

Hosokawa and Odani (1957) tied the limits on the period of assimilation to the loss of carbon from respiration. They found that those species at the tree base (*Thuidium cymbifolium* (Figure 49), *Loeskeobryum cavifolium* (Figure 50), *Thamnobryum subseriatum* (Figure 51), *Homaliodendron scalpellifolium* (Figure 52) had a minimum light requirement of 400 lux, whereas those species higher in the trunk had a higher **light**

compensation point (light level at which photosynthetic gain = respiration loss on daily basis). On cloudy days, only the mosses at the tree base could reach their compensation point.

The CO₂ levels differ throughout the canopy. In a subalpine forest of Taiwan, higher CO₂ levels occur in the lower canopy (Kao *et al.* 2000). Low CO₂ levels can limit photosynthesis, but higher levels can help to compensate for limited light.

Cao *et al.* (2005) found a correlation between epiphylls and light, moisture, habitat, and disturbance due to human activities. They found that the number of epiphytes increased from the center of the city to the outer suburbs. In the city, 67.4% of the epiphytes had a Levin's niche width of less than 0.1.

Gehrig-Downie *et al.* (2011) found that the lowland cloud forest had significantly more epiphytic biomass than did the lowland rainforest without fog in French Guiana (Figure 39). The lowland cloud forest is characterized by the high air humidity and morning fog that characterize river valleys in hilly areas, explaining the higher epiphytic bryophyte biomass.

Some of our understanding of microhabitat differences can be derived from studies on the effects of disturbance. For example, Werner and Gradstein (2009) conducted the first study comparing tracheophytic epiphytes and bryophytes along a disturbance gradient in a dry forest. They compared various degrees of disturbance in closed-canopy mixed acacia forest (old secondary), pure acacia forest (old secondary), forest edge, young semi-closed secondary woodland, and isolated trees in grassland (Figure 53). They found that density of bryophytic epiphytes on 100 trees of *Acacia macracantha* (in northern Ecuador; Figure 54) was significantly lower in edge habitat and on isolated trees than in closed forest. Forest edge was more impoverished than semi-closed woodland and had similar floristic affinity to isolated trees and to closed forest types. The microhabitats among these habitat types varied, contributing to the diversity. As they pointed out, "Assemblages were significantly nested; habitat types with major disturbance held only subsets of the closed forest assemblages, indicating a gradual reduction in niche availability." They found no diversity effect from distance to the forest for epiphytes on isolated trees. Species density was closely correlated with crown closure. They concluded that microclimate, not dispersal constraints, determined most of the epiphyte assemblage. Their most important conclusion is that in these dry environments, tracheophytic epiphyte diversity is not affected by disturbance, whereas bryophyte diversity is clearly affected. They attribute this to the poikilohydric

bryophyte condition that is more sensitive to changes in microclimate as compared to that of the homoiohydric tracheophytic epiphytes. The importance of microclimate for niche assembly of epiphytic bryophytes and absence of dispersal constraints is further supported by Oliveira *et al.* (2009) in the Guianas.

Oliveira (2018) noted that the major differences from base to outer canopy are those of relative abundance. She then tested character traits of 104 species of epiphytic *Lejeuneaceae* (Figure 6, Figure 23) in the Amazonian terra firme forests. She examined dispersal ability, dark pigmentation of leaves, ability to convolute leaves when

drying, possession of thickened cell walls, monoicous vs dioicous reproduction, and facultative epiphyllous habit. Four of these six traits proved useful in separating canopy and/or understory communities. Interestingly, high dispersal ability did not vary much along the height gradient. She further noted that asexual propagules were not over-represented in the dynamic environment of the canopy, seemingly challenging the bryophyte life strategy theory.

Oliveira (2018) found that facultative epiphylls were over-represented on the tree bases. Dark pigmentation and convolute leaves were significantly more common in the canopy and less common at the base. These two traits can protect against high light intensity and prolong periods of hydration, respectively. The paucity of these species at the bases of trees may be the result of high temperatures and low light, made lower by the pigmentation, while the prolonged hydration in these conditions would add to a high rate of respiration relative to photosynthesis.

Stuntz *et al.* (2002) noted that microclimate goes two directions. Bryophytes not only respond to the microclimate around them, but they can have a major impact on the microclimate of the forest around them. To put it in the descriptive wording of the researchers, they "air-condition the forest."

Although their study included only two orchids and a bromeliad, Stuntz *et al.* (2002) showed that the space around these epiphytes had significantly lower temperatures than did areas of the same tree with no epiphytes. Evapotranspiration was reduced almost 20% compared to microsites with no epiphytes. This study would suggest that the effect of bryophytes on the microclimate in tropical forests could likewise be significant.

Understanding of the microclimate is important in management strategies if one wants to protect the bryophytes (Sporn 2009; Sporn *et al.* 2009). These researchers sampled understory trees in a natural forest and in two types (natural shade trees and planted shade trees) of *Theobroma cacao* (cacao; Figure 55) agroforests in Central Sulawesi, Indonesia. The two agroforests had low air humidity and high afternoon temperatures. Although bryophyte species richness differed little among the habitats, the species composition was markedly different between the natural forest and the agroforests. These differences were most likely the result of microclimate differences.

Nutrient Dynamics

Akande *et al.* (1985a) found that the nutrients in the tested corticolous bryophytes increased from the dry season to the wet season. The nutrient fluctuations were more pronounced in mosses than in the liverworts tested. They concluded that bryophytes must be significant in the nutrient cycling of tropical ecosystems.

We are beginning to understand now how bryophytes play a major role in nutrient dynamics in the tropical forest. Their ability to sequester rain and fog water consequently means that they can sequester the nutrients dissolved in this water. When they dry out, damaged membranes release the nutrients, and the early stages of precipitation dissolve these released nutrients and carry them downward.

Vitousek (1984) summarized known nutrient relationships in lowland tropical forests, based on published studies from 62 tropical forests. He found that these forests and higher nitrogen levels lower ratios of dry mass to nitrogen in the litterfall compared to that ratio in most temperate forests. Nevertheless, the nitrogen return is comparable to that of temperate forests. Phosphorus return is very low in many of these tropical forests, whereas calcium return is high. The phosphorus cycling seems to be very efficient.

Sometimes the nutrients in the host affect the colonization by epiphytes. Benner (2011) found that epiphytes in the unfertilized Hawaiian montane forests (Figure 56) colonized high-phosphorus (fertilized) host trees more frequently than they did unfertilized trees. Mosses were less responsive to the fertilization than the cyanolichens. The cyanolichens were good predictors of chlorolichen and bryophyte abundance at three out of four Kauai, Hawaii, sites, indicating high bark and leaf phosphorus. Benner and Vitousek (2007) found that after 15 years of P fertilization in the forest, there was a "dramatic increase" in both abundance and species richness of the canopy epiphytes. There was, on the other hand, no response to fertilization with nitrogen or other nutrients.

Nadkarni (1983, 1986) noted the importance of epiphytes in making a significant contribution to the overall nutrient cycling in both temperate forests and tropical rainforests. In both forest types they absorb nutrients collected from the atmosphere during the dry season. The net release from branches with epiphytes during the wet season is greater than that from branches stripped of their epiphytes. Chang *et al.* (2002) measured ion input in a subtropical montane forest in Taiwan and found that more than 50% of the ecosystem input arrived in fog deposition, suggesting that fog is an important nutrient contributor in some tropical ecosystems.

Nadkarni *et al.* (2004) found that the primary forest canopy of a cloud forest in Costa Rica had 63% of its organic matter as dead organic matter (DOM). Bryophytes comprised 12%. By contrast, the canopy organic matter of the secondary forest was 95% bryophytes, with only 3% DOM. Different locations within the primary canopy varied, with branch junctions having only dead organic matter and roots. Rather, bryophytes were the only organic matter at branch tips, subcanopy, and understory substrates. The trunks had diverse organic matter, but were dominated by tracheophytes and bryophytes; little dead organic matter was present. The secondary forest differed in having little difference in organic matter between trunks and branches. Canopy organic matter was high because of the strong presence of bryophytes. One surprise was that bryophytes were absent in branch junctions, although that is a likely place for them in other ecosystems. The researchers recommended transplant studies to try to determine the causes of the bryophyte distribution on the trees.

Rainfall vs Throughfall

Not all nutrients respond to their trip through the bryophyte sponges in the same way. Clark *et al.* (1998b) assessed net retention of ions by the canopy in a tropical montane forest, Monteverde, Costa Rica. They found that phosphate, potassium, calcium, and magnesium were leached from the canopy, but nitrogen compounds were retained.

Hölscher *et al.* (2003) determined that differences in the canopy structure of predominately *Quercus copeyensis* (Figure 57) forests and epiphyte (mosses, liverworts, and lichens) abundance in old growth vs two ages of secondary growth in Cordillera Talamanca, Costa Rica, resulted in large differences in the way nutrient transport was divided into stemflow and throughfall. Nevertheless, the nutrient transfers reaching the soil were similar. Significantly higher litterfall of non-tracheophyte epiphytes indicated the higher epiphyte load in the old-growth forest.

In seeming contrast to the findings of Clark *et al.* (1998b), in a Venezuelan rainforest with a low-nutrient forest floor, the fluxes in calcium, sulfur, and phosphorus in the rainfall were greater than those in the throughfall (Jordan *et al.* 1980). Other elements occasionally had greater fluxes in the rainfall than in throughfall. Jordan and coworkers suggested that the canopy epiphylls (algae, lichens) intercepted and modulated the nutrients, resulting in their conservation in the canopy. Phosphate, potassium, calcium, and magnesium were at sometime later leached from the canopy. Seasonal data suggest that biomass burning increased concentrations of NO_3^- and NH_4^+ in cloud water and precipitation at the end of the dry season.

Regardless, a large majority of the inorganic N in atmospheric deposition was retained by the canopy at this site.

Figure 57. *Quercus copeyensis* with trunk epiphytes. Photo through Creative Commons.

To help us understand the effects the rainforest has on the nutrients, Wilcke *et al.* (2001) established five 20-m transects on the lower slope of a tropical lower montane rainforest in Ecuador. In the soil, they found the total Ca ($6.3\text{--}19.3\text{ mg kg}^{-1}$) and Mg concentrations ($1.4\text{--}5.4$) in the O horizon were significantly different between the transects. The throughfall ranged 43–91% of the rainfall; cloudwater inputs were less than 3.3 mm yr^{-1} except for one of the five transects where it was 203. Even the pH was affected by filtering through the canopy and associated epiphytes, increasing from a mean of 5.3 in the rainfall to 6.1–6.7 in the throughfall.

The leaves in this rainforest increase the element (Al, TOC, Ca, K, Mg) concentrations in the throughfall due to leaching from the leaves and washing off the dry deposition (TOC, Cu, Cl^- , $\text{NH}_4^+\text{-N}$) (Wilcke *et al.* 2001). This could be an advantage for inner canopy bryophytes that receive these nutrients from the top of the canopy. Only Mn, Na, and Zn escape enhancement as a result of throughfall contacts. However, in high flow events, even Mn and Zn are elevated in the throughfall.

The nutrient input to forest bryophytes is higher at 2,250 m than at 3,370 m asl in two montane tropical rainforests of Colombia (Veneklaas 1990) attributed this to the greater precipitation volume at the lower altitude. The losses of nutrients from the canopy were likewise higher at 2,550 m. Veneklaas considered the differences between forests to be related to differences in precipitation, geographical situation, and soil nutrient availability.

Bryophytes can alter the nutrient dynamics of the forest in a variety of ways. They act as sponges, absorbing rainfall, and with it the nutrients carried by that rainwater. Epiphytes furthermore trap water and nutrients as they flow down branches and tree boles, retaining nutrients leached from bark, leaves, and other kinds of epiphytes or collected in their dust. They host a variety of nitrogen-fixing bacteria, most notably the **Cyanobacteria** (Figure 58).

Figure 58. *Scytonema*, a genus that performs nitrogen fixation in the phyllosphere. Photo by Yuuji Tsukii, with permission.

Nitrogen Dynamics

Bergstrom and Tweedie (1998) found that epiphytes were able to access at least three sources of nitrogen, including atmospheric, the phorophyte through decomposed litter, and a source of nitrogen fixation. The ^{15}N exhibited considerable spatial heterogeneity within the tree.

Clark and coworkers (Clark 1994; Clark *et al.* 2005) reminded us of the large role bryophytes can have in nitrogen dynamics of a tropical forest. The assemblages of epiphytic bryophytes, vascular epiphytes, litter, and associated humus harbor ~80% of the inorganic nitrogen retained in the canopy (Clark 1994). The forest canopies are able to trap and retain inorganic nitrogen from rainfall, dry deposition of gasses, vapors, and particles, and nitrogen previously trapped by clouds. Because they form much of the surface area in the canopy and lack a thick cuticle (many, perhaps all, bryophytes have a waxy cuticle, but it is very thin) and epidermis, they are able to trap and retain this nutrient much more effectively than the tree leaves. Clark and coworkers compared nitrogen retention of field samples of epiphytic bryophytes, epiphytic assemblages, epiphytic tracheophyte foliage, and host tree foliage to cloud water and precipitation in a tropical montane forest canopy in Costa Rica. They estimated, using models and field data, that epiphytic bryophytes and epiphyte assemblages retained 33-67% of the nitrogen deposited by cloud water and precipitation. The model predicted an annual retention of 50% of the inorganic nitrogen that arrived through atmospheric deposition. The bryophytes are important in the transformation of inorganic nitrogen such as nitrates to less mobile forms such as ammonia, but also deposit some of it in **recalcitrant** (unresponsive to treatment; resistant, *i.e.*, it doesn't break down easily, if at all) forms of biomass, litter, and humus.

The collected nitrogen that is added to the epiphytic biomass, litter, and canopy humus (Vance & Nadkarni 1990, 1992) is eventually added to the very large pool of nitrogen in the soil organic matter (Edwards & Grubb 1977; Grieve *et al.* 1990; Bruijnzeel & Proctor 1995). Clark *et*

al. (1998b) found that the net nitrogen accumulation was ~8-13 kg ha⁻¹.

Cloud loadings can contribute to nutrient availability. Clark and Nadkarni (1992) experimented with excised epiphytes from Monteverde, Costa Rica, by subjecting them to NO_3^- loadings; from 0% to 90% of that NO_3^- is retained by the epiphytes. Ammonium (NH_4^+) is considerably more variable, ranging from a 200% loss to a 90% gain. These bryophytic epiphytes retain ca. 85% of the nitrate N from the atmospheric deposition to the canopy.

Wania *et al.* (2002) used ^{15}N levels to compare nitrogen in various positions within the forest canopy of a lowland rainforest in Costa Rica. The ^{15}N levels of canopy soils did not vary significantly, but the content in the epiphytes (including bryophytes) in different canopy layers did. The researchers concluded that epiphytes in different levels exhibited different ^{15}N during nitrogen acquisition.

Wanek and Pörtl (2008) examined nitrogen (NO_3^- , NH_4^+ , and glycine) uptake in bryophytes of a lowland rainforest of Costa Rica. They found no significant differences between the epiphyllous and epiphytic bryophytes. The mean uptake rates for these bryophytes are 1.8 $\mu\text{mol g}^{-1} \text{dw h}^{-1}$ for nitrate, 3.6 $\mu\text{mol g}^{-1} \text{dw h}^{-1}$ for ammonium, and 3.4 $\mu\text{mol g}^{-1} \text{dw h}^{-1}$ for glycine, suggesting that amino acids such as glycine significantly contribute to bryophyte nutrition in these epiphytes.

Most of the nitrogen fixation probably occurs on leaves with epiphylls. In any case, it is an important contributor to the tropical forest nitrogen dynamics. Matzek and Vitousek (2002) found that the total nitrogen fixation in a Hawaiian montane rainforest (Figure 59) was highest in sites having low N:P ratios in the leaves and stemwood. They suggested that epiphytic bryophytes and lichens depend on canopy leachate for their mineral nutrients, but the heterotrophic nitrogen fixation is controlled by the nutrient supply in the decomposing substrate. Differences in substrate cover had a larger effect on total N input from fixation than did fixation rates, a conclusion consistent with the low fixation rates observed in young forests. Nitrogen fixation in the **phyllosphere** (space surrounding a leaf) will be discussed under epiphylls.

Figure 59. Hawaiian tropical wet montane forest. Photo by Djzanni, through Creative Commons.

In 1998, Clark *et al.* (1998a) used epiphytic bryophyte samples in enclosures to estimate rates of growth, net production, and nitrogen (N) accumulation by shoots in the canopy in a tropical montane forest in Monteverde, Costa Rica. They also used litterbags to estimate rates of decomposition and N dynamics of epiphytic bryophyte litter in the canopy and on the forest floor. They estimated N accumulation at $1.8\text{--}3.0 \text{ g N m}^{-2} \text{ yr}^{-1}$. The cumulative mass loss from litterbags in the canopy after one year was $17 \pm 2\%$ (mean ± 1 SE) and after two years $19 \pm 2\%$ of initial sample mass. Mass loss from litter in litterbags after one year on the forest floor was $29 \pm 2\%$, and from green shoots $45 \pm 3\%$. On the forest floor, ca 47% of the initial N mass was lost within the first three months. The N that remained in the litter was apparently **recalcitrant** (resistant to microbial decomposition), although there was no evidence for net immobilization by either litter or green shoots. The annual net accumulation of N by epiphytic bryophytes was ca $0.8\text{--}1.3 \text{ g N m}^{-2} \text{ yr}^{-1}$.

Akande and coworkers (Akande 1985a; Akande *et al.* 1985) concluded that the role of bryophytes in nutrient cycling of African tropics is significant and requires study. Nutrient contents of bryophytes fluctuate with season, and in three forests at Ibadan, Nigeria, the highest mean monthly nutrient composition of the bryophytes is in June to July, with the lowest in November to January. Magnesium is an exception, reaching its peak in October when the other nutrients are diminishing. There are considerable differences between species, although the phenological patterns are very similar, with mosses accumulating more than liverworts. Relationships of bryophyte concentrations to those of bark suggest that the bryophyte obtains its nutrients from stemflow containing leachates not only from the canopy leaves, branches, and canopy dust, but also from the bark, and that bryophytes do not get nutrients directly from the bark, but rather get them only from those leached out by rain. Akande *et al.* concluded that the predominant source of these nutrients was from dust and other pollutants such as smoke and sulfur dioxide.

Base cation and fluxes increase in throughfall, but $\text{NH}_4^+\text{-N}$ and $\text{NO}_3^-\text{-N}$ decrease relative to that in rainfall in a subtropical montane moist forest in Yunnan, southwest China (Liu *et al.* 2002). The throughfall inputs of N, P, Ca, and S come primarily from precipitation, whereas most of the potassium and 2/3 of the magnesium in throughfall come from canopy leaching. The cycling rates for mineral elements are generally low compared to other tropical forests. Epiphytes are abundant on the bole and affect the chemical composition of the stemflow through selective uptake or release of elements. The total N, $\text{NH}_4^+\text{-N}$, Mg, Na, and $\text{SO}_4^{2-}\text{-S}$ are enhanced, while $\text{NO}_3^-\text{-N}$, K, P, and Ca are depleted in stemflow. Nitrogen from nitrogen-fixing organisms is low, most likely due to constraints by low temperatures.

In a study in the subtropical forest of northeastern Taiwan (Figure 60), Hsu *et al.* (2002) noted that nutrients in epiphytes and tree foliage are more readily available than those in the woody parts of the tree, making the tiny bryophytes proportionally more important than their size would suggest.

Figure 60. Taiwan blue magpie in subtropical rainforest of Taiwan. Photo by Gulumeemee, through Creative Commons.

Pulse Release

One mechanism by which the bryophytes help the forest floor plants is through pulse release of nutrients. This burst of nutrients occurs when dry bryophytes with damaged membranes first get water that wets them. This pulse is especially important for nutrients that are typically held in nutrient pools within the cells. The damaged membranes resulting from drying permits the rain to leach these nutrients from their otherwise safe interior locations. Coxson (1991) estimated the efflux of these solutes from stem segments of canopy bryophytes in tropical montane rainforest in Guadeloupe (Figure 61). These reached $80.1 \text{ kg ha}^{-1} \text{ yr}^{-1}$ for potassium, $1.4 \text{ kg ha}^{-1} \text{ yr}^{-1}$ for phosphorus, and $11.8 \text{ kg ha}^{-1} \text{ yr}^{-1}$ for nitrogen in these rewetting episodes. On the other hand, estimates using intact bryophyte mats during natural field rewetting episodes were smaller, causing release of $28.7 \text{ kg ha}^{-1} \text{ yr}^{-1}$ for potassium and $0.2 \text{ kg ha}^{-1} \text{ yr}^{-1}$ for phosphorus. The lower numbers most likely result from internal recycling of released ions within the bryophyte mats.

Within the cloud forest canopy, and most likely elsewhere in the tropics, bryophytes accumulate considerable quantities of sugars (Coxson *et al.* 1992). In Guadeloupe, French West Indies (Figure 61), more than 950 kg ha^{-1} of sugars and polyols are released by epiphytic bryophytes per year as a result of wetting and drying cycles. The sugars come as a pulse during re-wetting, contributing to growth of the microbial flora both within and beneath the canopy. These sugars and polyols account for 17% of the dry weight of the upper canopy liverwort *Frullania atrata* (Figure 62), while providing less than 6% of the dry weight of the lower canopy moss *Phyllogonium fulgens* (Figure 63). (The name *Frullania atrata* may be incorrect as many species have incorrectly been identified as this one.)

Keystone Resource

Nadkarni (1994a) attributed to the canopy epiphytes the role of **keystone** resource in the nutrient cycling of tropical forest ecosystems. That is, this is a resource that is critical to the structure and function of the ecosystem, without which the system would cease to function as it does. The epiphytic bryophytes may have a key role in the nutrient dynamics of these forests.

In a subtropical forest of the Ailao Mountains in Yunnan, southwest China, Liu *et al.* (2002) found that bryophytes enhance the annual amounts of total N, NH_4^+ -N, Mg, Na, and SO_4^{2-} -S but deplete NO_3^- -N, K, P, and Ca in the stemflow. Although many kinds of N-fixing organisms often are associated with epiphytic bryophytes, their contribution to total N in the mountains of Yunnan is most likely constrained by low temperatures. In a montane rainforest of the warmer Hawaii, on the other hand, Matzek and Vitousek (2003) found that the potential nitrogen fixation ranges from $\sim 0.2 \text{ kg ha}^{-1} \text{ yr}^{-1}$ in a 300-year-old site to $\sim 1 \text{ kg ha}^{-1} \text{ yr}^{-1}$ in a 150,000-year-old site. They felt that the dependence of epiphytic bryophytes and lichens on nutrients leached from the canopy might account for the fact that the highest fixation rates occurred in sites with low N:P ratios in the leaves and stemwood of the trees. For heterotrophic fixation, the nutrient supply offered by the decomposing substrate is also important in controlling the fixation rate. Thus, older substrata with more epiphytes are likely to contribute more nutrients to these N fixers, and indeed Matzek and Vitousek did find that the fixation rates relate to substrate cover.

With an epiphyte biomass and associated soil of 44 tons ha^{-1} , the epiphytes form a significant contribution to the Colombian upper montane rainforests (Hofstede *et al.* 1993). The 20 kg of epiphytes exceeded the biomass of the

part of the tree that supported them. In this epiphytic community, the researchers found 2,360 g N, 215 g P, 1,350 g K, and 99 g Ca. The epiphytes create large accumulations of bryophytes, favored by low temperatures, continuous high humidity, low air turbulence, and the structure of the forest. The water-soluble phosphorus stored in the epiphytic biomass is higher than that of the forest floor soil.

Pentecost (1998) assessed the cryptogamic epiphytes in the upper montane forest of the Rwenzori Mountains of Uganda (Figure 64). He found that the lichens contain ~2% of the total above ground nutrients, whereas 8% occurs in the bryophytes. The concentrations of the three "fertilizer" nutrients were N (10 kg ha⁻¹), P (1 kg ha⁻¹), and K (3 kg ha⁻¹).

Figure 64. Rwenzori Mountains, western Uganda. Photo by Agripio, through Creative Commons.

Nadkarni (1984) reported 141.9 kg of epiphytes on a single *Clusia alata* (Figure 65) in a Costa Rican cloud forest. The nutrients in these epiphytes were estimated as 1062 g N, 97 g P, 678 g K, 460 g Ca, 126 g Mg, and 207 g Na. This is significant because this relatively small component (less than 2%) of the forest biomass holds up to 45% of the nutrients found in the foliage of similar forests and stresses the importance of epiphytes as keystone resources in the nutrient dynamics of these forests.

Canopy Roots

To me, the most intriguing relationship is the relationship of bryophytes with canopy roots, first discovered and described by Nalini Nadkarni in her classical paper in *Science* (1981). Laman (1995) reported the improved germination of *Ficus stupenda* in moss beds associated with canopy knotholes, attributing their survival to good moisture retention. However, seed harvesting ants (*Pheidole* sp.; Figure 66) killed many of the seedlings later in development.

Figure 66. *Pheidole pilifera* minor (left) and major (right) workers. Some species of *Pheidole* kill *Ficus stupenda* seedlings in epiphytic moss beds. Photo by M. L. Muscedere and J. F. A. Traniello, through Creative Commons.

Epiphytic bryophytes also provide a rooting medium for **adventitious roots** (roots that arise from stem tissue; Figure 67) of trees. In fact, a dynamic interaction may occur in which the bryophytes help the tree, and the tree roots likewise help the establishment of the epiphytic community (Nadkarni 1994b). The bryophyte mat traps inorganic nutrients (Nadkarni 1986) and organic nutrients (Coxson *et al.* 1992) that are leached from members of the epiphyte community. These nutrients nourish the roots of the tree (Nadkarni & Primack 1989). The two appear to grow in mutual benefit, with the roots benefitting from the nutrients and providing a larger anchoring system for the epiphytes as they grow (Nadkarni 1994b). As the bryophytes and organic matter increase, they provide more leachates, causing the tree roots to increase.

Figure 67. Adventitious roots of banyan tree (*Ficus benghalensis*). Photo through Creative Commons.

Nadkarni (1981) found that epiphytes, including bryophytes, stimulate the growth of adventitious roots. The bryophytes serve to trap nutrients for them, and the relationship is so strong that Nadkarni argues that evolution has selected for it.

In *Senecio cooperi* (Figure 68), a species in the tropical cloud forest, Nadkarni (1994b) experimented with epiphytes air-layered on stem segments. For comparisons, she used wet epiphytes or dry epiphytes plus associated humus, sponges wetted with either water or nutrient solutions, dry sponges, and controls with no added layering. The wet epiphyte-humus mix and sponges with nutrient solutions were most successful in producing roots. Nadkarni suggested that the epiphytes intercept nutrients that they retain and provide the "cue" for the host tissue to produce the roots.

Some adventitious roots take advantage of the microenvironment created by epiphytic bryophytes (Sanford 1987). The roots are able to grow upward, and can do this in as rapidly as 5.6 cm in 72 hours. The roots are less than 2 mm in diameter and grow on the exposed bark surfaces, in bark fissures, and beneath attached epiphytic mosses, ferns, and vines.

Epiphytes decompose in the canopy to form soil on the large branches (Hietz *et al.* 2002). Epiphyte groups differ, in part relating to uptake of N through mycorrhizae or nitrogen fixation. These different sources affect the highly

variable quantity of epiphytes, often depending on the systematic group and canopy position.

In Hawaii, the koa tree (*Acacia koa*; Figure 69) takes advantage of the bryophyte mats for moisture and other favorable conditions (Leary *et al.* 2004). The roots of this tree actually grow upward and form **nodules** (Figure 70) with the bacterium *Bradyrhizobium* (Figure 71) in pockets of organic soils within the canopy. These organic soils in the tree contain significantly higher levels of exchangeable cations and total nitrogen, and significantly lower aluminum levels than the ground soils. Some of these mats have significant bryophyte presence.

Herwitz (1991) examined the aboveground adventitious roots of *Ceratopetalum virchowii* (see Figure 72) in an Australian montane tropical rainforest. These roots developed from stems and branches of this canopy species. In this case, Herwitz could find no evidence that this tree requires the epiphyte mats to stimulate its root growth. Instead, it appears that the stemflow of this species is particularly rich in Ca^{2+} , Mg^{2+} , and Na^+ compared to the soil. The bark of this species remains moist for a long period of time, providing a suitable environment for the adventitious root.

Productivity and Biomass

Studies on productivity in the tropics are rare. Jacobsen (1978) published one of the earliest studies. Most seem to be simply reports of standing crops. Several look at the effects of temperature on net carbon storage (see above under Microclimate).

Köhler *et al.* (2007) reported that bryophytes dominate the epiphytic vegetation in both an old-growth cloud forest and a 30-year-old secondary forest on slopes of the Cordillera in northern Costa Rica. The combined epiphyte biomass and canopy humus was $16,215 \text{ kg ha}^{-1}$ in the old-growth forest and $1,035 \text{ kg ha}^{-1}$ in the secondary forest.

Figure 72. *Ceratopetalum apetalum*; *C. virchowii* forms adventitious roots but shows no evidence of influence by epiphytic bryophyte mats. Photo by John Tann, through Creative Commons.

Van Dunne and Kappelle (1998) studied epiphytic bryophytes on five small stems of *Quercus copeyensis* (Figure 57) in a Costa Rican montane cloud forest (Figure 73). They found 22 species of mosses and 22 species of liverworts. Biomass of the bryophytes correlates with their frequency, with bryophytes contributing 54-99% of the biomass. Nearly 90% of the biomass is contributed by only 14% of the species, with the predominant contributors being the mosses *Pilotrichella flexilis* (Figure 10), *Rigodium* sp. (Figure 74), *Porotrichodendron superbum* (Figure 75), *Prionodon densus* (Figure 76), *Neckera chilensis* (see Figure 77), and the leafy liverwort *Plagiochila* (Figure 78).

Frahm (1987) raised the question of how altitude affected the biomass and productivity of epiphytes in the tropics. Researchers had typically assumed that it related to greater light and lower temperatures at higher altitudes, permitting greater photosynthesis, but no physiological studies had been used to support this hypothesis. In his study, he used a transect with sampling at 200-m intervals from 200 to 3,200 m asl in Peru. He determined biomass in the field and measured CO₂ gas exchange in a series of light and temperature combinations in the lab. The lab experiments used specimens from 2,300 m asl collected in Colombia in October. These were 150 cm² specimens of the mosses *Neckera* sp. (Figure 77), *Heterophyllum affine* (Figure 79), *Porotrichum* sp. (Figure 80), and the liverwort *Metzgeria* (Figure 81). These experiments support the

hypothesis that it is a combination of high temperatures and low light that limits most of these tropical bryophytes at lower elevations. They are unable to store enough carbon in the low light to balance that lost to respiration at the high temperatures of the lowland forest. This is supported by experiments with temperature on the moss *Plagiomnium rhynchophorum* (Figure 82-Figure 83), but unfortunately, no methods were provided.

Figure 83. Photosynthesis of *Plagiomnium rhynchophorum* (Figure 82) under various temperature conditions at 1500 lux. The montane forest conditions of 5° and 15°C yield sufficient net photosynthesis; the lowland condition of 25°C permits photosynthesis throughout the day but no net photosynthetic gain. At 35°C no net photosynthesis occurs during the day. Graph modified from Frahm 2003b.

Wolf (1993b) found that altitude explains most of the variation in the epiphytic bryophytes and lichens on selected bark types of canopy trees, using 15 sites on an altitudinal transect from 1,000 to 4,130 m asl in the Central Cordillera of Colombia (Figure 84). Species richness varies among the three groups (mosses, liverworts, and lichens). Liverworts reach their greatest species richness (ca 100 taxa) at mid-elevational sites (2,550-3,190 m asl). In this case, biomass of bryophytes and lichens increases with altitude, coinciding with an increase in humidity.

Figure 84. Cordillera in central Colombia. Photo by Samuel Rengifo, through Creative Commons.

Hofstede *et al.* (1993) examined the relationship between the epiphytic biomass and the nutrient status in a Colombian upper montane forest near the treeline at 3,700 m asl with a massive presence of epiphytes. The amount of accumulated epiphytic mass, suspended soil, and living plants on a full-grown tree was 32.7 g dry weight per dm² surface area, the highest documented value ever. This high value is attributed to a combination of low temperatures, high humidity, low wind velocities, and structural characteristics of the tree.

Müller and Frahm (1998) sampled epiphytic bryophytes in a montane rainforest in the Andes of Ecuador at about 2,000 m asl. They measured the dry weight on various parts of the trees and found that on trunks it was 80 g m⁻², on branches 1,873 g m⁻², and on twigs 1,230 g m⁻².

Clark *et al.* (1998a) conducted one of the few studies on retention of carbon by the tropical epiphytic bryophytes. They found an annual net accumulation of carbon to be approximately 37-64 g C m⁻² yr⁻¹ in their study in a tropical montane forest in Monteverde, Costa Rica. Net production of epiphytic bryophytes in the forest was 122-203 g m⁻² yr⁻¹.

In the upper montane forest of the Rwenzori Mountains of Uganda, Pentecost (1998) found that large cushion-forming liverworts are dominant in the lower canopy. These are predominately *Chandonanthus* (Figure 85), *Herbertus* (Figure 86-Figure 87), and *Plagiochila* (Figure 88) species. Their productivity is controlled by light intensity and substrate tree age. In total, he found 14 species of bryophytic epiphytes. The total epiphytic biomass, including bryophytes, lichens, and algae, contribute nearly 1 ton ha⁻¹ standing crop, a figure that is approximately 10% of the above-ground standing crop.

Lösch *et al.* (1994) describe differences in environmental conditions and photosynthetic rates for bryophytes in a rainforest (800 m asl), a bamboo forest, and a tree-heath (2,200-3,200 m asl) in east central Africa. In the lowland rainforest, the climatic conditions are a nearly constant 24°C, 100% relative humidity, and PAR below 100 $\mu\text{mol photons m}^{-2} \text{ sec}^{-1}$. The mountain bryophytes exhibit approximately 6 times those daily sums of PAR while experiencing temperatures of 10-25°C and relative humidities of 60-100%. In the bamboo forest, the epiphytic mosses experience water loss down to less than 70% of their water content, but become saturated again from the vapor-saturated air at night. In these habitats, the photosynthesis peaks between 22 and 30°C. The lowland species exhibit higher optima than do those of the mountain sites. The light saturation points for all species are below 400 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$, but the slopes differ. Those bryophytes from the lowland have a smaller light compensation point (3-12 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$), accompanied by a steeper slope in the low-light range. In the highland, the compensation point is 8-20 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$.

Waite and Sack (2010) considered the relationship of moss photosynthesis to leaf and canopy structure. These include ground-dwelling species as well as branch and trunk dwellers: *Acroporium fuscoflavum* (Figure 89), *Campylopus hawaiiicus* (Figure 90), *Distichophyllum freycinetii* (Figure 91), *Fissidens pacificus* (Figure 92), *Holomitrium seticalycinum* (see Figure 93), *Hookeria acutifolia* (Figure 94), *Leucobryum cf. seemannii* (Figure 95), *Macromitrium microstomum* (Figure 96), *M. piliferum* (Figure 97), and *Pyrrhobryum pungens* (see Figure 98) (all mosses). Interestingly, they did not find any correlation between light saturation for photosynthesis and habitat irradiance. The bryophytes have low leaf mass per area and a low gas exchange rate. The nitrogen concentration, as well as A_{mass} , (maximum assimilation per unit leaf mass) has a negative correlation with the canopy mass per area. *Campylopus pyriformis* (Figure 99) exhibits a high A_{max} (maximum assimilation) that could be the result of its high leaf area index. Anatomical factors such as smaller cells, thicker cell walls, or physiological adaptations such as higher osmotic adjustment could lower the potential for a higher A_{max} in sun mosses.

Epiphyte Litterfall

Both bryophyte and tracheophyte litter can fall from the trees, especially during severe storms. This is a loss of canopy productivity, but provides a new source of nutrients for the soil, and in some cases these plants may continue growth on the ground.

Matelson *et al.* (1993) considered the rate of nutrient release from bryophytic and other epiphytic litter fall. They determined that it varies with microhabitat and suggested that both spatial and temporal distribution should be studied at the species level as they relate to microhabitat characteristics.

Köhler (2002) investigated total epiphytes in 10-15-year-old early secondary forest, a 40-year-old later-stage secondary forest, and an old-growth (primary) forest in Costa Rican mountain rainforests. Succession resulted in an increase in epiphytic litterfall. They estimated 4.8 g m^{-2} in early secondary forests (160 kg ha^{-1} at stand level), 12.0 g m^{-2} in later secondary forest (520 kg ha^{-1} at stand level), and 78.5 g m^{-2} in the old-growth forest (3400 kg ha^{-1} at stand level). Nevertheless, epiphytes constitute only a small part of the litter.

In a Neotropical cloud forest in Monteverde (Figure 100), Costa Rica, Nadkarni and Matelson (1992) found that epiphyte litter (bryophytes, lichens, and tracheophytes) comprises 5-10% of the total fine litter at that site. This litterfall contributes to the nutrients of the forest, with measurements (in $\text{kg ha}^{-1} \text{ yr}^{-1}$) of N (7.5), P (0.5), Ca (4.2), Mg (0.8), and K (0.1). These epiphytic litter components have a higher annual rate than does the litter from plants rooted in the ground. On the other hand, the turnover time of all nutrients except potassium is 4-6 times slower in the fallen epiphytic litter. Potassium turnover is ten times as fast. In a later study, Nadkarni (2000) determined that epiphyte litterfall in a lower montane cloud forest in Monteverde, Costa Rica, occurs at a rate of $50 \text{ g dry wt m}^{-2} \text{ yr}^{-1}$. This slow turnover of most bryophyte litter is most likely due to the high phenolic content that protects the bryophytes from herbivory and attack by fungi and bacteria.

When branches make contact with each other, by wind or storm, the impact can cause tiny branches at the tips to break, a phenomenon known as **crown shyness** (Figure 101) (Franco 1986). This can occur between the same species of tree, or among different species. The exact cause is not clearly known, but at least in some cases it appears that it is the result of **reciprocal pruning** as trees contact each other. It appears that lateral branch growth is usually not influenced by the neighbors until such mechanical abrasions occur. One such tree is *Clusia alata* (Figure 65). This branch breakage can cause any adhering bryophytes to be lost from the canopy as the branch tips fall away.

Summary

Bryophytes in the tropics, particularly epiphytes, undoubtedly have a crucial role in water and nutrient retention, releasing nutrients during re-wetting, but filtering them from the lower branches and ground during rain events. They are adapted by their life forms and physiology to withstand desiccation. **Anhydrobiosis** and **osmotic potential** are typically used as means of surviving dry periods. Dry areas typically have **mats**; in areas with high humidity these are replaced by **fans**, **wefts**, and **pendants** that are able to obtain water from fog and mist (**fog-stripping**). Many are **perennial stayers** or **perennial shuttle** species.

Species of highly exposed locations have higher light saturation and compensation points, higher dark respiration rates, more chlorophyll, higher chlorophyll *a:b* ratios, and higher N concentrations than those of shade species. Some are able to retain water and nutrients in **hyaline** cells that hold water and surround photosynthetic cells. But most lose water easily and survive by their ability to recover quickly from desiccation, without the need to make new chlorophyll.

Substrate, temperature, light, and moisture availability are the microclimate variables that drive the community structure of epiphytic bryophytes. Their biggest physiological problem is the need to store more carbon than they lose to respiration.

Nutrients are obtained from the atmosphere, rain, and the bark and collected on the bryophyte surface until it becomes moist and can absorb them. Hence, nutrients in the bryophytes increase from the dry season to the wet season. **Cyanobacteria** living in the microenvironment of the bryophytes contribute to the usable nitrogen of the ecosystem. The ability of the bryophytes to leak nutrients but retain them on their surfaces permits external nutrient storage until rainfall returns, but releases them to the ecosystem as heavy rains carry them away. Light rains and fog permit the bryophytes to hydrate and absorb the nutrients. This makes the epiphytic bryophytes a keystone resource for the forest. These nutrient-rich, wet bryophytes furthermore provide a suitable substrate for canopy roots for some species.

Biomass of the bryophytes correlates with their frequency, with bryophytes contributing 54-99% of the biomass at higher elevations. Biomass increases with altitude, coinciding with an increase in humidity. At lower elevations, the combination of high temperatures and low light severely limit bryophyte productivity. Epiphyte litter (bryophytes, lichens, and tracheophytes) comprises 5-10% of the total fine litter in the cloud forests and only a small amount in the lowland forest. Whereas leaf litter decays rapidly in the tropics, bryophyte litter is slow to decay due to its many phenolic compounds that inhibit insects, bacteria, and fungi.

Acknowledgments

My appreciation goes to Noris Salazar Allen for her efforts to make a very early version of this chapter reliable and up-to-date. Her helpful discussions kept me going on this part of the world I know so little about. S. Robbert Gradstein reviewed this subchapter for accuracy and suggested references to add. Michael Lüth generously permitted my use of his beautiful images for this and other subchapters.

Adaptations

Living on trees often puts the bryophytes at the mercy of rainfall (where there is no fog), either as throughfall or stemflow. Thus, special adaptations are necessary for those times when it is not raining, for the substrate is unlikely to do much to maintain the humidity (Frahm & Kürschner 1989). Gradstein and Pócs (1989) suggest a number of adaptations that permit these taxa to be so successful in this living habitat:

1. **Green, multicellular spores** with **endosporous** development (Figure 2) [e.g. *Dicnemonaceae* (Figure 3), *Lejeuneaceae* (Figure 6, Figure 8-Figure 9)] (Nehira 1983), permitting the protonema to get a quick start. **Anisomorphic** spores in *Macromitrium* *erythrocomum* (Figure 4) (Ramsay *et al.* 2017) could increase chances of dispersal at different times.
2. **Sexual dimorphism** and **phylloidioicy** (having dwarf males that live on leaves or tomentum of females; Figure 5), possibly increasing gene flow by ensuring that males are close to females. [e.g. dwarf males in *Macromitrium erythrocomum* (Ramsay *et al.* 2017)].
3. Numerous means of **asexual reproduction**, **monoicous** condition, and **neoteny** (sexual maturity at early developmental stage; Figure 6), permitting movement from place to place among **ephemeral** (short-lived) substrata [e.g. *Lejeuneaceae* (Figure 6, Figure 8-Figure 9)] (Schuster 1984; Richards 1984).
4. **Rhizoid discs** (Figure 7) for anchorage and adhesion (Winkler 1967).
5. **Lobules** [*Frullaniaceae* (Figure 70), *Lejeuneaceae* (Figure 6, Figure 8-Figure 9)] and **hyaline leaf**

margins for absorption and retention of water; *Colura* (Figure 8-Figure 9) even has a closing apparatus at the entrance of its lobule (Jovet-Ast 1953). Many **Calymperaceae** (Figure 10) have **hyaline cells** (Figure 11) in their leaves (Richards 1984).

6. **Cushion** life form (Figure 28) on branches of open montane forests (Pócs 1982).

Frey *et al.* (1990) studied the epiphytes in Mt. Kinabalu (Figure 12) in North Borneo. They examined distribution patterns of life forms and the water-storing structures in epiphytes. They also looked at their role in water leaching, an important aspect in tropical forest nutrient cycling. Other useful studies on adaptations include those of Thiers (1988 – **Jungermanniales**, *i.e.* leafy liverworts; Figure 6, Figure 8) and Kürschner (2000 – adaptations in the tropical rainforest).

Pigmentation

In their study of *Macromitrium* in the Wet Tropics bioregion of Queensland, Australia, Ramsay *et al.* (2017) questioned the appearance of red species there. This was particularly striking in the epiphyte *M. erythrocomum* (Figure 13). Although some bryophyte species have been studied for their use of pigmentation as protection against high light (*e.g.*, Marshall & Proctor 2004), no tropical species has thus far been used in such experimentation. In *Macromitrium* species, red, orange, and yellow pigments are likewise most pronounced in species adapted for high light (Vitt 1994). In mosses, these accessory pigments occur mostly in cell walls. For *M. erythrocomum*, the function of these pigments is elusive. These mosses grow in dense shade where protection from high light intensities is unnecessary. Ramsay *et al.* suggested that the pigmentation could be a genetic leftover from an ancestor adapted to high light.

Figure 13. *Macromitrium erythrocomium* from northern Queensland. Note young, green leaves at the bottom and mature yellow to reddish leaves on the mature plants with sporophytes. Photo from Ramsay *et al.* 2017, with permission.

This species also presents an interesting progression of leaf color in its life cycle (Ramsay *et al.* 2017). Young leaves are light green, having cells packed with chloroplasts and walls not colored (Figure 13). At this stage, the costa is already bright red. As the leaf ages, it loses its chloroplasts, making the cell lumen yellowish while retaining the red costa (Figure 13-Figure 14). It continues to develop red pigments, eventually filling the cells, and the walls also become colored, making the entire leaf red.

Figure 14. *Macromitrium erythrocomium* leaf with red costa. Photo from Ramsay *et al.* 2017, with permission.

Growth Forms and Life Forms

Growth forms, life forms, and life cycle strategies interact with other adaptations to provide the bryophytes with the best strategy for a particular environment. The main reference for growth or life forms of bryophytes is Mägdefrau 1982 and for life strategies During 1979. See also Volume 1, Chapter 4, of this series on Bryophyte Ecology for details on these.

Based on a number of pilot studies in the tropics (Frahm 1990; Frey *et al.* 1990, 1995; Frey & Kürschner 1991; Kürschner & Seifert 1995; Kürschner & Parolly 1998b; Kürschner *et al.* 1998), Kürschner *et al.* (1999) described generalizations of tropical growth forms, life forms, and life strategies for the epiphyte habitat. **Perennial stayers** and **perennial shuttle** species (see During 1979) are important life cycle strategies in most of the tropics. They dominate in the tropical lowland and submontane belt as well as in the cooler and more humid montane rainforest. However, in the former two they are **mat formers**, whereas in the montane rainforest they are mostly **fans** and **wefts** that rely on propagules and clonal growth. Some species have ciliate leaves that are able to collect water from fog. In the more xeric conditions of the

open, upper montane forests, **short turfs**, **tall turfs**, and **cushions** predominate, but are also **perennial stayers** and **perennial shuttle** species. **Colonists**, by contrast, occur almost exclusively in secondary forests. Kürschner and coworkers considered these relationships to apply throughout the tropics.

In the Sulawesi rainforest (Figure 15) in Indonesia, the understory has a preponderance of **dendroid** and **fan-like** species of bryophytes, whereas the crowns of the trees have more **tuft** species than other types (Sporn *et al.* 2010). Like many other factors, this reflects the differences in microclimate between the upper canopy and the understory, but it also reflects differences in substrate provided by understory trees vs canopy trees.

Figure 15. Mountains of South Sulawesi, Indonesia. Photo by Achmad Rabin Taim, through Creative Commons.

Kürschner and Seifert (1995) described epiphytic communities in the eastern Congo basin (Figure 16) and nearby mountain ranges. These included consideration of life forms and water storage.

Figure 16. Forests in the Democratic Republic of the Congo. Photo from Bobulix, through Creative Commons.

Bryophyte life forms in flooded and non-flooded habitats in the Colombian Amazon (Figure 17-Figure 18) reflect the differences in humidity (Benavides *et al.* (2004). In the floodplains, the **fan** and **mat** forms predominate,

whereas more epiphytic liverworts occur in the non-flooded forest.

Leerdam *et al.* (1990) described the epiphytes of a Colombian cloud forest (Figure 19). Bryophytes comprise most of the biomass. They found a sequence of life forms along the canopy branches, creating two groups: inner canopy and outer canopy. These are mostly **tall turfs** and **smooth mats**, respectively. The life forms corresponded with microclimatological factors, water and nutrient availability, and substratum age. The phorophyte species also influence the type of growth and life forms that grow there.

Figure 17. Amazon rainforest. Photo by Phil Harris, through Creative Commons.

Figure 18. Colombian Amazon. Photo by Actorsuarez, through Creative Commons.

Figure 19. Colombian cloud forest with White Yarumo. Photo by Alejandro Bayer Tamayo, through Creative Commons.

Some striking life forms that are almost exclusively tropical are the **feather**, **bracket**, and **pendent** (Figure 20) forms. These seem to reflect the high atmospheric humidity around the first few meters of the tree bole, where little air stirs to carry away the moisture quickly.

Pendent (Figure 20) bryophytes are common in areas with high humidity. Proctor (2004) examined the light and desiccation responses of two of these **pendent** taxa [*Weymouthia mollis* (Figure 21) and *W. cochlearifolia* (Figure 22)]. *Weymouthia cochlearifolia* is more typical forming patches on the trunk and branches, but it can grow as a **pendent** form. *Weymouthia mollis* typically grows as a **pendent** form. *Weymouthia cochlearifolia* reached 95% saturation at $160 \mu\text{mol m}^{-2} \text{s}^{-1}$ PPFD, whereas *W. mollis* ranged $176\text{--}307 \mu\text{mol m}^{-2} \text{s}^{-1}$ PPFD or even more. They demonstrated the primary needs of **pendent** forms: high levels and reasonably regular precipitation, shelter from wind, and moderate shade. From this they surmised that exposure and the high evaporation rate that accompanies it will favor **small cushions** or **smooth mat** life forms. Proctor reasoned that exposure would minimize the boundary-layer resistance to CO_2 uptake and maximize the mechanical effects of wind. **Tight cushions** and **smooth mats** can more easily resist these. On the other hand, the more open life forms are more exposed for efficient light interception and CO_2 uptake.

Figure 22. *Weymouthia cochlearifolia*, a species that can form both **mats** and **pendent** forms. Photo by Niels Klazenga, with permission.

Some bryophyte species develop different life forms based on their habitat (Ford 1994). For example in Queensland *Papillaria* (Figure 23) spp. on *Sloanea woollsii* (Figure 25) exhibit forms ranging from **long pendent** forms in the canopy branches to **creeping mats** on lower branches and the upper trunk. **Dendroid** forms are especially common on tree trunks. Stumps have mosses such as the dominant *Camptochaete vaga* (see Figure 24), but also can have *Dicranum* spp. (see Figure 26)

Additional references on tropical bryophyte life forms include those of Kürschner and Parolly (1998a, 2005, 2007).

Life Cycle Strategies

One of the most important adaptations to tropical climates is that of life cycle strategies. These must be timed to coordinate with wet and dry periods. Sperm require at least some water for transfer. Spores are dispersed best by dry winds.

Furthermore, life strategies of epiphytic bryophytes change with altitude. Frey *et al.* (1995) compared these strategies in the eastern Congo basin (Figure 27), a tropical lowland. In the primary rainforests of the tropical lowland and lower montane, the epiphytes were generally **perennial shuttle** species and **perennial stayers**. These had low to moderate sexual and asexual reproduction. This strategy combination is well suited for the high temperature and humidity regime, particularly for the leafy liverworts that dominate these communities. In the montane rainforests and cloud forests the perennial shuttle species have high asexual reproduction, with both propagules and clonal growth contributing. In **secondary woodlands** (areas of regrowth), ericaceous woodlands, and subpáramo of African volcanoes, the perennial shuttle and perennial stayers with high levels of sexual reproduction reach their greatest numbers. This is facilitated by the regular production of sporophytes in the **xeric** (dry) conditions with a strong **diurnal** (daily) climate. This reproductive strategy is typical of epiphytes in xeric woodlands.

Figure 27. Lowland rainforest, Congo Basin, Cameroon. Photo by Mauri Rautkari, through Creative Commons.

Kürschner (2003) described the life strategies of two epiphytic bryophyte associations in southwestern Arabia. The species are mostly drought tolerant. Their life strategies are distinctly correlated with their ecological site conditions. The *Orthotricho* (Figure 28)-*Fabronietum socotranæ* (Figure 29) is a drought-tolerant association dominated by **cushions**, **short turf**, and **mats** – **perennial stayers** with regular sporophyte formation. By contrast, in the sub-humid *Leptodonto* (Figure 30)-*Leucodontetum schweinfurthii* (Figure 31) association, the typical life forms are **tails** and **fans**. These are **pleurocarpous perennial shuttle** species that have large spores. These large spores limit them to short-range dispersal, relatively low reproductive rates, and generative reproduction. This association has a much higher diversity of life forms and life strategies, including liverworts.

Figure 31. *Leucodon julaceus*; this genus forms the *Leptodonto-Leucodontetum schweinfurthii* association in humid Arabia. Photo by Bob Klips, with permission.

Spore size is an adaptive trait wherein small spores have a good chance for long-distance dispersal and large spores do not, but have a greater chance for successful germination and establishment (Kürschner & Parolly 1998a). Few bryophytes are able to use both strategies. However, one notable exception is an epiphytic **heterosporous** (having two sizes of spores) moss of the Andes of northern Peru – *Leptodontium viticulosoides* (Figure 32). More recently, this was reported in *Macromitrium erythrocomum* (Figure 4, Figure 13) from the Australian Wet Tropics (Ramsay *et al.* 2017).

Figure 32. *Leptodontium viticulosoides*, a heterosporous species that uses both long-distance dispersal of small spores and more successful establishment of large spores. Photo by Claudio Delgadillo Moya, with permission.

Having similar adaptive traits in similar conditions is common among bryophytic epiphytes (Kürschner 2003, 2004a) – a product of convergent evolution. This convergence is common among life strategies of tropical bryophytes.

Additional studies on life strategies include Egunyomi and Olarinmoye (1983), Kürschner (2004b), Kürschner and Parolly (2005, 2007), and Kürschner *et al.* (2006, 2007).

Dispersal and Colonization

Colonization must be preceded by dispersal. Thus, to examine colonization rates, we must necessarily understand the limitations to dispersal.

Yeaton and Gladstone (1982) examined colonization patterns of epiphytic orchids on calabash trees (*Crescentia alata*; Figure 33) in Costa Rica. They hypothesized that the number of propagules produced by the species determined the colonization pattern. The same hypothesis can be considered for bryophytes.

Figure 33. *Crescentia alata* in Guanacaste dry forest. Photo by Daniel H. Janzen, through Creative Commons.

Wolf (1994) examined the factors that control the distribution of bryophytes and lichens in the northern Andes (Figure 34). He concluded that randomness of propagule supply appears to be the most important factor in determining the epiphyte composition on branch and trunk segments.

Figure 34. Northern Andes in Colombia. Photo by Conocer, through public domain.

But Mari *et al.* (2016) reached a somewhat different conclusion. They avoided the differences among **phorophytes** (plants on which epiphytes grow) by sampling only one tree species, *Aldina heterophylla* (a legume). This is a dominant species in the Amazonian white-sand habitats and sports heavy loads of epiphytes. Mari and coworkers attempted to quantify the importance of the tree zone in colonization by comparing geographic distances at scales of 100 m² and 2,500 km². At the larger, regional scale, the tree zone explained approximately two-thirds of the primary compositional gradient – a factor more than double that accounted for by site differences.

On the other hand, spatial effects were absent at the fine scale of 100 m², with more dissimilarity than expected by chance when compared to communities on neighboring phorophytes. The researchers concluded that microsite availability, not dispersal limitation, is the most important factor in structuring the epiphytic communities of this forest type.

The **phorophyte** itself can play a role in the colonization (Olarinmoye 1977). Such factors as bark roughness and smoothness determine whether a propagule is able to adhere once it arrives. Leachates from the host leaves could inhibit growth, but for the leafy liverwort *Radula flaccida* (Figure 35), it was only extracts, not leachates, that inhibited growth (Olarinmoye 1981, 1982).

Figure 35. *Radula flaccida* habit with gemmae. Extracts, but not leachates, from tree leaves inhibited growth on the phorophyte host. Photo by Michaela Sonnleitner, with permission.

Oliveira *et al.* (2009) noted the gradient of bryophyte species communities from the base of the tree to the top of the canopy in the Guianas (Figure 36), highlighting the role of niche assembly in defining these communities. They set out to test whether niche assembly, rather than dispersal limitation, drives species composition of epiphytic bryophyte communities on a large spatial scale. Using three lowland forests, they sampled six different height zones of several trees in each. They tested whether specialists maintain a preferred height zone across the Guianas. They found that 57% of the species had a preferred height zone throughout the localities. In fact, the communities were more similar across 640 km at the same height zone than they were among the heights on any single tree. Hence, they concluded that niche assembly was a stronger determinant of the communities than were dispersal factors on both local and regional scales.

While the similarity within a zone is greater even at 640 km than among height zones of a tree, the similarity within the same locality is greater than that with greater distances (Oliveira & ter Steege 2015). Using nine localities across 2800 km from east to west in the Amazon forest (Figure 17), these researchers again demonstrated that height zone explains most of the variation among communities. The outer canopy communities exhibit the greatest similarity between trees and localities. The variation at the geographic scale could be explained primarily by elevation and temperature.

Figure 36. French Guiana tropical forest. Photo by Cayambe, through Creative Commons.

Oliveira and ter Steege (2015) furthermore found that establishment limitation is strongest at the extremes of the vertical gradient. Communities of the tree base and the outer canopy draw individuals from outside the habitat species pool at a rate of 0.28 and 0.22, respectively, in contrast with values between 0.55 and 0.76 of other height zones, contrasting with the hypothesis that species inhabiting the canopy have higher chances of engaging in long-distance dispersal events (see *e.g.* Gradstein 2006, p. 17). Whereas the canopy may have a greater exposure to propagules that are in the air currents, they are also subject to winds that can dislodge the propagules. They might also be limited by propagule availability as those propagules might be constrained by their canopy of origin, preventing them from entering the air currents. Oliveira and ter Steege suggested that bryophytes in these two extreme zones (outer canopy and tree base) might be, through time, subjected to stronger selection.

Hietz (1997) studied the population dynamics of epiphytes in a Mexican humid montane forest. He used repeated photographs to follow 5,124 individuals (44 species) for more than two years. This study demonstrated the importance of branch loss as a contributor to the mortality of epiphytic flowering plants and ferns.

Nadkarni (2000) performed one of the few experimental studies on colonization by epiphytes. She stripped branch surfaces of their epiphytes in a lower montane cloud forest, then tracked what landed where and whether it was able to remain where it landed. Epiphytes are lost from the canopy due to sloughing, branch breakage, and treefalls, typically caused by wind or heavy rainfall. Most of our understanding of colonization patterns has been from studying forests of a series of ages and comparing their floras. In the temperate forest, colonization is rapid, with up to 6 cm elongation in the first year. Furthermore, the composition is similar to that of the original community. But in the tropical forest, colonization is very slow, exhibiting no colonization in the first five years! The new colonization furthermore differs markedly from the original communities. Instead of the dead organic matter, bryophytes, and tracheophytes of the mature branch community, the new community begins with crustose and foliose lichens. Even more surprising is that instead of encroachment from the sides, the colonizers enter the bare areas from the bottom up. In the sixth year, algae and

bryophytes begin to colonize the lower sides of branches. This appears to be related to the greater moisture on that side of the branch.

Nadkarni (2000) concluded that bare branches, typically with smooth bark, retain little moisture and are unsuitable for the developing epiphytes. Once early lichens become established, more water is retained, permitting growth of species adapted to frequent drying. As colonization increases, nutrients as well as water are retained, permitting larger and less xerophytic species to survive. She further surmised that at the branch tips, where colonization is much more rapid, the small branches are more able to trap and hold propagules, and they are more exposed to fog and mist, thus having more available moisture. In both cases, once the bryophytes become established, the better retention of water and nutrients facilitates a more rapid continuation of the colonization.

In a separate study, Nadkarni *et al.* (2000) experimented with artificially dispersing bryophyte fragments in a tropical montane cloud forest of Costa Rica, using quadrats above branches of saplings and mature trees of *Ocotea tonduzii* (see Figure 37). Only 1% of the dispersed fragments were retained by the sapling crowns for the six months of the study. On the other hand, branches in the forest canopy, already possessing intact epiphyte communities, retained 24% of the dropped bryophytes. Branches that had been stripped of their epiphytes retained only 5%.

Figure 37. *Ocotea minarum*; *Ocotea tonduzii* was used to study adherence of bryophyte fragments in Costa Rica. Photo by Denise Sasaki, through Creative Commons.

Colonization of bryophytes can be important to establish a suitable habitat for larger epiphytes such as orchids. Zotz and Vollrath (2003) found that epiphytes on the palm *Socratea exorrhiza* (Figure 38-Figure 39) become established in bryophyte clumps (Figure 39) more often

than could be expected from randomness, but they nevertheless do not seem to depend on them 100%. This enhancement of the habitat by bryophytes most likely accounts for the delay in tracheophyte colonization until the trees are at least 20 years old.

Figure 38. *Socratea exorrhiza* in Brazil. Photo by Andrew J. Henderson, Palmweb, through Creative Commons.

A number of ant species live in the trees in the tropics and some even build nests using tracheophytes (Longino & Nadkarni 1990; Blüthgen *et al.* 2001). In Costa Rica, these ants often make nests in arboreal litter, mosses, and humus that accumulate under the canopy epiphytic tracheophytes. The species in the canopy are rarely found on the ground and their travels among the canopy branches are likely to contribute to the dispersal of bryophyte fragments, gemmae, and spores. Their role in dispersal needs to be explored quantitatively.

In contrast with the experimental colonization study by Nadkarni (2000), Frahm *et al.* (2000) observed that crustose lichens seemed to inhibit epiphytic bryophyte growth. They tested extracts of these lichens and bark samples on spore germination of the soil bryophytes *Ceratodon purpureus* (Figure 40) and *Funaria hygrometrica* (Figure 41). These extracts inhibit spore germination of these two species. They also tested the extracts on seeds of the bromeliad *Vriesea splendens* (Figure 42) and the soil-dwelling mustard *Lepidium sativum* (Figure 43). The extracts reduce the germination of seeds of *Vriesea*, but they actually promote germination of *Lepidium*. Thus we cannot conclude from this study of soil species whether the crustose lichens actually inhibit growth of bryophytes that are normally epiphytes, but the results suggest that such interaction needs to be tested.

Figure 40. *Ceratodon purpureus* with young sporophytes, a soil-dwelling species whose spore germination is inhibited by at least some lichen extracts. Photo by Hermann Schachner, through Creative Commons.

Barkman (1958) and Pócs (1980) suggested that bryophytes may cause their own displacement by retaining water that makes tracheophytic epiphyte presence possible. They furthermore form humus, accelerate bark decay (Barkman 1958), and facilitate anchorage of seeds and other propagules.

Host Trees

Specific bryophyte-host relationships have been reported a number of times in temperate regions where tree species richness is very low, as for example those found by Slack (1976). As is often the case, she found strong preferences among eastern North American trees, but none of the bryophytes occurred exclusively on one tree sp.

Wolf (1995) summarized the forces leading to presence and abundance of species in epiphytic bryophyte communities in the canopy of an Upper Montane Rain Forest, Central Cordillera, Colombia. He considered two ways to look at these communities: emphasis on quality or quantity of preceding propagule supply; within community interactions such as competition. For the first of these, researchers have placed great importance on observed distribution patterns and high variability between epiphyte communities in seemingly identical habitats. But the great cover and biomass in these tropical montane rainforests suggests that competitive interactions may also be important. In his own study, Wolf found 120 bryophyte taxa (and 61 macrolichens). He recognized four community types from outer to inner canopy. Nevertheless, these four communities share many species and exhibit a species richness of about 100 taxa each. The inner canopy, with thick branches (21-80 cm diameter) had significantly fewer taxa per unit surface area, with an average of 1.72 taxa per dm² compared to 3.2 from the thinner middle canopy branches. Richness was even higher in the outer canopy, with 7.8 taxa per dm². If time were the most important factor, then the inner crown should have the highest number of species. Instead, one finds that the thick inner branches and trunks carry large patches of individual clones, suggesting competition through horizontal growth.

In the subtropical Tenerife, Canary Islands, González-Mancebo *et al.* (2003) described epiphytic bryophyte communities from five tree species in a laurel forest (Figure 44). Most of these bryophytes (37 species total) are **facultative epiphytes**, living on other substrates as well. And many are found on several tree species, with five being found on all five tree species. They further supported the observations that the species composition varies with bark characteristics, leeward vs windward exposure, height on tree, tree size, and degree of uprightness. Growth and life forms also relate to the moisture conditions of the bark.

Figure 44. Laurel forest on Tenerife, Canary Islands. Photo by Inkaroad, through Creative Commons

In tropical forests that have high tree species richness, such host-tree relationships are absent; at the same height, one can expect to find mostly the same bryophytes in the same forest. However, in tropical forests with low tree species diversity, clear host-tree relationships may be observed. The best example is demonstrated by Cornelissen and ter Steege (1989; ter Steege and Cornelissen 1989) on dry evergreen forest in Guyana dominated by two tree species (*Eperua grandiflora* (rough-barked) or *E. falcata*) (wallaba, smooth-barked; Figure 45-Figure 46). Not surprisingly, the two tree species host different epiphytic bryophyte assemblages, with the rough bark of *E. grandiflora* supporting more epiphytes.

Figure 45. *Eperua falcata*, Guyana, showing smooth bark. Photo by Bernard Dupont, through Creative Commons.

Figure 46. *Eperua falcata*, a species that has smooth bark and inhabits dry sites. Photo by Hiobson, through Creative Commons.

Rudolph *et al.* (1998) examined host tree characteristics in a western Andean rainforest in Ecuador (Figure 47). Müller and Frahm (1998) elaborated on the epiphytic mosses in an Ecuadorian montane rainforest in the Andes. They found 65 species (24 mosses, 41 liverworts) on the ten trees they examined. They found no significant correlation between species number and branch diameter, branch exposure, or elevation. However, as bark pH increased, the number of epiphytic bryophyte species decreased.

Figure 47. Ecuador tropical rainforest in middle of Rio Tiguono at Bataburo Lodge. Photo by Andreas and Christel Nöllert, with permission.

Thus, even in cases where host specificity is absent, certain characteristics seem to encourage or discourage bryophytes. As noted earlier, bark differences in the tropics can be important for some bryophyte species, but have little effect on bryophyte communities or species richness.

Host "trees" can also include tree ferns. Jaag (1943) examined the foliage renewal rate, leaf life, and epiphyte "involvement" on tropical tree ferns. Frahm (2003) described the meager studies on epiphytes on tree ferns. In Southeastern Brazil, he identified 142 species on *Cyathea* (Figure 48-Figure 49) and *Dicksonia* (Figure 50) trunks. Most of these seem to be chance occurrences, with only 20 species occurring on more than 10% of the fern trunks in the study. Vital and Prado (2006) found a species new to Brazil (*Ceratolejeunea dentatocornuta*; see genus in Figure 51) occurring on *Cyathea delgadii* (Figure 52-Figure 53). These were in a fragment of the Atlantic forest in the state of Sao Paulo. In total, the researchers found 35 bryophyte species, 12 of mosses and 23 of liverworts. Medeiros *et al.* (1993) reported epiphytes on *Cibotium* species (Figure 54) and *Sphaeropteris cooperi* (= *Cyathea cooperi*; Figure 55), both tree ferns, in a Hawaiian rainforest (Figure 56).

Using a line-intercept method, Batista and Santos (2016) studied the epiphytic bryophytes in the Atlantic Forest of southeastern Brazil (Figure 57). They identified 71 taxa. The mean coverage did not vary significantly among the various phytophysiognomies. Nevertheless, the species compositions were distinct among these phytophysiognomies, but no cohesive or isolated groups emerged. There was, however, a correlation between bryophyte cover and tree DBH. Bark pH of the palm *Euterpe edulis* (Figure 58) and bark roughness of members of the tree fern family *Cyathea* (Figure 52-Figure 53, Figure 55) also affected species composition.

In areas with many plantations and more than one host species, more specificity may present itself. For example, in Nigeria over 60% of *Octoblepharum albidum* (Figure 59) collections were from *Elaeis guineensis* (Egunyomi 1975, 1978), whereas *Calymperes palisotii* (Figure 60) prefers *Albizia saman* (Figure 61-Figure 62) over the relatively smooth, non-fissured bark of *Lagerstroemia* sp. (Figure 63-Figure 64) (Egunyomi & Olarinmoye 1983). Different agroforests [mango (Figure 65) and *Citrus* (Figure 66)] house unique bryophyte communities. Ezukanma *et al.* (2019) found that each of these two communities had 12 bryophyte species, but only five were common to both.

Height on Tree

Andersohn (2004), working in central Guatemala, asked the question "Does tree height determine epiphyte diversity?" He listed the epiphytes, including the bryophytes. Many other studies have provided insight into this question.

Like epiphytes in other parts of the world, communities at the base, trunk, and crown differ due to light, moisture, and nutrients [Cornelissen & ter Steege 1986; Montfort & Ek 1990; Kürschner 1990 (studied only base and trunk)]. In some forests, the tree bases receive so little light that even bryophytes are unable to grow there. The branches, on the other hand, can have complex, dense growths that sometimes surround the entire branch like a winter muff (Figure 1) for warming one's hands. In the crown, high light intensity and dryness become limiting. For example, in the dry evergreen (wallaba – *Eperua falcata*; Figure 45-Figure 46) forest of Guyana, bryophytes and lichens on the canopy twigs of mature *Eperua* trees are predominantly of two types, the sun-tolerants and the pioneers (facultative epiphylls) (Cornelissen & ter Steege 1989). Many researchers follow the zones as described by Johansson (1974) (Figure 67-Figure 68).

Campos *et al.* (2019) evaluated The bryophyte epiphytes in six height zones of four forests in the northwestern Amazon. Among the 64 trees sampled, they found 63 species that they considered indicator species for their zones. The tree base (zone 1) exhibited the highest number of species, followed by the outer canopy (zone 6). There was a gradual change in bryophyte communities with height zone, and these indicated the importance of the environmental differences encountered in the vertical gradient of a single tree.

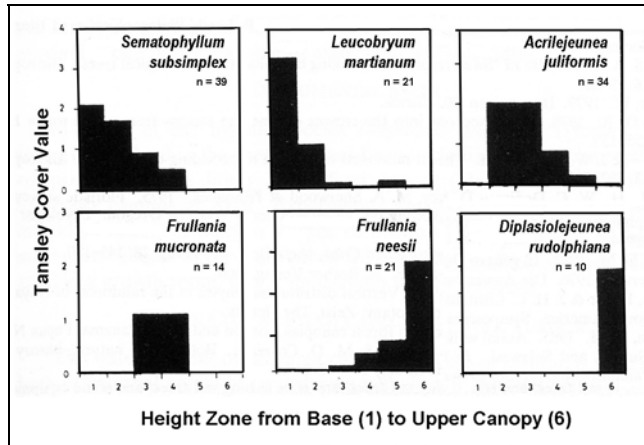

Figure 67. Vertical distribution (see Figure 68) of four moss and two leafy liverwort species in Guyana. Height zones are in Figure 68. Modified from Cornelissen & ter Steege 1989.

Figure 68. Epiphyte zones on a tree. Modified from Johansson 1974.

Zonation patterns occur from branch tips to center of the crown as well. Freiberg and Freiberg (2000) found that in the two lowland and two montane forests they studied in Ecuador (Figure 69), the epiphytic biomass per branch surface decreases from the center of the crown to the periphery.

Figure 69. Montane forests, Ecuador. Photo by Martin Zeise, through Creative Commons.

Pócs (1982) found that mosses dominate the base of the trunk, but leafy liverworts, especially the ever-present *Frullania* (Figure 70) and *Lejeuneaceae* (Figure 6, Figure 8-Figure 9), dominate the branches.

Figure 70. *Frullania* sp., a genus that dominates branches of tropical trees. Photo by George Shepherd, through Creative Commons.

In French Guiana (Figure 37), Gehrig-Downie *et al.* (2013) compared the diversity and vertical distribution of epiphytic liverworts between the lowland rainforest and the lowland cloud forest. These lowland cloud forests occur in river valleys with high air humidity and morning fog. This combination creates ideal conditions for epiphytic leafy liverworts. The researchers found a significantly higher species richness of these liverworts in the cloud forest and

the species composition differed (Figure 71) in all six height zones (Figure 68).

Figure 71. Number of epiphytic liverwort species in each tree height zone (see Figure 68) in the lowland cloud forest and lowland rainforest. $n=24$ trees per forest type. Boxes are upper and lower quartile, unbroken lines are medians, dotted lines are means, whiskers are 95 percentile, and circles are max and min. $*P<0.05$, $**P<0.01$ for t-test differences. Modified from Gehrig-Downie *et al.* 2013.

The lowland cloud forests included more indicator species, particularly shade epiphytes and generalists that also occur in the montane forests (Gehrig-Downie *et al.* 2013). The lowland rainforest exhibited sun epiphyte indicators that characterize dry, open sites. At least in this case, liverwort species richness differs more between forest types than it does among elevation types. Furthermore, the lowland cloud forest may be more species-rich than are the montane rainforests. As is typical throughout most tropical habitats, the **Lejeuneaceae** (Figure 6, Figure 9, Figure 20, Figure 51) represents the largest family, with 95 species. This was followed by **Plagiochilaceae** (9 spp.; Figure 72) and **Frullaniaceae** (7 spp.; Figure 70). In the **Lejeuneaceae**, *Lejeunea* (Figure 73) had 14 species; *Ceratolejeunea* (Figure 51), *Cololejeunea* (Figure 74), and *Plagiochila* (Figure 72) each had nine species there.

Jarman and Kantvilas (1995), working on epiphytes of an old Huon pine (*Lagarostrobos franklinii*; Figure 75) in Tasmania, found 76 species of lichens, 55 of bryophytes, and 16 tracheophytes on that single tree. One factor accounting for the high diversity is that there is little

overlap in species between the base and canopy taxa. Bryophytes dominate at the base, but lichens dominate in the more exposed crown. The bryophytes and lichens on these older trees build sufficient biomass peat on the branches that terrestrial tracheophytes are able to become established in the peat.

Oliveira and ter Steege (2013) used a standardized sampling method across the Amazon Basin (Figure 76) to describe the epiphytic bryophytes in five height zones from the forest floor to the canopy. They sampled eight canopy trees per locality, generating 3,104 records. They were able to identify 222 species and 39 morphospecies. As expected, the leafy liverwort family **Lejeuneaceae** (Figure 6, Figure 9, Figure 20, Figure 51) was the most common (55%), followed by the moss families **Calymperaceae** (Figure 10) (8%), **Leucobryaceae** (Figure 5) (4%), and **Sematophyllaceae** (Figure 102) (4%). Among these, 155 species occur in more than one locality, with 57 species considered to be specialists. In the canopy they found 29 species that are exclusive to the canopy.

Figure 75. *Lagarostrobos franklinii*, a species that hosts lots of bryophytic epiphytes in Tasmania. Photo by Krzysztof Ziarnik, through Creative Commons.

Sporn *et al.* (2010) reported a record number of 146 epiphytic bryophyte species on eight canopy trees and eight trees from the understory of a submontane rainforest in Central Sulawesi, Indonesia (Figure 77). The trunks of

canopy trees have significantly different species composition from that of the understory trees. Furthermore, 45% of the species are restricted to canopy tree crowns, whereas only 12% are restricted to the understory. This study emphasized that inventories of epiphytic bryophytes in a tropical forest should not only focus on canopy trees but also include the small understory treelets and shrubs, which may add at least 10% more species. A similar conclusion was reached by Krömer *et al.* (2007) in a study on tracheophytic epiphyte diversity in tropical submontane and montane forests.

Krömer *et al.* (2007) found that 90% of the tracheophytic epiphytes in the submontane and montane forests of the Bolivian Andes were represented in tree zones Z1-Z2 in the Johansson tree zones (Figure 68). Canopy tracheophytes were primarily orchids and ferns that had special adaptations to the frequent drought conditions. This vertical distribution responds to microenvironmental gradients of the tree, including light intensity, wind speed, and air temperature that increase with height, and moisture that decreases with height. But just what role do bryophytes have in their success?

Figure 76. Amazon rainforest aerial view in Brazil. Photo by Lubasia, through Creative Commons.

Figure 77. Sulawesi forest. Photo by T. R. Shankar Raman, through Creative Commons.

In lowland rainforests around Mabura Hill (Figure 78), Guyana, South America, Cornelissen and Gradstein (1990) reported 134 (52 mosses, 82 liverworts) bryophytes species. Of these, ~30% are **Lejeuneaceae** (Figure 6,

Figure 9, Figure 20, Figure 51). Mountaineering techniques permit study of the forest canopy. There, 50% of the bryophyte species are exclusive to the canopy. The mixed forest has more exclusive species than does the dry evergreen forest, largely because of the outer canopy effect where xerophytic species occur. The canopy species in the dry evergreen forest have wider vertical distributions than do those in the mixed forest, a difference the researchers attribute to the more open canopy foliage in the dry evergreen forest.

Wolf (1994) examined epiphytic vegetation in the northern Andes (Figure 34). He restricted the bark type and sampled four full-grown forest trees at altitudinal intervals of ca 200 m from 1,000 to 4,130 m asl. The variation he found did not seem to relate to any environmental factor. Rather, as noted above, it seemed to relate to randomness in propagule supply. Nevertheless, ordination indicates that distribution patterns relate to altitude and height within the host tree. Interestingly, Oliveira and ter Steege (2015) found the same relationship in Amazonian lowland rainforest (Figure 76). Unlike many other studies, Wolf also found a relationship between the epiphytic vegetation and the host species, particularly for the host *Brunellia occidentalis* (see Figure 79-Figure 80), a high altitude species with rapid growth. There is no indication of a relationship with chemical characteristics of suspended soil.

Oliveira *et al.* (2010) noted that, like tracheophytes, bryophytes demonstrate a species gradient from the base to the upper canopy of the host trees. They set out to test the role of niche assembly on a regional scale. They sampled six height zones on several trees in each of three lowland forests of the Guianas (Figure 37) and found that height zone was relatively consistent in the three localities, despite distances up to 640 km, and that that consistency was greater than among communities within the height zones of a single tree (30-50 m in height). More than half (57%) of the species exhibited a height zone preference.

Overall, Oliveira (2010) identified 225 species and 38 morphospecies of Amazonian basin epiphytic bryophytes. As we might expect, the leafy liverwort family **Lejeuneaceae** was the most species-rich family (55% of species). Among the mosses, the most common families were **Calymperaceae** (8%), **Leucobryaceae** (4%), and **Sematophyllaceae** (4%). All four of these families occurred in all 9 sampling locations. The most common species was the leafy liverwort *Cheilolejeunea rigidulus* (see Figure 81), followed by *Ceratolejeunea cornutus* (Figure 82), *Octoblepharum pulvinatum* (Figure 83), *Octoblepharum albidum* (Figure 59), *Archilejeunea fuscescens* (see Figure 84), *Sematophyllum sub simplex* (Figure 85), *Lopholejeunea subfuscus* (Figure 86), and *Symbiezidium barbiflorum* (see Figure 87). These eight species accounted for 21% of the known species in the study.

Oliveira (2010) found that a total of 155 species occurred in more than one locality, and of these 57 were considered to be specialists (37%), whereas 98 (63%) were considered generalists. The specialists were typically found at the extremes of the gradient, either in zone 1 or zone 6. Only 8 seemed to be specialists in other tree zones. Oliveira concluded that the structure of the communities fit the Neutral Model of Biodiversity and Biogeography, *i.e.*, being there by random recruitment from the local environment. The distribution of the species appears to be influenced by two processes. On a local scale, the interaction between the environment and local abundance provide the greatest influence. Within the Amazon basin, the abundance of the species in the **metacommunity** (sum of all communities sampled in localities and linked by dispersal) are the primary influence. Furthermore, the frequency of long-distance dispersal increased with the height of the zone in the tree. What seems strange is that the greatest genetic distance occurs between the canopy and subcanopy.

In the constant clouds of the dense montane **ombrophilous** (capable of withstanding or thriving in presence of high rainfall) forest (1,000 to 1,500 m asl) in southern Brazil (Figure 88), Santos *et al.* (2018) characterized six vertical zones on 28 trees and identified 96 species of bryophytes in 31 families. The leafy liverwort family **Lejeuneaceae** (Figure 6, Figure 8-Figure 9) was the most species-rich family, followed by **Frullaniaceae** (Figure 70). Liverworts predominated. Species diversity was high, ranging from $H'=2.6$ to $H'=4.1$, with high abundances. Of the 28 trees sampled, across this elevation range, the species composition was similar, with only two differing by more than 50%. Bryophyte cover ranged from 3.04% (2 m high to first branches; epiphylls) to 8.97% (0.0-0.5m) in the six phorophyte zones.

Tree Base

In the rainforests, the least light reaches the bases of the great trees (Pócs 1982). At the same time, the bases have the highest humidity in the forest. The bole height of dense bryophyte growth is limited by humidity and the physical condition of the bark, but where it is extremely wet it can reach as high as the first main branches, which may reach 8-10 m high (Richards 1954; Pócs 1982). More typically, it reaches up to 1-3 m, being limited by humidity that sinks to 60% during dry periods (Pócs 1974).

Figure 88. Brazilian southern highlands. Photo by Cecilio, through Creative Commons.

On tropical tree bases one is likely to find **mats** and **wefts** of various *Thuidium* (Figure 89) species, intermixed *Fissidens* (Figure 90), and the leafy liverworts in **Lejeuneaceae** (Figure 6, Figure 9, Figure 20, Figure 51) and small turfs of mosses in **Orthotrichaceae** (Figure 28) (Gradstein & Pócs 1989). More suitable, porous bark often supports growths of the mosses *Leucobryum* (Figure 5), *Leucophanes* (Figure 10), and *Calymperes* (Figure 91). Farther up one might find **turfs** of the mosses **Dicranaceae** such as *Leucoloma* (Figure 92). As the **wefts** and **turfs** grade away from the base, one can find the **feather** type forming horizontal shelves on the bole (Figure 93) (Gradstein & Pócs 1989). The **dendroid**, **feather**, and **bracket** forms are specialists on the more narrow stems of small trees and branches of shrubs in this low-light zone, but they can also be found at the base (Pócs 1982). These include the mosses *Lopidium* (Figure 94) and *Pinnatella* (Figure 95) on all continents with tropical forests.

In the lowland rainforest of Guyana (Figure 96), Cornelissen and ter Steege (1989) found that the tree base community is characterized by the abundance of pleurocarpous mosses. In the wet, very shady habitats of tree bases these pleurocarpous species include **pendent** and **dendroid** mosses in the **Neckeraceae** (Figure 97-Figure 98) and **Pterobryaceae** (Figure 116) (Pócs 1982). In Asia and northern Australia, these include the mosses *Homali dendron* (Figure 99) and *Neckeropsis* (Figure 97-Figure 98), both in **Neckeraceae**; in Africa one finds the mosses *Renauldia* and *Hildebrandtiella* (Figure 100) in the **Pterobryaceae** and *Porotrichum* (**Neckeraceae**; Figure 101). In the Neotropics, *Neckeropsis disticha* (Figure 97) and *N. undulata* (Figure 98) are ubiquitous. The mosses *Sematophyllum* (Figure 102) and *Taxithelium* (Figure 117) are likewise common in this zone. The number of species seems to vary in this synusia, with ~100 species in Vietnam, 60 in East Africa, and 50 in Cuba.

In Costa Rica, Holz *et al.* (2002) documented the diversity, microhabitat differentiation, and distribution of life forms in the tropical upper montane *Quercus* forest [*Q. copeyensis* (Figure 103), *Q. costaricensis* (Figure 104)], using seven freshly fallen trees. They were surprised to find that not only is the tree base bryophyte community distinct from that of the rest of the tree, it is fundamentally the same as that of the forest floor! They also noted the importance of the understory as bryophyte habitat. On **lianas** (vines), poles, twigs on shrubs, ferns, and palms they found 65 species. More details of the Holz *et al.* study are in the subchapter Tropics – Altitude.

Figure 104. *Quercus costaricensis*, a species whose tree base bryophytes match those of the forest floor. Photo by Stan Shebs, through Creative Commons.

Further descriptions of the epiphyte bryophyte habitat can be found in Richards (1954) from Guiana (Figure 37), Iwatsuki (1960) from southern Japan, and Tixier (1966) from South Vietnam.

Equihua and Equihua (2007) examined spatial distributions of *Bryopteris filicina* (Lejeuneaceae; Figure 105) on tree trunks in Chiapas, Mexico (Figure 106). They found it to be over-represented on *Ampelocera hottlei* (Figure 107), *Brosimum alicastrum* (Figure 108), and *Guarea glabra* (Figure 109), all species with smooth bark. Its distribution was determined by height on the tree, bark texture, and orientation, preferring smooth texture and a north-facing orientation.

Upper Trunk

The upper trunks have mostly appressed species (Schofield 1985, pp. 313-314). These are most commonly leafy liverworts such as *Frullania* (Figure 70) and *Lejeuneaceae* (Figure 6, Figure 9, Figure 20, Figure 51) (Pócs 1982). Among the mosses one can find **smooth mats** and thread-like *Sematophyllaceae* (Figure 102) again, as well as *Hypnaceae* (Figure 110) and *Mitthyridium* (Figure 111), again being appressed.

Figure 110. *Hypnum cupressiforme* var. *heseleri*, a smooth mat former. Photo by Robin Stevenson, with permission.

Kürschner and Parolly (1998c) used the **Braun-Blanquet method** (system using cover-abundance classes; Poore 1955) to describe the various associations on tropical rainforest tree boles. The distribution patterns of the trunk-epiphytic vegetation can be generalized pantropically. Three alliances fall into two orders. Their distribution is correlated to structural parameters of the phorophyte stands and to **isothermic** (equal temperature) intervals: tropical lowland and submontane alliances (20-27°C mean annual temperature); subtropical and montane alliances of the montane rain- and cloud forests (12-20°C); temperate, boreal to subalpine alliances of elfin forests and ericaceous woodlands ((5)8-12°C). A fourth unit (<8°C) includes the

Afro-subalpine *Syntrichion cavallii* (see Figure 112), mostly known outside the moist tropics and typical of the subpáramo vegetation.

Lower Branches

The lower, thick canopy branches are typically inhabited by large **mats** of robust epiphytic bryophytes such as *Plagiochila* (Figure 72), *Bazzania* (Figure 105, Figure 113), *Macromitrium* (Figure 114), and others (Cornelissen & ter Steege 1989). Using mountaineering techniques, Cornelissen and ter Steege sampled the *Eperua* trees [*Eperua grandiflora* and *E. falcata* (Figure 45-Figure 46)] in the dry evergreen forest of Guyana (Figure 45) from the base to the highest canopy twigs. This revealed a clear vertical distribution pattern of species and life forms for bryophytes. The upper canopy twigs are particularly species rich with both sun epiphytes and pioneers (facultative epiphylls).

Figure 113. *Bazzania* from the Neotropics. Photo by Michael Lüth, with permission.

Figure 114. *Macromitrium* sp. from the Neotropics. Photo by Michael Lüth, with permission.

Epiphyllous bryophytes, predominantly leafy liverworts in the **Lejeuneaceae** (Figure 6, Figure 9, Figure 20, Figure 51), abound in this lower branch zone, but also occur in abundance in the forest understory (Gradstein & Pócs 1989), in both cases living out of the damaging and desiccating reaches of the sun. The general trend observed for epiphylls is a reduction of species richness from the understory to the canopy (see Montfoort & Ek 1990), while species richness of epiphytes usually increases. These epiphyllous communities are discussed in the subchapter Tropics: Epiphylls.

Twigs

Wolf (1993a, b, c, 1995) described the changes in epiphytic bryophyte community structure of the montane forest, from the canopy twigs to the thickest lower canopy branches, in admirable detail. The lower branches and terminal twigs (Figure 115) of lowland forests support the **pendent Meteoriaceae** (Figure 115) and **Pterobryaceae** (Figure 116), provided it is sufficiently humid, and also the ever-present leafy liverworts *Frullania* (Figure 70) and **Lejeuneaceae** (Figure 6, Figure 9, Figure 20, Figure 51) (Pócs 1989). Here one finds **Neckeraceae** (Figure 97-Figure 98) and **Pterobryaceae** such as *Lopidium* (Figure 94) or *Pinnatella* (Figure 95), or others that are more specific to certain continents (Pócs 1982). *Sematophyllum* (Figure 102) and *Taxithelium* (Figure 117) reach their peak here. Farther up on the main branches, bryophytes must withstand high light and desiccation. There, dense mats occur, including the mosses **Cryphaeaceae** (Figure 118), **Erpodiaceae** (Figure 119-Figure 120), **Orthotrichaceae** (Figure 28), and **Sematophyllaceae** (Figure 102), as well as the liverworts *Frullania* and **Lejeuneaceae** (Figure 6, Figure 9, Figure 20, Figure 51). For those of us from the north temperate and boreal zones, only **Orthotrichaceae** and a few *Frullania* and **Lejeuneaceae** taxa are familiar.

Several species found on the fine canopy twigs are not restricted to this habitat but also occur lower down in the forest on the upper trunks or on living leaves in the forest understory (Cornelissen & ter Steege 1989). These species are considered pioneer species of the rainforest, well adapted to growth on open, unstable substrates. Most of them are small **Lejeuneaceae** (Figure 6, Figure 9, Figure 20, Figure 51) and copiously reproduce by vegetative propagules.

Romero (1999) found the most abundant **pendent** bryophytes on the thin branches (<1 cm diameter). The highest biomass per unit substrate occurred on branches of shade-tolerant species.

Canopy

The canopy, especially the outer canopy, can be a very different and stressful habitat in the forest. It is exposed to the full force of the wind. But based on turbulence analysis of two Amazon rainforest canopies (Figure 17, Figure 76), Kruijt *et al.* (2000) reported a sharp daytime attenuation of turbulence in the top third of the canopies. Thus, within the canopy there is very little air movement. Their hypothesis is that "the upper canopy air behaves as a plane mixing layer." This suggests that tropical rainforest canopies differ from other forests where there are rapid, coherent downward sweeps that penetrate the lower canopy. This penetration does not occur in these Amazonian rainforests. Rather, there is strong heat absorption by the canopy leaves near the top. The weak turbulence is unable to destroy the temperature gradient that is present through the large canopy depth. The inversion is likely to be maintained by strong heat absorption in the leaves concentrated near the canopy top, with the generally weak turbulence being unable to destroy the temperature gradients over the large canopy depth.

Sillett (1991) studied canopy bryophyte communities of six mature *Ficus aurea* (Figure 121-Figure 122) trees to elucidate the canopy bryophyte community and compare microhabitats. He divided these into three intact cloud forest and three isolated trees in Costa Rica. He used hemispherical canopy photography to compare light in the crowns, determining that the interior crowns of isolated trees were twice as bright as those in the intact forest. Isolated trees had lower species richness and life-form

diversity. He found 41 species of mosses on the intact forest trees compared to only 29 on the isolated trees, with 50 species in total. The bryophytes on the forest trees are dominated by **pendants**, **fans**, **wefts**, and **tall turfs**, whereas the isolated trees have more **short turfs**. As in other studies, variation of bryophyte communities is greater within a single tree than among trees. Furthermore, the among-tree variation is greater in the forest than among isolated trees.

Figure 121. *Ficus aurea*, a species that supports many more epiphytes when in the forest than when isolated in the open. Photo by Forest and Kim Starr, through Creative Commons.

Gradstein (2006) described the lowland cloud forest of French Guiana (Figure 123) (in moist river valleys below 400 m asl) where the climate differs from that of the mixed lowland rainforest, but differs by the frequent presence of fog and a large presence of epiphytes, especially liverworts. This forest has species richness of epiphytic liverworts that is similar to that at 2,000 m asl in the Andes and exhibits three times the richness of the Amazonian lowland forest (Figure 17, Figure 76). The moisture counterbalances the high temperatures, permitting the large diversity. The taxonomic composition and abundance differ from those in the tropical montane cloud forest. In the lowland cloud forest, asexual reproduction and dispersal are significantly more common in the canopy than in the forest understory. These canopy species have significantly wider ranges than that found among understory species. Gradstein suggested that these wider ranges are due to long-range dispersal by spores.

Logs and Rotten Wood

Where lumbering or wind and hurricane disturbances occur, logs become a visible feature of the landscape (Figure 124). They also result from the normal aging and death of a tree. These logs provide a different habitat, especially in the **epixylic stage** (after bark is lost; Figure 125), than that of tree trunks.

Figure 124. Illegal export of rosewood logs from Madagascar. Photo by Erik Patel, through Creative Commons.

Figure 125. Decorticated log with epixylic bryophytes. Photo from UuMUfQ, through Creative Commons.

Winkler (1976) conducted some of the earliest studies of tropical bryophytes on rotten wood. Frahm (2003) compared the taxa on rotten wood in the tropics. This is the primary available substrate in lowland forests due to the heavy cover of leaf litter elsewhere on the forest floor. Logs usually are inhabited by **Sematophyllaceae** (Figure 102), **Hookeriaceae** (Figure 134), and **Leucobryaceae** (Figure 5) among the mosses. At Monteverde, one can also find *Pyrrhobryum spiniforme* (Figure 126) (Gradstein *et al.* 2001). In the cloud forest of Monteverde, Costa Rica (Figure 127), one can find the bryophytes on logs that can differ from these (see subchapter Tropics: Altitude, part 2).

Figure 126. *Pyrrhobryum spiniforme* in Hawaii. Photo by Alan Cressler, with permission.

Figure 127. Monteverde cloud forest, Costa Rica. Photo by Haakon S. Krohn, through Creative Commons.

The rotten wood of moist tropical montane forests supports a rich bryophyte flora. Such logs on Mt. Meru and the Usambara Mountains in Tanzania (Figure 128) supported 102 taxa of bryophytes on logs (86 mosses, 16 liverworts), including 71 taxa in 51 20x20 cm plots. (Mattila & Koponen 1999). Cornelissen and Karssemeijer (1987) presented a scale to determine the decomposition stage of the wood: 1 – knife does not penetrate, 2 – penetrates one centimeter, 3 – penetrates several centimeters, 4 – penetrates to the handle. (See also Frahm 2003 for its use in the tropics.)

In Neotropical Puerto Rico, Sastre-de Jesús (1992) found that **Lejeuneaceae** (Figure 6, Figure 8-Figure 9) and **Calymperaceae** (Figure 10, Figure 91) dominated the logs with bark intact. Softwood logs frequently had *Taxithelium planum* (Figure 117) and *Isopterygium tenerum* (Figure 129). Bryophytes on heavily decayed logs tended to have species with higher water requirements, presumably due to the relatively constant water content of these logs.

Figure 128. Western Usambara Mountains, Tanzania. Photo by David Ashby, through Creative Commons.

Figure 129. *Isopterygium tenerum*, a species that occupies softwood logs in Puerto Rico. Photo by Scott Zona, through Creative Commons.

Rotten logs and rotting wood with bryophytes are able to retain good moisture (Laman 1995). This in turn provides a suitable and important substrate for the germination of seeds such as *Ficus crassiramea* subsp. *stupenda* (Figure 130-Figure 131).

Figure 130. *Ficus crassiramea* subsp. *stupenda*, a species that germinates on bryophyte-covered logs in the tropics. Photo by Pia Tan, through Creative Commons.

Figure 131. *Ficus crassiramea* subsp. *stupenda*, a species that germinates on bryophyte-covered logs in the tropical rainforest. Photo by Reuben C. J. Lim, through Creative Commons.

Parolty and Kürschner (2005) reported that under the relatively stable climatic conditions of tropical montane forests, the decay process is predictable. These conditions favor the **weft** and **mat** life form, following **perennial stayers**, a succession similar to that of the trunk epiphytic communities. Flood disturbance is more likely to favor species that are **dendroid** and **mat-forming shuttle species** that utilize a diaspore bank to return after flooding. In dry conditions, species are more likely to be **short-turf-forming colonists**. Shady sites are most suitable for **wefts**, giving them greater exposed surface area to take advantage of the low light conditions.

In the remnant Atlantic forest (seasonal coastal deciduous forest; Figure 132) of Brazil, Germano and Pôrto (1996, 1997) found 35 epixylic species of bryophytes. These comprised 11 families of mosses [*Calymperaceae* (Figure 10, Figure 91), *Pilotrichaceae* (Figure 133), *Fissidentaceae* (Figure 90), *Hookeriaceae* (Figure 134), *Hypnaceae* (Figure 135), *Leucobryaceae* (Figure 5), *Leucomiaceae* (Figure 136), *Orthotrichaceae* (Figure 28), *Plagiotheciaceae* (Figure 137), *Sematophyllaceae* (Figure 102), *Thuidiaceae* (Figure 138)] and 5 families of liverworts [*Aneuraceae* (Figure 139), *Frullaniaceae* (Figure 70), *Geocalycaceae* (Figure 140), *Plagiochilaceae* (Figure 72), *Radulaceae* (Figure 35)]. Note the absence of *Lejeuneaceae*. They related the species composition to the decomposition stage of the substrate (Germano & Pôrto 1997).

Figure 140. *Geocalyx graveolens* (Geocalycaceae), in a family that occurs on logs in the Atlantic forest of Brazil. Photo by Michael Lüth, with permission.

In forest fragments in the Atlantic forest (Figure 132) of northeastern Brazil, Silva and Pôrto (2009) used 100 m transects and small (<100 ha), medium (100-500 ha), and large (>500 ha) fragments to examine fragmentation and

edge effects on bryophytes growing on decaying wood. They identified 99 species of epixylic bryophytes (52 liverworts, 47 mosses); liverworts barely predominated here. They found that fragment size was important in determining composition, richness, diversity, and abundance on epixylic substrata. Furthermore, species richness, coverage, and shade tolerance did not correlate with the distance from forest edge. Rather, edge effects seemed to be non-linear, extending beyond 100 m from the forest edge.

In Pernambuco, Brazil, Germano and Pôrto (1996) described the dominant bryophytes in several community types. They found that *Cololejeunea sicaefolia* (see Figure 141), *Lejeunea quinque-umbonata* (Figure 142), both in the Lejeuneaceae, and *Riccardia* spp. (Figure 139) are exclusively epixylic in their study area.

Sampling

Many bryophytes grow high in the canopy and this provides a particular challenge for collection. Popular recent methods include rope-climbing (Figure 143) (Perry 1978; Whitacre 1981; Cornelissen & ter Steege 1986) and bow-and-arrow techniques (Dial & Tobin 1994). These methods can even be used to collect the tiny leafy liverworts that hide among the larger bryophytes and tracheophytes. Tweedie and Bergstrom (1995) developed a

hierarchical approach for bryophytic epiphytes that could handle their spatially complex ecosystems.

Figure 143. Rope-climbing to sample the canopy of a lowland rainforest in the Colombian Amazon. Photo by Laura Campos, courtesy of Robbert Gradstein.

Pardow *et al.* (2012) concluded that bryophyte life-form analysis of the canopy can be accomplished from the ground in the lowland rainforest of French Guiana (Figure 37). When this is the case, life forms could be used easily to indicate functional diversity.

Several sampling techniques for estimating abundance of non-vascular epiphytes, including bryophytes, have been developed over the past decade. The efficacy of those techniques, however, has never been investigated. Lovai *et al.* (2012) compared three protocols for sampling epiphytic bryophytes in tropical montane rainforests. They examined ladder quadrats, 10 x 10 cm quadrats at intervals of 40 cm, and a 10-cm-wide strip around the stem. The use of 10 x 10 cm quadrats at intervals of 40 cm proved to be the most effective and efficient sampling method for quantifying bryophyte cover and demonstrated a typical species-area curve (Figure 144).

Bryant *et al.* (1973) used **R-mode analysis** (species x species) and **Q-mode analysis** (principal component analysis for linear discriminant analysis) (Lee *et al.* 2017) of area x area to compare the distributional patterns of 155 species of leafy liverworts in the Luquillo Mountains of Puerto Rico (Figure 145). They compared high altitude with low-altitude areas, shaded, moist habitats with open, more exposed habitats, and disturbed, low-elevation habitats with less disturbed habitats at all elevations. R-mode and Q-mode produced nearly identical distribution patterns. Therefore, either method can be used to determine which species are the best indicators of habitat differences.

A technique that has been used in ecological studies in several ecosystems is that of recording **morphospecies** (species forms). This permits the researchers to use a team of novices and accomplish a wide survey in a short time (Gradstein *et al.* 2003). Using the technique for bryophytes, lichens, and tracheophytes, but not epiphylls, they estimated that they could inventory one hectare of tropical rainforest in two weeks. No identifications were attempted, enabling a team of six with three specialists (bryophytes, lichens, tracheophytes) and three assistants to accomplish the survey.

Figure 144. Species-area curve for epiphytic bryophytes and lichens in a lowland rainforest of French Guiana, based on Montfoort & Ek 1990.

Figure 145. El Yunque National Forest, Luquillo Mountains, Puerto Rico. Photo by Kai Griebenow, through Creative Commons.

Gradstein *et al.* (2003) developed a standard protocol of recording morphospecies (species forms) for rapid and representative sampling of epiphyte diversity of one hectare of tropical rainforest. Based on species-accumulation curves they found that inventories of 5 whole trees, using standard plots in all height zones, may be sufficient to sample 70-80% of the diversity of the epiphytic bryophytes of the forest. For vascular epiphytes and epiphytic lichens, however, more trees must be sampled. Using the protocol, the bryophyte inventory of one hectare can be

accomplished in two weeks by a team of one specialist and one field assistant. The results obtained by means of the standard protocol have been used for making comparisons of bryophyte species richness along elevational gradients (Gehrig-Downie *et al.* 2013) and along disturbance gradients (Gradstein & Sporn 2010). A standardized technique also permits comparisons between locations (countries) and hopefully even among researchers.

Quadrats

Nadkarni (2000) established "cylindrads" that she used to track colonization. In a lower montane cloud forest, Monteverde, Costa Rica, she used photography to track the colonization in these epiphytic plots. She also wrapped a clear acetate sheet around the branch, then placed a second clear sheet with a matrix of 100 dots (10x10). Using five random locations around the branch segment she counted the number of dots that touched epiphytes. These counts were converted to percent cover.

Affeld *et al.* (2008) used single samples (30 x 25 cm) from 96 epiphyte assemblages located on inner branches of 40 northern rata (*Metrosideros robusta*; Figure 146-Figure 147) trees to show that epiphytes are important in determining community structure on South Island, NZ.

Figure 146. *Metrosideros robusta* with epiphytes. Photo by Phil Bendle, through Creative Commons.

Wolf (1993d) used **relevés** (visual descriptions of vegetation of area plus habit and habitat data) to study epiphytes in the tropical montane rainforest in the northern Andes (Figure 34). This usually involves examining all the microhabitats and niches to find all possible species. They used rope-climbing techniques to reach the bryophytes.

Rope Climbing

Early tropical researchers, in an attempt to get better representation of the canopy bryophytes, frequently used ropes to help them climb the trees (Wolf 1993a, b, c, 1995; Gradstein *et al.* 1996; Nadkarni 2000).

Sillett (1991) set out to develop a quantitative method for sampling tropical canopy bryophytes. He used hemispherical canopy photography to learn that interior crowns of isolated trees (Figure 148) are twice as bright as the interior crowns of intact forest trees of the same species (*Ficus tuerckheimii*; Figure 149). He climbed the trees to sample them. Sillett used a cost-benefit analysis that indicated more branches per tree and fewer plots per branch minimizes time but provides similar information.

Older techniques such as tree climbing for collecting canopy bryophytes can present several problems. Many twigs and small branches cannot be reached from those branches that are strong enough to support the climber. Pole-climbing techniques require using a harness and the climbing spikes used can dislodge bryophytes and other epiphytes and put holes in the tree trunks, providing entry sites for pathogenic fungi and insects (Perry 1978). Inspired by Perry (1978), Cornelissen and ter Steege (1989) developed a rope-climbing technique that has been used by many researchers, including Dimitri Montfoort, Renske Ek, Jan Wolf, Ingo Holz, Nicole Nöske, Simone Sporn, Sylvia Mota de Oliveira, Laura Campos, and Angel Benitez, among others.

Using this method, Lücking *et al.* (1996) and Gradstein *et al.* (1996) reported that trees can be prepared for rope climbing in an hour, permitting the researcher to climb to 30 m in 5-10 minutes. Unfortunately, the outer branches are too fragile for climbing and must be sawed off.

Non-bryologists who collect may be fascinated by the epiphyllous species and usually do not provide representative sampling of the branch species. They furthermore often fail to provide the necessary data, such as substrate, that helps the taxonomist to identify the samples. While their collections are valuable to increase our knowledge of the species in an area, they can miss whole groups of taxa and should be used with caution for quantitative conclusions or ecological inferences.

Bow and Arrow

Perry (1978) modified the pole climbing techniques by adding ropes to the equipment. Once the rope is thrown over a sturdy branch, it can be used to help hoist the climber to the level of the branches. The placement of the rope is facilitated by use of an 80-pound pull crossbow and weighted arrow tied to 30-pound test monofilament. The weight of the arrow insures that the arrow will fall to the ground. A spool can be wrapped around the line to prevent tangling.

This is only the first step. Next, a 120-240 pound test braided line is attached to the first, smaller line (Perry 1978). The line that can support the climber is too heavy for the bow and arrow. The heavier (240 pound test) line is needed if there are many large branches because abrasion by the branches can break the lighter-weight line. Safety is a foremost concern.

Ter Steege and Cornelissen (1988) described rope techniques (Figure 150-Figure 153) to climb trees to capture epiphytic bryophytes. These were based on previous use by Day (1962), Pike *et al.* (1975), Perry (1978), Perry and Williams (1981), Whitacre (1981), Hoi (1984). Ter Steege and Cornelissen (1986) used a rope technique in Guyana (Figure 96), Wolf (1986) in Colombia, Montfoort & Ek (1990) in French Guiana (Figure 143).

Ter Steege and Cornelissen (1988) emphasized safety aspects: making sure the branch is strong enough and has an angle of less than 45°; using a proper, strong knot; avoiding branches infected by parasites and hemiparasites. The technique requires shooting an arrow over the selected branch (Figure 150), carrying with it a strong nylon fishing line (50-60/100). Tangles are prevented by keeping the line on a fishing reel, preferably a sea-fishing reel, attached to the bow. The arrow head is weighted with lead to help it return to the ground through the branches. The arrow is then removed and a 3-mm cord is tied to the fishing line using a double sheet bend knot (Figure 150). Winding the reel helps to pull the line and attached cord over the branch. An 11-mm speleocord is attached to the 3-mm cord using a double sheet bend knot (see Figure 150 for knots). This 11-mm cord is hauled over the limb by hand power. Construct a lasso with a figure of eight knot and pull it against the limb. The 3-mm cord is attached to the free end of the knot to facilitate pulling the knot down after use. Test the strength of the branch by having **two** people hang onto it with their full weight. Be prepared to get out of the way if the branch breaks! Hang two ascenders or jumars (Figure 151) on the rope to facilitate ascent. Attach one ascender to a seat belt and the other to the climber's feet (Figure 151). Always use locking karabiners to link the ascenders (Figure 152-Figure 153). Another rope can be tossed over desired branches higher up, using a load attached to a 3-mm cord. The procedure of hanging a rope is then repeated. I recommend reading the original article for details. And if this vocabulary is unfamiliar to you, you might not have enough experience to use this method safely.

Other Canopy Access

Hallé (1990) used an inflatable raft carried by a hot-air dirigible to gain access to canopy epiphytes. Other methods include the use of cranes (Figure 154-Figure 155) (Parker *et al.* 1992; Zotz & Vollrath 2003) and special platforms and walkways (Figure 156) (McClure 1966; Grison 1978; Perry 1978). Lowman *et al.* (2012) provide the standard modern reference on canopy research methods.

Role

Gotsch *et al.* (2016) emphasized the importance of epiphytic material in tropical montane cloud forests (Figure 156). As noted earlier, they intercept both nutrients and moisture from the atmosphere and contribute these over an extended period of time to the forest floor. The amounts of these contributions vary with stand age and microclimate. This epiphytic biomass provides food sources for both birds and mammals, and birds use bryophytic biomass for nest building. Gotsch and coworkers state that more than 200 species of birds use the epiphytes. Wilding *et al.* (2016) cited a number of pendent genera of mosses and liverworts that are used in nest building. These included the mosses *Papillaria*, *Floribundaria*, *Meteorium*, and *Squamidium* and the liverworts *Frullania* and *Plagiochila*.

Barkman (1958) and Pócs (1980) suggested that bryophytes may cause their own displacement by retaining water that makes tracheophytic epiphyte presence possible. They furthermore form humus, accelerate bark decay (Barkman 1958), and facilitate anchorage of seeds and other propagules.

Adventitious Roots

Herwitz (1991) found that adventitious roots of the montane tropical rainforest canopy tree species *Ceratopetalum virchowii* (see Figure 157) take advantage of the nutrient-rich stemflow, whereas the stemflow of other canopy tree species is nutrient-poor. Such observations as this raise the question of the role of bryophytes in the development of adventitious roots.

Figure 157. *Ceratopetalum apetalum*; *Ceratopetalum virchowii* is a canopy tree in the tropical montane rainforest and uses adventitious roots to gain nutrients from stemflow. Photo by John Tann, through Creative Commons.

Nadkarni (1994) found that epiphytic bryophytes do provide a rooting medium for adventitious roots of trees. In fact, a dynamic interaction may occur in which the bryophytes help the tree, and the tree roots likewise help the establishment of the epiphytic community. The bryophyte mat traps inorganic nutrients (Nadkarni 1986) and organic nutrients (Coxson *et al.* 1992) that are leached from members of the epiphyte community. These nutrients nourish the roots of the tree (Nadkarni & Primack 1989). The two appear to grow in mutual benefit, with the roots benefitting from the nutrients and providing a larger anchoring system for the epiphytes as they grow (Nadkarni 1994). As the bryophytes and organic matter increase, they provide more leachates, causing the tree roots to increase.

Leary *et al.* (2004) found that nodulation of the legume *Acacia koa* (Figure 158) occurred in the canopy in Hawaii. These nodules contain the bacterium *Bradyrhizobium* (Figure 159) in pockets within the canopy. These pockets provide organic soils with trapped nutrients and often form among bryophytes. They even have lower aluminum levels than the terrestrial soils.

Substrata for Tracheophytes

Zotz and Vollrath (2003) used a canopy crane (Figure 154-Figure 155) to explore the epiphyte flora of the palm *Socratea exorrhiza* (Figure 38-Figure 39) in a primary lowland rainforest of Panama. They examined each palm in a 0.9 hectare and identified 701 tracheophyte epiphytes and hemi-epiphytes on 118 palm trees, identifying 66 species. The tracheophytes usually do not colonize trees less than 20 years old. These tracheophytic epiphytes are significantly associated with bryophytes, but the researchers could find no species that seemed to depend on the bryophytes. On the other hand, one must wonder if the bryophytes are important in maintaining moisture for the roots and storing nutrients trapped during precipitation events, as well as providing a suitable anchor for germinating seeds.

In Madagascar, orchids commonly grow in beds of *Leucoloma* (Figure 160) on tree trunks (Pócs 1982; Catherine La Farge, Bryonet September 2004). The bryophytes trap nutrients that make them a suitable substrate for epiphytes.

Figure 160. *Leucoloma* sp, India, common substrate for orchids on tree trunks. Photo by Shyamal L., through Creative Commons.

But finding orchids among bryophytes does not indicate any necessary role for the bryophytes. Tremblay (2008) relocated a rare epiphytic orchid after its dislocation from Hurricane Georges. He found that the orchid population size did not correlate with the percent of moss cover on the standing trees. Nevertheless, the orchids seemed to be more frequent when the tree bole had 40-90% moss cover. We need studies to determine the role in bryophytes in trapping and holding seeds and seedlings until the orchids and other plants are able to attach to the tree.

Probably the best example of a moss-dwelling epiphyte is the neotropical fern genus *Melpomene* (Figure 161). Almost all species in this genus grow in dense epiphytic bryophyte mats (Lehnert 2007). Sylvester *et al.* (2014) noted that the highest epiphyte elevation known for a tracheophyte was from the southern Peruvian Andes. They reported three species of the fern *Melpomene* from *Polylepis pepeii* (see Figure 162) forests above 4,250 m, with *Melpomene peruviana* reaching close to 4,550 m asl. Could it be that bryophytes contribute in some way to their ability to live at these high elevations?

Figure 161. *Melpomene firma* and *M. monoliformis* – grammitid ferns, both species that grow in dense bryophyte mats in trees. Photo by Marcus Lehnert, courtesy of Robert Gradstein.

Ferns often inhabit bryophyte mats, where the bryophytes may support the heavy weight of the rhizome on vertical surfaces. Kelly *et al.* (2004) reported that *Elaphoglossum hoffmannii* was typically associated with mosses, specifically with *Syrrhopodon gaudichaudii* (Figure 163). *Elaphoglossum wawrae* (Figure 164) is a Hawaiian epiphytic endemic that occurs in moss mats, and is among the tracheophyte species that characterize the montane zone (Higashino *et al.* 1988; Kitayama and Mueller-Dombois 1992). *Elaphoglossum glabellum* growing on *Epeura falcata* (Figure 45-Figure 46) is restricted to small moss mats that occur around forks and knots found only in the lower canopy in the lowland rainforest of Guyana (Figure 96) (ter Steege & Cornelissen 1989). On *Epeura grandiflora*, this species occurs on bryophyte mats from the lower trunk to the middle canopy. The bryophyte mats provide a longer supply of water. But bark differences may account for the differences in bryophyte cover, with *E. grandiflora* having rougher bark than that of *E. falcata*. They may also provide a chemical buffer against toxins in the bark (Frei 1973).

On the other hand, Werner and Gradstein (2008) studied the factors important for seedling establishment of tracheophytic epiphytes in the Andes and found no relationship to bryophyte cover. Rather, isolated trees closer to the forest had significantly greater colonization by these plants, but colonization did not correlate with greater canopy or bryophyte cover.

Friend or Foe?

Cacao plantation owners had concerns over the epiphytes on the leaves, removing them in an effort to improve productivity of the fruit crop (Sporn *et al.* 2007). Removal of epiphytes from cacao had no notable effect on the harvest size of the cacao trees.

But sometimes the bryophytes seem to have negative effects on these trees. Akinfenwa (1989) reported that the epiphytic moss *Erythrodontium barteri* (Figure 165) reduced yield of the *Theobroma cacao* (Figure 166) trees. They cause a "dressing" effect on palms wherein the leaf bases collect soil in the leaf axils. This soil supports an epiphytic community with microbial activities in the soil. The result is decay of leaf bases, causing the joints to weaken. They can no longer support the epiphytic community, causing it to fall gradually along with the remains of the leaf bases. This process continues as the trees age and grow taller, resulting in smooth boles and consequently fewer leaves for photosynthesis.

Faunal Habitat

The epiphytes provide a suitable habitat for a number of arthropods in the Neotropical cloud forest (Yanoviak *et al.* 2004). The arthropod morphospecies are similar between green and brown portions of the epiphyte mats, but relative abundances often differ. The most common of these arthropods was an oribatid mite; these preferred the brown portion in laboratory trials.

Bryophytes are home to a variety of frogs and salamanders and are even used by chimpanzees to gather water. Birds use them for nesting material. These interesting interactions are discussed in the volume on Interactions.

Summary

Bryophytes exhibit a number of adaptations to the epiphyte living style. Many of these relate to the usually dry habitat and short duration of available water. The adaptations include green, multicellular spores, sexual dimorphism, asexual reproduction, monoicous condition, rhizoid discs, hyaline leaf margins, and cushion life forms. Their life strategies are typically **perennial stayers** and **perennial shuttle species**. In humid lowland areas **mats** are typical, contrasting with the **fans** and **wefts** that rely on propagules and clonal growth in the montane rainforest. Ciliate leaves collect water. In the xeric open, upper montane forests, **short turfs**, **tall turfs**, and **cushions** predominate. The understory often has **dendroids** and fans while the crowns have more **tufts**. In other cases, the inner branches have **tall turfs** and the outer ones have **smooth mats**. **Fans** and **mats** predominate in floodplains. **Colonists** occur almost exclusively in secondary forests.

The large spores facilitate short-distance dispersal and rapid development when water is available. Arrival on the tree bark appears to be a random event. Succession begins with crustose and foliose lichens and typically proceeds from the underside of the branch upward, although some observers conclude that the lichens inhibit the bryophytes. Ants may sometimes help in the dispersal. Rough bark is more easily colonized and holds more water for growth.

Host specificity is less important than tree characteristics. These relate to bark characteristics, leeward vs windward exposure, height on tree, tree size, and degree of uprightness. The inner canopy has thick branches and fewer bryophyte taxa compared to the thinner middle canopy branches, with greatest richness in the outer canopy. Many species are **facultative** epiphytes. Increasing bark pH seems to result in decreased bryophyte richness. Tree base, trunk, and crown differ due to light, moisture, and nutrients. Approximately 45-50% of the species occur in the crowns of rainforest trees.

Tropical forests have an array of vertical niches, but on a horizontal scale, 4-5 trees are adequate to find 95% of the diversity. The **Lejeuneaceae** are common in the canopy as branch epiphytes and as epiphylls. Tree bases often have **mats** and **wefts** of **Thuidium** spp., with **Fissidens** spp., **Lejeuneaceae**, and **Orthotrichaceae**. Farther up the trunk are **feather** types. **Dendroids**, **feathers**, and **brackets** occur on narrow stems of small trees and branches of shrubs in the understory. Species on the upper trunk are more appressed and correlate with structure of the phorophyte stands and to temperature zones. The lower branches and thick canopy branches typically have large **mats**; epiphyllous **Lejeuneaceae** abound. In moist forests, twigs support **pendent Meteoriaceae**, **Pterobryaceae**, **Frullania**, and **Lejeuneaceae**. On drier twigs one can find **Cryphaeaceae**, **Erpodiaceae**, **Orthotrichaceae**, **Sematophyllaceae**, **Frullania**, and **Lejeuneaceae**. The outer canopy contrasts with the inner canopy by having more light and less moisture, creating a stressful environment.

Logs and decaying wood are the primary substrate on the forest floor, raised above the thick litter layer. Dominant bryophytes are in the **Sematophyllaceae**, **Hookeriaceae**, and **Leucobryaceae**. Under stable climatic conditions, **perennial stayers** precede **wefts** and **mat**, a succession similar to that of the trunk epiphytic communities. Flood disturbance favors **dendroid** and **mat-forming shuttle species** that utilize a diaspore bank. In dry conditions, species are more likely to be **short-turf-forming colonists**. Shady sites are most suitable for **wefts**.

Epiphyte sampling is best done with ropes or bow and arrow, unless cranes or skywalks are available, minimizing damage to the trees and their flora. Quadrats in all tree zones can permit quantitative sampling. **Life forms** are suitable for assessing functional ecology.

Bryophyte clumps can provide moist rooting media for adventitious roots, and rooting media for ferns and orchids. They retain water, and store nutrients that can be released in pulses. Numerous invertebrate and amphibian species live among them.

Acknowledgments

My appreciation goes to Noris Salazar Allen for her efforts to make this chapter reliable and up-to-date, albeit many years ago. Her helpful discussions kept me going on this part of the world I know so little about. Andi Cairns was very helpful in providing literature and checking my information on Australian bryophytes.

CHAPTER 8-5

TROPICS: EPIPHYTE GEOGRAPHIC DIVERSITY

Figure 1. Wet forest of Kohala Mountain, Hawaii, with abundant epiphytes. Photo by Melora Purell, through Creative Commons.

Diversity

As is generally true in the tropics, many species have been named multiple times under different names in different countries (Pócs 1984). Hence, understanding the diversity is difficult, as is understanding the bryogeography. As herbaria have become established in more tropical locations, comprehensive studies of various genera and families is untangling some of these taxonomic problems (see, for example, the revision of African **Lepidoziaceae** (Figure 2) by Pócs 1984).

Figure 2. *Bazzania hookeri* (Lepidoziaceae) from the Neotropics. Photo by Michael Lüth, with permission.

The **Pterobryaceae** (Figure 21), a family restricted to the tropics, is almost exclusively epiphytic and mostly large, including **dendroid** and **pendent** forms (Churchill & Salazar Allen 2001). Consequently, that family, along with **Neckeraceae** (Figure 3), **Sematophyllum** (Figure 10), and **Taxithelium** (Figure 4), indicates very shady, wet habitats (Pócs 1982). Typically, mosses dominate the base of the trunk, but leafy liverworts, especially the ever-present **Frullania** (Figure 48-Figure 49) and **Lejeuneaceae** (Figure 14), dominate the branches (Pócs 1982; Gradstein 1992).

Australia

The largest number of tropical and subtropical species in the world occur as epiphytes (Ramsay *et al.* 2017). Australia is no exception, where more than 85% of the epiphytic bryophytes occur in the Wet Tropics of north Queensland (Ramsay & Cairns 2004). Of the 21 species of **Orthotrichaceae** reported by Vitt and Ramsay (1985) reported 21 species of **Orthotrichaceae** in all of Australia, but now we know there are at least 24 in tropical Queensland alone (Cairns *et al.* 2019). Many of these Queensland **Orthotrichaceae** species occur above 1200 m, including *Macromitrium dielsii*, *M. funiforme*, and *M. erythrocomum*, all endemic to the Australian Wet Tropics (Ramsay *et al.* 2017). In the **Orthotrichaceae**, 17 taxa are endemic (Ramsay *et al.* 2012). Vitt *et al.* (1995) suggested that such high-elevation taxa are often narrow endemics.

Ramsay *et al.* (1987) found seven genera of mosses that occur in all the major rainforest types in Australia (not all Australian rainforests are tropical): **Macromitrium** (Figure 5), **Racopilum** (Figure 6), **Hymenodon** (Figure 7; not in tropical Australia), **Rhizogonium** (Figure 8), **Pyrrhobryum** (Figure 9), **Sematophyllum** (Figure 10), and **Thuidium** (*Pelekium*?; Figure 11). Epiphyte succession there can occur rapidly in the right microclimate. In the crown, species change from prostrate or small upright plants to large cushion mosses such as **Leptostomum inclinans** (Figure 12; not in tropical Australia). These large mosses occur only on the upper surfaces of branches. But large cushions become unstable, falling to create new habitats. Bark furrows create niches where mosses can become established.

Asia

The **Lejeuneaceae** (Figure 14, Figure 51) is the most abundant and diverse tropical family. In Asia, Gradstein (1991) found 88 species in 17 genera of **Lejeuneaceae**, subfamily **Ptychanthoideae**. This subfamily has more species but fewer genera in Asia than in the Neotropics, and the species in these two floras are very different. Asia is the center of diversity for the tribe **Ptychantheae** (Figure 13); the Neotropics, on the other hand, has its greatest number of species of **Ptychanthoideae** in the tribe **Brachiolejeuneae** (Figure 14). The two floras (Asia vs Neotropics) are distinctly different taxonomically. Gradstein considered the higher species diversity in Asia to

be related to the greater latitudinal extension of the rainforest in the Far East. In the Far East, 22% of the **Ptychanthoideae** are non-tropical species, whereas in the Neotropics the non-tropical species are less than 2%.

Gradstein and Culmsee (2010) reported 150 bryophyte species on tree bases of only eight canopy trees in montane Sulawesi (Figure 15), Indonesia. Using only tree bases, they compared bryophyte communities based on tree diameter and bark roughness at a series of elevations. Low elevation bryophytes were characterized by the mosses in **Calymperaceae** (Figure 52-Figure 53), **Fissidentaceae** (Figure 16), **Hypopterygiaceae** (Figure 17-Figure 18), **Leucobryaceae** (Figure 19), **Meteoriaceae** (Figure 20), **Neckeraceae** (Figure 3), **Pterobryaceae** (Figure 21), and

Thuidiaceae (Figure 11), and the leafy liverworts in **Lejeuneaceae** (Figure 14, Figure 51), **Lophocoleaceae** (Figure 22), **Porellaceae** (Figure 23), and **Radulaceae** (Figure 24).

Figure 22. *Lophocolea cf polychaeta* (Lophocoleaceae) from the Neotropics, in a low-elevation genus in Sulawesi. Photo by Michael Lüth, with permission.

By contrast, bryophytes at higher elevations in Sulawesi (Figure 25) were predominately in the leafy liverwort families **Herbertaceae** (Figure 26), **Lepidoziaceae** (Figure 2), **Mastigophoraceae** (Figure 27-Figure 28), **Scapaniaceae** (Figure 29), **Schistochilaceae** (Figure 30), and **Trichocoleaceae** (Figure 31-Figure 32) (Gradstein & Culmsee 2010). In the submontane and lower montane, **Lejeuneaceae** (Figure 14, Figure 51) has the most species; **Plagiochilaceae** (Figure 33) is also important in the lower montane forest. In the upper montane forest that high diversity is found in the **Lepidoziaceae** (Figure 2). Rough bark is preferred by some species, but none prefer smooth bark. A few species correlate with trunk diameter, but species composition and richness do not. As elevation increases, liverwort species richness generally increases and moss richness decreases. This is a common trend in the tropics. Differences between communities on tree trunks increase with distance, reaching only about 25% similarity between Sulawesi and Borneo. At continental distances, similarity is nearly zero.

Ariyanti *et al.* (2008) considered that forest disturbance and land use altered for agriculture was changing the landscape in Central Sulawesi, Indonesia (Figure 34), at a drastic rate. Nevertheless, total bryophyte richness did not differ among forest types. But mosses and liverworts reacted differently. Moss richness was lowest in the cacao **agroforests** (Figure 34); liverwort richness was equal in all forest types. But in contrast, moss cover was unaffected, whereas liverwort cover decreased significantly in the agroforest. These differences resulted because species composition changed in the cacao agroforests. The more open agroforests were populated by drought-tolerant species. The species composition also differed markedly between large and small trees in the agroforests, but not in the natural forests. The authors suggested that these effects of tree size were due to changes in stemflow of precipitation water.

Kürshner (2008) identified six floral elements in southwest Asia, creating a heterogeneous flora. This included endemics with various origins. There is a very strong tropical influence on the bryophyte flora, particularly of the **Palaeotropical** and **Afromontane** elements. Nevertheless, nearly 10% (>95 taxa) are of xero-tropical origin. Many are unique relicts of a formerly more widely distributed flora and are concentrated primarily in the escarpment mountains of the Arabian Peninsula and Socotra Island.

Magdum *et al.* (2017) collected nine species of corticolous mosses in Panhalgad in the Western Ghats, India, in different seasons, providing the first record of the mosses from the Kolhapur District. These mosses were *Pogonatum microstomum*, *Campylopus flexuosus* (Figure 35), *Leucobryum bowringii* (Figure 36), *Fissidens bryoides* (Figure 37), *Fissidens macrosporoides*, *Loiseaubryum nutans*, *Anomobryum auratum* (Figure 38), *Bryum capillare* (Figure 39), and *Bryum uliginosum* (Figure 40).

Kürschner (2003) conducted a phytosociological analysis in southwestern Arabia in the Asir Mountains. The characteristic species are drought-tolerant Afromontane mosses, with *Orthotrichum diaphanum* (Figure 41) and *Syntrichia laevipila* (Figure 42) being most prominent. Life forms and life strategies correlate with the environment. The *Orthotricho-Fabronietum socotranae* (see Figure 43) is a drought-tolerant association that is both xerophytic and tolerant of high light. This formation is dominated by **cushion**, **short-turf**, and **mat-forming perennial stayers** that have regular sporophyte production. The *Leptodonto* (Figure 44)-*Leucodontetum schweinfurthii* (see Figure 45) association is typical of sub-humid areas with **sciophytic** (shade-loving) vegetation. Its bryophytes are liverworts in addition to the mosses that are predominantly tails or fan-forming pleurocarpous perennial shuttle species. The mosses typically have large spores, adapting them for short-range dispersal that is either passive (with moderately low reproduction) or generative reproduction. This sciophytic group has a much higher diversity of life forms and life strategies than the xerophytic group.

Additional references that may be useful regarding tropical epiphyte diversity in the Asian region include Frahm (1990 – Malaysia), Tixier (1966 – Indonesia), Osada & Amakawa (1956 – Tsushima Islands, Japan).

African Region

Exploration of tropical African bryophytes is relatively new. Augier (1974) listed **corticolous** (growing on bark) bryophytes in the submontane forest of western Cameroon (Figure 46). Akande *et al.* (1982) examined **corticolous** bryophytes in Ibadan, Nigeria. On the 8 phorophytes on two sites they examined, they identified 20 bryophyte species. *Entodontopsis nitens* (Figure 47) is common and present on both sites. They considered *Frullania dilatata* (Figure 48-Figure 49) and *Entodontopsis tenuinervis* to be accidental species. They found the pH of the bryophytes to be similar to that of their bark substrate. In 28 comparisons, 11 bryophyte species combinations have a similarity of 50% or more. *Entodontopsis nitens* and *Pelekium gratum* (Figure 50) have a high degree of association, as do *E. nitens* and *Mastigolejeunea florea* (see Figure 51), *Entodontopsis nitens* and *Erythrodontium barteri*, *Entodontopsis nitens* and *Calymperes palisotii* (Figure 52-Figure 53), and *Erythrodontium barteri* and *M. florea*. Light is important in determining the height of the bryophytes on the trees. There seems to be no indication of preference for tree species, but the number of trees sampled was limited.

Odu (1985) found a greater species richness of epiphytic bryophytes in lowland and freshwater forests than in the mangrove forests of the Niger Delta in Nigeria (Figure 54). He suggested that atmospheric humidity and air impurities may be influencing the bryophytes found. *Calymperes* (Figure 52-Figure 53, Figure 55) and *Octoblepharum* (Figure 56) occur all over the Niger Delta, whereas others are restricted to the lowland freshwater forests. Those in the mangrove forests require adaptations that permit their tolerance of salt water. Further discussion of the mangrove forest is in the Tropics subchapter Hydric and Xeric Habitats.

Figure 56. *Octoblepharum albidum*, a common species in the mangrove forests of Thailand. Photo by M. C. Nair, K. P. Rajesh, and P. V. Madhusoodanan, through Creative Commons.

Akinsoji (1991) reported 26 tracheophytic epiphytes from a tropical rainforest in southwestern Nigeria. As noted elsewhere regarding bryophytes, bark texture makes a difference. Akinsoji found that rough bark is able to collect soil, nutrients, and moisture for epiphytic growth, all features that could benefit bryophytes as well. Trees with smooth bark lacked debris and dust accumulation or moisture retention and had only one or two epiphytes.

More recently, Ezukanma *et al.* (2019a, in review) examined corticolous bryophytes in agroforests of southwestern Nigeria. Only 14 bryophytes were identified. Seven leafy liverwort species were present, but in only two families – **Lejeuneaceae** (Figure 14, Figure 51) and **Radulaceae** (Figure 24). Similarly, seven moss species were found, but they were distributed in five families – **Calymperaceae** (Figure 52-Figure 53), **Entodontaceae** (Figure 57), **Fissidentaceae** (Figure 16), **Hypnaceae** (Figure 58), and **Leucomiaceae** (Figure 59) with one species each, and **Plagiotheciaceae** (Figure 60) with two species. Cashew forests (Figure 61) had eight species, kola (Figure 62) had seven, and cocoa (Figure 63) had six. Only the liverworts *Thysananthus nigrus* (see Figure 64) and *Mastigolejeunea auriculata* (Figure 65) were found in all three forest types. *Entodontopsis nitens* (Figure 47) was the most frequent species, occurring in the kola forest and having a frequency of 27.6%. Next in frequency were *Mastigolejeunea auriculata* (23.65%) and *Entodontopsis nitens* (18.92%) in the cocoa agroforest.

Figure 65. *Mastigolejeunea auriculata*, a liverwort found in all three of these types of agroforests in Nigeria. Photo by Paul Davison, with permission.

Ezukanma *et al.* (2019b, in press) also assessed the epiphytic bryophytes in the urban agroforests of Ibadan, Nigeria. They studied the corticolous bryophytes up to 2m on the phorophytes of 30 trees in *Citrus* (Figure 66) and *Mangifera* (Figure 67) plantations. Here they identified 19 species, 13 leafy liverworts and 6 mosses. Five species

were in both forest types. The mango forests had higher bryophyte diversity and more even distribution of species. The researchers suggested that this might relate to the frequent pruning of the crowns in the mango agroforest. The moss *Calymperes palisotii* (Figure 52-Figure 53) was the most abundant species, especially in the *Citrus* plantations. Corticolous species were generally absent at the base of the phorophyte, occurring with a mean height of 1.39 m (range of 1.17-1.60) on *Mangifera* and 1.11 m (range of 0.48-1.8) on *Citrus*. The moss *Rhacopilopsis trinitensis* (Figure 68) had the highest mean height, extending up to 1.8 m. *Ceratolejeunea beninensis* (see Figure 80-Figure 81) was second in abundance, likewise in the *Citrus* forest. As in the cashew, kola, and cacao forests, *Mastigolejeunea auriculata* (Figure 65; in the *Mangifera* forests) and *Entodontopsis nitens* (in the *Citrus* forests; Figure 47) were species with high frequencies. There were 13 liverwort species, 12 in *Lejeuneaceae* (Figure 14, Figure 51) and 1 in *Jubulaceae* (Figure 69). The six moss species were in four families, with 3 in *Stereophyllaceae* (Figure 47) and 1 each in *Calymperaceae* (Figure 52-Figure 55, Figure 82), *Hypnaceae* (Figure 58), and *Leucomiaceae* (Figure 59). Twelve species occurred in both forest types.

Biedinger and Fischer (1996) compared the diversity of epiphytic tracheophytes, bryophytes, and lichens in the montane rainforests and dry forests of Rwanda and Zaïre. They identified 167 species of tracheophytes, 45 of mosses, 82 of liverworts, 78 corticolous lichens, and 57 epiphyllous lichens. While the numbers may be replaced with more recent studies, the proportions are likely to be more accurate.

In South Africa, Dilg and Frahm (1997) explored the epiphytic flora in southern Drakensberg. They found only 38 species, 12 of which were liverworts and 26 were mosses. The *Podocarpus* (Figure 70) forest provides a habitat with high humidity and fire protection; it has the highest number of bryophyte species.

Figure 70. *Podocarpus cunninghamii* trunk with epiphytic bryophytes. Photo by Rudolph89, through Creative Commons.

In addition to these studies, Frahm (1994) reported on ecology of epiphytic bryophytes on Mt. Kahuzi in Zaire. Additional references that may be useful regarding epiphytic diversity in the African tropics include Kürschner (1984 – Saudi Arabia; 1990a – moss societies on Mt. Kinabalu, North Borneo; 1995 – Eastern Congo), Pócs & Szabo (1993 – Mt Elgon, Kenya), Gill & Onyibe (1986 – phytosociology of epiphytes on oil palm in Benin City, Nigeria), Ezukanma (2012 – agroecological corticolous species in southwestern Nigeria). A number of references by Ah-Peng and coworkers will be addressed in other appropriate subchapters of this chapter.

Neotropics

The Neotropics are rich in bryophyte species. In a six-hectare upper montane *Quercus* forest (Figure 71) in Costa Rica, Holz *et al.* (2002) found 206 species, comprised of 100 moss species, 105 liverwort species, and 1 hornwort. They found three main groups of microhabitats in the forest: forest floor, including the tree base; the **phyllosphere** (space surrounding the leaf); other epiphytic habitats. Life forms differ with the humidity and light levels, as discussed in earlier subchapters. Van Reenen (1987) noted that the epiphytic cover of bryophytes in the

Andes of Colombia increases with altitude. Wolf (2003) found that the greatest liverwort diversity occurs in the transition zone where two distinct floras are in contact.

Sillett *et al.* (1995) examined the bryophyte communities of six *Ficus tuerckheimii* (Figure 72) trees in a Costa Rican lower montane wet forest. They found 109 species on the three intact forest trees and only 76 on the three isolated trees. Of these, 52 species occurred only on the intact forest trees; 18 were only on the isolated trees. Species richness, cover, and frequency of **pendants, tall turfs, tails, and fans** were significantly higher on the trees in the intact forest. Isolated trees had higher rates of evaporation from the inner crowns, more macrolichen cover, and higher levels of sunlight compared to the intact forest trees. Ordination analysis revealed a desiccation gradient ranging from the sheltered intact forest trees to the exposed isolated trees.

Richards (1954) considered the Moraballi Creek in Co-operative Republic of Guyana to have four main bryophyte **synusiae** (structural units of major ecological community characterized by relative uniformity of life form or height): high epiphytes, shade epiphytes, epiphylls, dead wood communities. Although these communities are very distinct in both structure and composition, several species, such as *Calymperes lonchophyllum* (see Figure 52-Figure 55) and *Octoblepharum albidum* (Figure 56), occur in all but the epiphyllous synusiae. The epiphyllous species are highly specialized, as will be discussed in a later subchapter. Korpelainen and Salazar Allen (1999) demonstrated genetic variation in three species of *Octoblepharum*, perhaps explaining their ability to occur in multiple community types. Richards (1954) found that Moraballi Creek synusiae differ in their growth (and life) forms of the species, creating differences in community structure. This results in differences between the very dry habitat of the high epiphyte synusiae and the more moderated shade epiphyte synusiae. The latter is characterized by freely projecting or dangling shoots and large thin-walled cells. The Moraballi Creek rainforest bryophyte synusiae differ markedly from those of temperate forests by the absence of ground-dwelling bryophyte synusiae, the presence of epiphyllous bryophytes, and the preponderance of liverworts, especially *Lejeuneaceae* (Figure 14, Figure 51).

In a semi-deciduous tropical forest of southern Guyana (Figure 73), Sipman (1997) found 100 species of lichens, with 8 out of 14 trees lacking lichens on leaves completely, whereas 3 had 34-46 taxa! Instead, the foliicolous lichens are most likely to grow close to the ground. In contrast to the 34-46 species of lichens on a single tree, they were able to find only 18 bryophyte taxa on canopy leaves.

Figure 73. Guyana waterfall and forest near Paramakatoi. Photo by Kevin Gabbert, through public domain.

Large trees support more species than small ones, with a typical logistic curve of increasing numbers of species related to both plot size and tree **DBH** (diameter at breast height) (Figure 74) (Gradstein *et al.* 1996).

Figure 74. Relationship between number of epiphyte species and plot size and tree DBH in Mexico. Species-area curves are **solid** symbols, cumulative number of species vs cumulative diameter of all trees sampled are **open** symbols. **Squares** represent humid montane cloud forest; **circles** represent humid lowland forest. Modified from Gradstein *et al.* 1996.

Gradstein *et al.* (1990) investigated the epiphytic bryophytes in the dry evergreen forest and mixed forest of the Guianas (Figure 73) using mountaineering techniques. They discovered that the lowland rainforest is not as poor in species as had been thought, once the bryophytes of the canopy are included in the exploration. More than 50% of the local species may occur in the canopy. The mixed forest has the most species. A single tree can support up to 67 species, with 50 species being an average number. The 28 trees sampled supported 154 species of bryophytes. Only a few trees are needed to find most of the species of the local area. Most of the species in this area are rather common, with 80% being widespread in the Neotropics.

In the Colombian Amazon (Figure 75), Campos *et al.* (2015) established 384 plots on 64 trees in four localities.

These exhibited 160 species of epiphytic bryophytes, with a preponderance of liverworts (116 species; 44 species of mosses). These included collections from the base to the outer canopy, including 16 trees at each locality. The highest representation of families (Figure 76) included the leafy liverworts **Lejeuneaceae** (Figure 14, Figure 51) (55%) and **Lepidoziaceae** (Figure 2) (8%), and the mosses **Calymperaceae** (Figure 52-Figure 55) (10%), **Octoblepharaceae** (Figure 56) (6%), and **Sematophyllaceae** (Figure 10) (5%). The most common genera were members of **Lejeuneaceae** – *Cheilolejeunea* (Figure 77) (11%), *Pycnolejeunea* (Figure 78) (8%), *Archilejeunea* (Figure 79) (8%), and *Ceratolejeunea* (Figure 80-Figure 81) (8%) – and the moss *Syrrhopodon* (**Calymperaceae**; Figure 82) (7%).

Wolf *et al.* (2003) found that the richness per surface area decreases significantly with branch diameter (Figure

83) in the upper montane rainforest of the Cordillera in Colombia. Diversity is highest when the standing crop is at intermediate levels and is negatively correlated with the area of the largest species. On the other hand, **evenness** (similarity of frequencies of different units making up population or sample) is less on older branches. The inner canopy species have the smallest niche widths. When only branch segments are sampled, the vegetation is highly variable, whereas that on whole trees is more uniform. The species follow a species area curve that approaches a flat line after sampling only four trees. The liverworts have the greatest richness in the contact transition zone between two distinct floras. Wolf and coworkers suggested that the arrival time of aggressive competitors such as those that form large patches may be "crucial." Many accidental species maintain a high richness and suggest that dispersal of propagules is important in creating richness.

Figure 83. Branch or trunk diameter in the canopy of the upper montane rainforest and Simpson's index of diversity. **Open circles** indicate a group of seven samples that do not adhere to increasing dominance with diameter. Modified from Wolf *et al.* 2003.

In flooded (Figure 84) and "tierra firme" (upland habitat where elevation does not allow water, even during high water season, to inundate forest; Figure 85) forests of the Colombian Amazon, Benavides *et al.* (2004) found 109 bryophyte species on 14 0.2-ha plots. Mosses and liverworts had opposite responses to moisture, with many more liverworts than moss species in the **tierra firme**, but total richness (mosses + liverworts) differed little between the flooded and non-flooded habitats (Figure 86). The use of the habitat differed between the two forest types, with differences in humidity being the major factor in determining bryophyte communities. Nevertheless, soil was a little-used substrate for both groups in both habitats (Figure 86). Epiphyll species assemblages (*e.g.* Figure 87) were not strongly affected by floodplain vs tierra firme. Life forms differed between the two habitat types, with more **fan** and **mat** bryophyte species in the floodplains, and more epiphytic liverworts (hence, almost no **wefts**) in the tierra firme forest (Figure 88).

Oliveira and ter Steege (2013) determined that epiphytic bryophytes in the terra firme forests of the Amazon Basin exhibited a typical species abundance distribution (Figure 89).

Kelly *et al.* (2004) described the epiphytic communities of a montane rainforest in the Venezuelan Andes (Figure 90). They surveyed 20 trees, all in a site of only 1.5 ha at 2600 m asl. The non-tracheophyte epiphytes were recorded in 95 sample plots and yielded 22 moss and 66 liverwort species, as well as 46 species of macrolichens. Few of the bryophytes in these communities are **endemic** (native distribution restricted to a certain country or area), although they are mostly restricted to the Neotropics. The dominant bryophyte on the lower trunks is *Syrrhopodon gaudichaudii* (Figure 91), along with the fern *Elaphoglossum hoffmannii* (Figure 92). The intermediate levels are dominated by the leafy liverwort *Omphalanthus filiformis* (Lejeuneaceae; Figure 93) and the orchid *Maxillaria miniata* (see Figure 94). The upper crowns are dominated by the lichens *Usnea* (Figure 95) and *Parmotrema* (Figure 96). Diversity of non-tracheophytes is

greatest in the upper crowns; tracheophyte diversity is greatest at the intermediate levels. As noted in a number of other studies cited herein, similarity is low among plots of the same community, but between-tree and between-stand similarities are relatively high.

By comparison, Costa (1999) studied the epiphytic bryophyte diversity of both primary and secondary lowland rainforests in southeastern Brazil, a subtropical region. Unlike many earlier studies, hers included the forest canopy. She found 75 bryophyte species, 39 mosses and 36 liverworts. The highest species richness is exhibited by the mature secondary hillside rainforest, with 43 species. The highly degraded hillside rainforest has the lowest diversity, with only 6 species, and the hillside secondary rainforest with only 5 species. As in so many other studies, the leafy liverwort family **Lejeuneaceae** (Figure 14, Figure 51) is the "most important" with 23 species (30 %) and the moss family **Sematophyllaceae** (Figure 10) with 7 species (10%). Demonstrating the importance of the canopy species in understanding species diversity, Costa found that 45% of the bryophyte species occurred exclusively in the canopy. The most common life form is the **mat**, describing 45% of the species. Forest destruction is more detrimental to shade species than to sun species. Even after 20-45 years, many bryophytes had not returned, but after 80 years the communities were similar to those of primary forest.

In 2017, Gradstein and Benitez added 15 liverwort species to the known flora of Ecuador. They furthermore described two species new to science.

One might not think of looking in a savannah for epiphytes because of the high exposure to sunlight and low moisture. Nevertheless, bryophytic epiphytes do grow there in an Amazonian savanna in Brazil (Figure 97). Gottsberger and Morawetz (1993) found that lichens dominate on the young trees, typically becoming less abundant as the tree ages. Bryophytes are most abundant on older trees and seem to suppress the lichen growth.

Additional references that may be useful regarding tropical diversity in the Neotropical epiphytes include Chung (1996 – Panama), Wolf (1993 – Colombia); Jovet-Ast (1949 – groupings of epiphytic mosses in the French West Indies); Frahm (1987a, b – composition of moss vegetation in Peruvian rainforests); Frahm (1987a, c – composition of moss vegetation in Peruvian rainforests).

Summary

Full understanding of the bryogeography of epiphytes is still hampered by our need for comprehensive systematic studies that identify synonyms and demonstrated genetic relatedness.

In Australian tropical rainforests, epiphyte succession is usually rapid, with seven genera occurring in all the major rainforest types (including non-tropical ones): **Macromitrium**, **Racopilum**, **Hymenodon**, **Pyrrohobryum**, **Rhizogonium**, **Sematophyllum**, and **Thuidium** (**Pelekium**?).

In general, the mosses in **Pterobryaceae** and **Neckeraceae** occur as epiphytes throughout the tropics, along with **Sematophyllum** and **Taxithelium**. The liverworts **Frullania** and **Lejeuneaceae** dominate the branches. The tribe **Ptychantheae** is predominant among Asian **Lejeuneaceae**, whereas the tribe **Brachiolejeuneae** predominates in the Neotropics. In Indonesia, the characteristic low-elevation tree-base moss families are **Calymperaceae**, **Fissidentaceae**, **Hypopterygiaceae**, **Leucobryaceae**, **Meteoriaceae**, **Neckeraceae**, **Pterobryaceae**, and **Thuidiaceae**, and the leafy liverwort families **Lejeuneaceae**, **Lophocoleaceae**, **Porellaceae**, and **Radulaceae**. By

contrast the higher elevations have mostly leafy liverworts in **Herbertaceae**, **Lepidoziaceae**, **Mastigophoraceae**, **Scapaniaceae**, **Schistochilaceae**, and **Trichocoleaceae**. In Africa, **Calymperes** and **Octoblepharum** species occur all over the Niger Delta, whereas in agroforests Ezukanma *et al.* (2019 in review) found only **Lejeuneaceae** and **Radulaceae** among the liverworts, but found five families of mosses. African studies are limited and promise many more species on future expeditions. Bryophyte diversity in the Neotropics is particularly rich and increases with altitude. Intact forests typically have **pendants, tall turfs, tails, and fans**. **Calymperes lonchophyllum** and **Octoblepharum albidum** are common in all communities except as epiphylls. Larger trees support more species than do small ones by providing more niches. For the Neotropics in general, the **Lejeuneaceae** are again the most species-rich family; the most highly represented moss families are **Calymperaceae**, **Octoblepharaceae**, and **Sematophyllaceae**. Fewer endemics occur here compared to those of the flowering plants, and as more systematic studies occur, the number is diminishing.

Acknowledgments

My appreciation goes to Noris Salazar Allen for her efforts to make this chapter reliable and up-to-date. Her helpful discussions kept me going on this part of the world I know so little about. Andi Cairns helped me to resolve some of the apparent conflicts in the Australian literature and bring information up to date.

CHAPTER 8-6

TROPICS: EPIPHYLLS

JANICE M. GLIME AND TAMÁS PÓCS

Epiphyllous Communities

A unique community occurs in the tropics, especially in the wet rainforests, the **epiphyllous** community (Figure 1), *i.e.* those bryophytes, lichens, algae, fungi, and bacteria that live on the leaves of higher plants. Among these, bryophytes contribute most of the biomass (Bentley 1987). A discussion of tropical epiphytes would not be complete without considering these bryophytes that spend their lives on leaves.

Some of the earliest bryophyte studies in the tropics were on epiphyllous species, typically on trees and shrubs. These included studies by Goebel (1888, 1889), Massart (1898), Busse (1905), Pessin (1922), Richards (1932), Allorge *et al.* (1938), and Allorge & Allorge (1939). Later, Winkler (1967, 1970) reported on epiphyllous communities of both upland and lowland rainforests of tropical Americas.

Foliicolous bryophytes occur predominantly on the upper surface of leaves (**epiphyllous**), but some do occur on the lower surface (**hypophyllous**) (Santesson 1952). This leaf habitat is termed the **phyllosphere** (Ruinen 1961). These communities are mostly restricted to the rainforests of the humid tropics and subtropics, but some have been

reported, albeit not well-developed, in wet temperate regions as well: Japan (Schiffner 1929), the Appalachian Mountains, USA (Schuster 1959; Ellis 1971), British Columbia (Vitt *et al.* 1973), the Caucasus (Pócs 1982b; Vězda 1983), Macaronesia (Sjögren 1975, 1978) and the Pyrenees (Vězda & Vivant 1972).

In equatorial regions, these foliicolous communities occur from sea level to about 3000 m asl, where they become limited by lack of forest substrate. Pócs (1976a, 1982a) concluded that the upper limit is determined by the frequency of night frosts and the degree of oceanity. Optimal conditions, on the other hand, occur in the lower montane rainforest belt. In East Africa this occurs at ~1500-2000 m.

Luo (1990) noted the need for very moist air in the habitats of epiphyllous liverworts. This defines the primary distribution of epiphyllous liverworts in the tropical or subtropical regions of IndoMalay, Central and South America, central Africa, and the Asian-Pacific regions of South Korea and southern Japan south to Australia.

Among the early studies, Jaag (1943) investigated epiphytes and epiphylls on ferns (Figure 2-Figure 3), examining these as they related to the leaf renewal rate and leaf life.

Figure 2. *Blechnum loxense* tree fern at treeline in the Ecuadorian Andes at 3500 m asl, with Jan Peter Frahm. Members of this genus often have epiphylls. Photo courtesy of Robbert Gradstein.

usually occur only near streams and in swampy areas. Exceptionally, they can occur also in dry woodlands if they are affected by mist/cloud formation regularly (Pócs.1976b).

The long-lived, somewhat leathery leaves of tropical forest trees make it predominantly possible for bryophytes to become established there, particularly in the more humid sites. But they can also occur on bamboo (Doei 1990) and palm leaves as well (Schuster & Anderson 1955), even on fern and other herbaceous plant leaves and exceptionally on succulents.

In western Nigeria, for example, as many as 1200 shoots/colonies can occur on one 58x35 mm leaf of *Citrus sinensis* (Figure 4) (Olarinmoye 1975c).

Figure 4. *Citrus sinensis*, a species that can house as many as 1200 epiphytic shoots on a 6 x 3 cm leaf section. Photo by Antandrus, through Creative Commons.

Figure 3. *Lejeunea cf. epiphylla* on *Blechnum watsii*. Photo by Tom Thekathyl, with permission.

Richards (1952) has written one of the definitive treatises on tropical plant ecology. In it, he describes the epiphyllous community as common in tropical, montane, and subtropical rainforests, particularly in wet forests. The epiphylls occur mostly on the upper surfaces of evergreen leaves. In tropical forests that are seasonally dry, they

Filmy fern leaves usually have a special epiphyllous community formed by tiny *Cololejeunea* (Figure 5-Figure 6) and hookeroid moss species (Pócs 1978).

Figure 5. *Cololejeunea minutissima*, in a genus that is among the epiphylls in the world. Photo by Michael Lüth, with permission.

Figure 6. *Cololejeunea magnilobula*, in a genus that is among the epiphylls in the world. Photo by Yang Jia-dong, through Creative Commons.

In the 1990's Pócs (1996, 1997) reported 1,000 epiphyllous species of liverworts worldwide. Although this includes epiphyllous species that are not exclusively tropical, most are in the tropics (Figure 7). Among these, Asia had the highest reported number of any continent at 504 species, with 224 in the Malesian archipelago alone. These worldwide epiphylls are divided among the **Lejeuneaceae** genera *Cololejeunea* (389 species; Figure 5-Figure 6), *Ceratolejeunea* (114 spp.; Figure 8), *Drepanolejeunea* (98 spp.; Figure 9), *Colura* (76 spp.; Figure 10), *Diplasiolejeunea* (68 spp.; Figure 11), *Prionolejeunea* (59 spp.; Figure 12), *Aphanolejeunea* (54 spp.; Figure 13; this genus is now included in *Cololejeunea*), *Leptolejeunea* (48 spp.; Figure 14), and *Microlejeunea* (34 spp.; Figure 15), the **Radulaceae** genus *Radula* (13 spp.; Figure 16), and another 12 genera with fewer than 10 species each. This distribution of genera and numbers of species is likely to have changed since that time as synonyms have been identified and genera have been split or unified and new species have been described. For example, TROPICOS lists only 29 currently accepted species names in *Diplasiolejeunea*, listed above as having 68 in the tropics, but the World Checklist of liverworts and Hornworts (Söderström *et al.* 2016) lists more than 90! These epiphyllous genera are susceptible to losses whenever the forest is disturbed.

In 1997 Lücking estimated the number of epiphyllous bryophyte species to be only about 535 worldwide. He found 83 species of epiphyllous bryophytes in a Costa Rican tropical rainforest. A single leaf of the palm *Welfia georgii* (Figure 17; see also Figure 18) had 24 species. Nearly all the epiphylls were liverworts, with 78 species in the family *Lejeuneaceae* (Figure 6-Figure 15). The others were *Radula* (*Radulaceae*; Figure 16), *Metzgeria* (*Metzgeriaceae*; Figure 19, Figure 127), and *Frullania* (*Frullaniaceae*; Figure 20). *Crossomitrium patrisiae* (Figure 21) was the only epiphyllous moss species. Only 17% of the bryophytes are widely distributed on more than one continent in the tropics; the others in this study are Neotropical, with 11% known only from Costa Rica.

Epiphylls can include rare and endangered species, not to mention many species yet to be discovered. For example, Reiner-Drehwald and Drehwald (2002) discovered the extremely rare and critically endangered epiphyllous *Lejeunea drehwaldii* (Figure 22) in northern Peru. It exhibits some of the more common adaptations of epiphyllous species: leaf lobes that are bordered by hyaline cells, strongly inflated lobules, and cylindrical perianths, characters that are common to its family, *Lejeuneaceae* (Figure 6-Figure 15).

Figure 22. *Lejeunea drehwaldii* on leaf. Photo by Elena Reiner-Drehwald and Uwe Drehwald, with permission.

Identification problems have made ecological studies difficult. On the one hand, many species have multiple names in various places throughout the tropics. Others have never been described and some important epiphyllous genera do not yet have an up-to-date revision. And some species that have been described represent multiple cryptic species that cannot be distinguished morphologically, as demonstrated in the epiphyllous genus *Diplasiolejeunea* (*Lejeuneaceae*; Figure 11, Figure 23) (Dong *et al.* 2012).

Figure 23. *Diplasiolejeunea plicatiloba*, in a genus with cryptic species. Photo by David Tng, <www.davidtng.com>, with permission.

Because of the need for a stable substrate that lasts several years and maintains sufficient humidity, these associations are almost entirely restricted to tropical and subtropical regions with few notable exceptions, such as those living on the leaves of *Thuja* (Figure 24) species (Vitt *et al.* 1973). One of the northernmost records of non-*Thuja* epiphylls in North America is in Louisiana, where

leafy liverworts have been found on *Rhododendron maximum* (Figure 25), *Leucothoe editorum* (Figure 26) (both in *Ericaceae*) (Schuster 1959), and *Magnolia grandiflora* (Figure 27) (Guerke 1973). The moss *Taxithelium planum* (Figure 28) occurs on Sabal palmetto (*Serenoa repens*; Figure 29) (Schuster & Anderson 1955). On *Buxus colchicus* leaves at the foot of the Caucasus Mountains five liverwort species occur that are growing otherwise on different substrates (Pócs 1982b). All these host species have leathery, persistent leaves. Even in the boreal coniferous zone a few epiphyllous lichens occur on needle-like gymnosperm leaves.

The success of many epiphylls may reflect the fact that the tiny leafy liverworts have leaves in two rows that look as if they were ironed to the substrate (Figure 22). Such a flattened conformation provides the least exposure to the drying atmosphere (Figure 30).

Figure 30. *Lejeuneaceae* epiphylls showing their flattened habit. Photo by Janice Glime.

Some epiphylls are **facultative** (capable of functioning under various environmental conditions). Geissler (1997) considered five populations (4 species) of the leafy liverwort *Marchesinia* subgenus *Marchesiniopsis* (Figure 31) to be "accidentally **foliicolous**" (accidentally growing on leaves), *i.e.*, facultative. She considered their rainforest habitat to correspond with optimal conditions in equatorial primary forest in Latin America and Africa.

Figure 31. *Marchesinia* subg. *Marchesiniopsis*; *M. brachiata* from St. Helena, a species growing here on bark, but that can be an accidental epiphyll. Photo By M. Wigginton, courtesy of Robbert Gradstein.

Alvarenga and Pôrto (2007) found that species richness and abundance of epiphytic bryophytes increased with altitude in lowland and submontane areas of Pernambuco, Brazil. However, fragmentation can negate that effect. Fragment size and isolation are important factors, with isolation having a negative effect for epiphylls in particular. Furthermore, species with smaller niches were more affected than those with large niches.

Sipman (1997) studied the lichens and bryophytes in the crowns of semi-deciduous trees in southern Guyana.

Whereas the lichens grew preferentially close to the ground, the bryophytes could be found in the crowns. He found 18 taxa of bryophytes associated with canopy leaves. These seemed to follow a distribution pattern similar to that of the lichens.

Other studies that describe this fascinating group of communities include those of Kiew (1982) on leaf color, epiphyll cover, and damage on *Iguanura wallichiana* (Figure 32) in Malaya. Lücking (1995a, b) described the diversity, ecology, and interactions of epiphylls in a tropical rainforest in Costa Rica; Lücking and Lücking (1998) examined adaptations and convergences of organisms living in the **phyllosphere** (space surrounding the leaf, where epiphylls are found). Baudoin (1985) analyzed the distribution patterns of epiphyllous bryophytes on the Soufrière de Guadeloupe. Pócs (1978) reported on the distribution of epiphyllous communities in East Africa, and Reynolds (1972) reported on stratification of tropical epiphylls. Farkas and Pócs (1997) reported on systematics, distribution, ecology, and uses. Winkler (1967, 1970) reported on the epiphyllous bryophytes in cloud forests of El Salvador and Colombia. Olarinmoye (1977) examined the relationship of the epiphylls to the host tree. Gradstein and Lücking (1997) summarized a symposium on epiphyllous bryophytes. The symposium emphasized floristics and ecology, including diversity analyses and the role of these bryophytes in the tropical rainforest.

Figure 32. *Iguanura wallichiana* var. *major*, a species that appears to be harmed by epiphylls. Photo by David J. Stang, through Creative Commons.

Fossil Records

The oldest evidence of bryophytes is a fossil record from the Middle Carboniferous period, 330 million years ago. But fossil records of bryophytic epiphylls have been lacking (Barclay *et al.* 2013). Barclay *et al.* (2013) described an epiphyllous moss, *Bryioides utahensis*, from a single fossil leaf specimen from the middle Cretaceous, at least 95 million years ago. The moss presence was only 450 μm long, represented by a spore and protonema. This fossil suggests that central North America had a tropical maritime climate at that time.

Biomass Contributions

Pócs (unpublished) has found the foliicolous biomass in tropical montane rainforest (mossy forest) with well-

developed foliicolous communities to be 0.139 g 100 cm^{-2} of host leaf area, or 0.216 g g^{-1} of host leaf dry mass. This figure can be extrapolated to 69.5 kg foliicolous biomass ha^{-1} (assuming that leaves occupied by foliicolous communities cover at least half the ground area at these localities). The interceptive capacity of this foliicolous biomass is 2.357 g 100 cm^{-2} host leaf area, or 1175 L ha^{-1} according to experiments by Pócs (unpublished). These figures include the entire community of algae, bacteria, lichens, fungi, and bryophytes. They are valid only where conditions are optimal, such as condensation zones (van Reenen & Gradstein 1983). Under less favorable conditions, foliicolous communities are restricted to certain moist habits such as streamside and near waterfalls, to certain forest layers such as leaves of the lower shrubs, or are lacking entirely. By comparison, Carroll (1979) found the biomass of foliicolous communities in oceanic temperate regions to be $\sim 50 \text{ kg ha}^{-1}$, of which 30 kg is composed of fungi and 20 kg of algal cells.

Microclimate

Epiphyllous species require shade and high humidity, thus confining them mostly to the understory and lower parts of the canopy (Gradstein 1992). On the other hand, in lowland cloud forests they can also occur in higher parts of the canopy (Gradstein *et al.* 2010). An average of 3-13 species of bryophytes can occur on a single leaf.

Light and available moisture appear to play the most important roles in the distribution of epiphyllous bryophytes within the tropical evergreen forests. In Costa Rica, Reynolds (1972) found that bryophytic epiphylls existed up to about 10 m under a 24-m canopy, where they disappeared, but lichens persisted nearly to the top of the canopy. Reynolds attributed this limited bryophyte distribution to availability of continuous moisture.

In the subtropical evergreen forests of southeast China (Figure 33) the light intensity in the open can be 632 times as great as that in some forested areas supporting epiphyllous liverworts (Wu *et al.* 1987). For these liverworts to thrive through the winter, they require about two hours of direct light and ten hours of diffuse light. In general, it seems that shade and moisture promote growth while high light and drought hinder it. Heavy rains hinder colonization (Busse 1905), most likely contributing to the greater biomass found on lower branches than on upper ones.

Figure 33. China – Emei Shan lush misty forest in the Sichuan Basin, China. Photo by McKay Savage, through Creative Commons.

Wu *et al.* (1987) found that temperature and humidity, in addition to light, are the main factors influencing communities of epiphyllous liverworts in subtropical evergreen forests of southeast China. They observed that these liverworts did not occur in very shady or dark forests. They studied the light intensities in a subtropical evergreen forest beside streams where the dominant epiphyllous liverworts were *Cololejeunea ocelloides* (Figure 34), *Leptolejeunea elliptica* (Figure 14) (both *Lejeuneaceae*), *Radula acuminata* (Figure 35; *Radulaceae*), and *Frullania moniliata* (Figure 36; *Frullaniaceae*). They sampled at 0.5 m intervals in the range of 0.5-2 m. There was no discernible difference in species composition in the heights sampled, but 10 m from the streams the epiphyllous liverworts were rare.

Jiang *et al.* (2014) noted that epiphyllous liverworts usually grow in areas that are constantly moist with evergreen forest trees in the tropical and subtropical regions. They also considered them to be species that are very sensitive to both pollution and climate change. They also found that humidity, temperature, and light are important limiting factors for these epiphylls. The researchers used the Area Under the receiver operating characteristic Curve (AUC) and True Skill Statistic (TSS) and the Wilcoxon paired test in comparing model performances. These tests indicated that climatic and remotely sensed vegetation variables were the best predictors of bryophyte composition on a macrohabitat scale. The researchers concluded that epiphyllous liverworts could be useful indicators of forest degradation at broad spatial scales.

Reyes (1981) has shown that epiphylls are very good indicators of air pollution. In Cuba, in a large area around the Nicaro nickel metallurgical works, epiphylls do not occur even among favorable macro-climatic conditions. Pócs (1989) has found that epiphylls disappear when the forest canopy is partly loosened by invasive tree species, due to the decreasing air moisture.

Marino and Salazar Allen (1991) compared the tropical epiphyllous communities (all liverworts) on two shrub species on Barro Colorado Island, Panama. They used five randomly selected shrubs in each site (dry light, dry shade, wet light, wet shade) for each of *Hybanthus prunifolius* (Figure 37) and *Psychotria horizontalis* (Figure 38). To determine cover, they used leaf transects (midrib and 2 parallel to midrib) to determine the epiphyll cover. The small gaps with greater light clearly had more cover than did the shaded sites. Interestingly, the dry ridges had significantly more cover than did the wet creek area. There was little difference in epiphytic communities (15 species overall) between the two shrub species in the same environmental conditions. The dry site epiphylls were dominated by *Cololejeunea sicifolia* (see Figure 120); in the wet sites, *Leptolejeunea elliptica* (Figure 14) dominated. They suggested that *C. sicifolia* was rare in the wet site due to competition from *L. elliptica*. On the other hand, *L. elliptica* was limited by insufficient moisture on the dry sites.

Figure 38. *Psychotria horizontalis*, a species that supports epiphyllous bryophytes on Barro Colorado Island, Panama. Photo by Daniel H. Janzen, through Creative Commons.

Freiberg (1999) looked at microclimate as it affects the **Cyanobacteria** (Figure 39) on leaves in a premontane rainforest of Costa Rica. He found seven species of **Cyanobacteria**, with the two most frequent being *Scytonema javanicum* and *Scytonema hofmannii* (Figure 39). He found that air humidity is more important than light in determining their relative abundance, a factor that also determined abundance of the epiphyllous bryophytes. On moist sites, these two **Cyanobacteria** species and the bryophytes appeared nearly simultaneously on leaves that were 6-9 months old. However, on drier sites, the **Cyanobacteria** did not appear until 6-9 months after the bryophytes became established. When *Spathacanthus hofmannii* (Figure 40) leaves were 2-5 years old, the average leaf cover of bryophytes was 20-30%, that of *Scytonema javanicum* 2-3%, and that of *Scytonema hofmannii* 0.1-0.2%. When bryophytes were present, the *Scytonema hofmannii* was more frequent, whereas *Scytonema javanicum* did not seem to be influenced by bryophyte presence.

Figure 39. *Scytonema hofmannii* (**Cyanobacteria**); *Scytonema javanicum* and *S. hofmannii* grow as epiphylls on Barro Colorado Island, Panama. Photo from Utex, through Creative Commons.

Figure 40. *Spathacanthus hofmannii*, a host for epiphyllous bryophytes and **Cyanobacteria**. Photo by Armando Astrados, with online permission.

Kraichak (2014) found that the **beta diversity** (ratio between regional and local species diversity) of epiphyllous bryophyte communities on Moorea, French Polynesia (Figure 129), fluctuated with the microclimate. The beta diversity among these epiphylls on different host types tended to increase as the daily range of vapor pressure deficit increased at that site. Kraichak suggested that the high fluctuations in these microclimatic conditions might augment the habitat quality differences among the host types, causing greater dissimilarities among these epiphyllous communities. However, Kraichak detected no change in niche breadth.

In western Nigeria, Olarinmoye (1974) followed the growth of four epiphyllous liverworts [*Radula flaccida* (Figure 41), *Caudalejeunea hanningtonii* (see Figure 42), *Leptolejeunea astroidea* (see Figure 14), and *Cololejeunea obtusifolia* (Figure 43)] for ~18 months. Growth of larger species always exhibited faster growth. The wet and dry seasons caused a growth periodicity, but there was no dormancy. However, growth was reduced considerably during the dry season.

Figure 43. *Cololejeunea obtusifolia*, an epiphyllous species with no dormancy, but with seasonal growth in Nigeria. Photo by Tamás Pócs, with permission.

Sonnleitner *et al.* (2009; Sonnleitner 2008) explored microclimatic effects by sampling epiphyllous bryophytes on two leaves per tree of 57 individual trees in a tropical lowland rainforest in Costa Rica. They sampled from three adjacent sites that had different microclimates and found that pronounced daily humidity fluctuations placed considerable restraints on the epiphyll distribution and colonization. Phorophyte species, air temperature, and light availability were only weakly correlated with epiphyll cover and diversity. Nevertheless, all of these factors influenced the species composition of the epiphyll communities. The ability of the forest to buffer the microclimate seems to be important to the success of these epiphylls. Lücking (1995a) provides additional information on microhabitat preferences of epiphylls in a tropical rainforest in Costa Rica.

Monoculture affects epiphyll establishment and success differently from the natural forests. Arnold and Fonseca (2011) examined the effects of monoculture that replaced the *Araucaria* forest (Figure 44) in southern Brazil. The natural *Araucaria* forest (Figure 44) has a larger percentage of leaves with epiphylls than does the *Eucalyptus* plantation (Figure 45), a fact the researchers attribute to the shadier and moister microclimate of the natural forest. Nevertheless, monocultures help to maintain epiphylls in areas that might otherwise be devoid of forest.

Figure 44. *Araucaria* forest, an epiphyll host that is being replaced by monoculture plantations such as *Eucalyptus* in southern Brazil. Photo by Jason Hollinger, through Creative Commons.

Figure 45. *Eucalyptus* plantation in Nilgiris, India. Such plantations have fewer epiphyll species than native *Araucaria* forest in southern Brazil. Photo by Shyamal, through Creative Commons.

Monge-Nájera (1989) found that both absolute and relative cover by epiphylls are higher in forest clearings than in the understory at Monte Verde, Costa Rica. They suggested this was due to the high atmospheric humidity in the area and the presence of **heliophilic** (sun-loving) bryophyte species.

Colonization

Kursar *et al.* (1988) determined rates of leaf colonization by epiphylls in Panama. Coley and Kursar (1996) found that epiphylls have both positive and negative effects on the host leaves. Conversely, the host leaf can affect the rate of epiphyll colonization.

For epiphylls, establishment on the host leaves is the most difficult step, requiring adherence of a spore or gemma and protonema through rainstorms that would attempt to wash them off. Young leaves are usually first colonized by lichens, then by liverworts, and perhaps mosses (Richardson 1981). Mosses seldom become established on the leaves, but more often grow onto them from neighboring twigs. Colonization can be rapid and dynamic, as demonstrated for a leaf from El Salvador that was colonized by 7 species in the period from May to December (Figure 46) (Winkler 1967). Winkler found that young leaves were colonized by liverworts within three months in the montane rainforest of San Salvador. Nevertheless, these could die during subsequent dry weather.

Figure 46. Progression of epiphyllous species on a leaf in El Salvador from May to December. **A.** May 1962. **B.** August 1962, with 3 colonies. **C.** October 1962, with 2 additional colonies and 2 lost. **D.** December 1962, with 2 new colonies and 2 colonies lost. From Winkler 1967.

Succession

There is a succession in leaf colonization. There are pioneer species (like members of the genus *Leptolejeunea* – Figure 14), which can appear even on short-lived (e.g. banana – Figure 47) leaves, and those which occur only in a well-established epiphyllous community on perennial leaves.

Richards (1932) made the first observations of succession in foliicolous communities, using leaf pairs of different ages in the Guyana rainforest. Harrington (1967) in West Africa and Winkler (1967) in Central America made careful studies on colonization and growth of foliicolous communities by observations on host leaves in sample plots for periods of over 200 days. All authors concluded that foliicolous growth in bryophytes and lichens does not exceed 3-7 mm annually, hence does not differ

significantly from the growth rate of non-foliicolous species (cf. Hawksworth & Chater 1979). According to Winkler (1967) and Olarinmoye (1975c), colonization and growth rate of foliicolous liverworts coincide with climatic periods and are greatest during rainy seasons when atmospheric humidity is high. The host leaves are colonized first by **eufoliicolous** (true leaf-dwelling) taxa possessing an adhesive apparatus (*Aphanolejeunea* – Figure 13, *Cololejeunea* – Figure 5-Figure 6, *Drepanolejeunea* – Figure 9, *Leptolejeunea* – Figure 14, and others) and by hemiepiphyllous taxa. Many of the early colonizers are soon overgrown by others that lack special devices to adhere to the leaf surface (Pócs 1978).

Daniels (1998) conducted an extensive study on establishment and succession of epiphyllous bryophytes on the understory palm *Geonoma seleri* (see Figure 48) in Costa Rica. Using 914 pinnae from 100 individual palms, he inferred chronology based on the position of the frond on the palm. He also selected 50 pinnae and examined them repeatedly from frond emergence to abscission. Daniels concluded that there is no succession in the classical sense. Rather, the composition of species is highly variable. However, as expected, the cover values of individual species does change significantly over time. But no stable climax community emerges. Furthermore, the bryophyte assemblage development is not influenced by the season of emergence of the frond. It is somewhat

surprising that canopy closure and height of palm tree have no significant effect on total cover of epiphyllous bryophytes.

Kiew (1986) studied epiphyll colonization in a Malayan rainforest. Leaves on the shrub *Thottea dependens* (see Figure 49) live up to 70 months and become completely covered with epiphylls. The longest-living leaves were those of the palm *Iguanura wallichiana* (Figure 50). These leaves had no epiphyll colonists in the first 6 months. Bryophytes didn't colonize until approximately 2 years, but they then covered half the leaf surface in another 6 months.

Figure 50. *Iguanura wallichiana* var. *major*, a species that is not colonized by epiphylls in the first 6 months, but bryophytes can cover half the leaf surface by 30 months. Photo by David J. Stang, through Creative Commons.

Olarinmoye (1975c) reports no orderly successional colonization or phenological rhythm in order of species establishment in his western Nigerian study. Rather, colonization depends on nearness of propagules, number produced, and their ability to become established. Subsequent succession, however, does at some locations seem dependent on competition and seasonal changes. Lichens are common cohabitants with the bryophytes, and liverworts seem always able to overgrow the crustose lichens, but the foliose lichens are able to overgrow even the large, fast-growing *Radula flaccida* (Figure 41). On the other hand, the large *Caudalejeunea hanningtonii* (see Figure 42) seems to be able to overgrow all types of lichens and algae, at least at Alkenne and Gambari, Nigeria. But even some of the algae can overgrow the small, slow-growing liverworts. The large, tufted or shelf-forming *Trentepohlia* (Figure 51-Figure 52) is one such alga, whereas the *Cyanobacteria* (Figure 39) tend to live in association with the liverworts without overtaking them. Despite all this competition, the ultimate winner seems to be *Radula flaccida*, which eventually occupies the entire leaf surface. That is, until the dry season in Erin-Odo, when only *Leptolejeunea astroidea* (see Figure 14) remains, mixed with scattered shoots of *Cololejeunea nigerica*. And at Ojo Rocks, where *Caudalejeunea hanningtonii* predominates in the wet season, it likewise disappears in the dry season, being replaced by thick felts of *Leptolejeunea astroidea*. It appears quite clear that the large *Radula flaccida* and *Caudalejeunea hanningtonii* are unable to prosper during the dry season.

Richards (1996) stated that epiphyllous species do not also occur on bark, but in fact, there are a number of examples where both substrates are occupied. He cites only one example for this, the genus *Floribundaria* (Figure 55), that establishes on twigs, then expands onto the leaves. He suggests that such species are not able to establish directly on a leaf.

Coley and Kursar (1996) examined the causes and consequences of epiphyll colonization in tropical forests. Coley *et al.* (1993) found that while lichen cover changed

little among their sites in Panama, liverwort cover increased with rainfall. In their experimental plots, liverwort cover increased from 1.7% in the controls to 20.5% in irrigated plots, whereas lichen cover decreased in response to the same watering regime. Surprisingly, liverworts at one site grew more quickly in high light compared to shade, and Coley and coworkers suggested that the liverworts were competitively superior to the lichens, resulting in the negative association between them. Contrasting sharply with the conclusion that bryophytic epiphytes require long-lived leaves, the short-lived leaves of *Alseis* (Figure 53) had 27% cover whereas the long-lived ones of *Ouratea* (Figure 54) had only 2% one year after removal of epiphytes. Within one year, the liverworts had colonized 45% of the leaves that had a lifetime of only one year, whereas they had colonized only 5% of the leaves of those with longer lives. This is, however, consistent with the known presence of chemical defenses of long-lived leaves against herbivores and pathogens. These defenses could affect the liverworts directly or by preventing growth of *Cyanobacteria* (Figure 39) or fungi that might benefit them.

Host Preference

There seems to be little preference by the foliicolous communities for a particular host species. Rather, their occurrence seems to depend primarily on microclimatic conditions and availability of suitable leaf surfaces (Santesson 1952; Tavares 1953; Richards 1984b).

Nevertheless, some species do seem to have preferences. Members of the **Hookeriaceae** (e.g. *Distichophyllidium africanum*, *Distichophyllum mniifolium* – see Figure 56), and certain liverworts (e.g. *Cololejeunea mocambiquensis* – Figure 57, *C. tanneri*, *Lejeunea gradsteiniana* – Figure 58, *L. lyratiflora*) occur primarily on filmy fern leaves, whereas others (*Diplasiolejeunea cavifolia* – Figure 11, *Cheilolejeunea xanthocarpa* – Figure 59) prefer hard, smooth, leathery leaf surfaces (Pócs 1978, 1985). Overall, the epiphylls have a relationship with size, age, and texture of phorophyte leaves.

Winkler (1967) considered leaf hair density and quality of phorophyte leaves to be important. He pointed out that a stellate hair cover may inhibit foliicolous growth. Foliicolous species also seem to avoid waxy, water-repelling leaf surfaces (Richards 1932), but may be abundant on other surfaces, e.g. on leaves of planted citrus trees (Figure 4) in rainforest clearings. Pócs (pers. comm. May 2019) suggested that it was the sugary, sticky exudates of the citrus leaves that discouraged the epiphylls. A long life for the host leaf is also important, although some leaves with only a 3-4-month life span are occasionally colonized. In Cuba, Pócs observed a large vegetation of *Leptolejeunea* sp. (Figure 14) on smooth banana leaves (Figure 47). In habitats that were relatively dry, but affected by mist, foliicolous species occurred only on evergreen leaves such as the succulent *Agave* (Figure 60), *Aloe* (Figure 61), *Sansevieria* (Figure 62), **Bromeliaceae** (Figure 143), and **Cactaceae** (Figure 63) leaves or **phyllocladia** (branches that look like leaves).

It appears that substrate preference diminishes further with increasing air humidity. In an everwet rainforest, foliicolous species occur on many kinds of host leaves. Several species tend to occur on other substrates as well (**elective foliicolous species**). On the other hand, **terricolous** (soil-dwelling), **rupicolous** (rock-dwelling), or

corticolous (bark-dwelling) species may occur on leaf surfaces in this kind of wet forest (**accidental foliicolous species** such as certain species of *Bazzania* – Figure 64).

Figure 64. *Bazzania peruviana*; some species of *Bazzania* become accidental epiphylls. Photo by Felipe Osorio-Zúñiga, with permission.

Growth Structure

Fitting (1910) considered three groups to classify foliicolous lichens on leaves:

1. species penetrating the leaf tissue
2. species growing subcuticularly on the epidermis
3. species growing supracuticularly

Fünstüch (1926) considered that most foliicolous lichens penetrate into the mesophyll, others (Santesson 1952; Brodo 1973; Margot 1977) disagreed with this concept. Nevertheless, even some liverworts do this and can take nutrients from the leaf tissue (Berrie & Eze 1975).

One can also distinguish between the **obligately foliicolous species** (those unable to grow elsewhere) and the **facultative foliicolous species** (those able to also grow on other plant parts and even on rocks). Sérusiaux (1977) divided this even further:

1. **strictly foliicolous**: never occurring on substrata other than leaves
locally eufoliicolous: restricted to the phyllosphere in a definite geographical area, while occurring on other substrata elsewhere
2. **pseudofoliicolous taxa**: not restricted to living leaves and occurring also on other substrata
elective pseudofoliicolous: showing highest vitality and abundance on living leaves
indifferent pseudofoliicolous: occurring both on living and other substrata and not showing any preference
accidental foliicolous species: normally corticolous, saxicolous, or terricolous, and occurring on leaves only accidentally (e.g. the leafy liverwort *Bazzania* – Figure 64; mosses in the *Meteoriaceae* (Figure 55).

To these, Pócs (1982b) added the bryophyte category of **hemiepiphyllous** – those species that start their lives on branches, but subsequently grow from the twig to the leaf blade via the petiole, subsequently forming a community there.

Bryophyte Adaptations

Epiphytic life forms in general are considered late results of evolution. Among phanerogams, almost all epiphytic groups are at the tips of phylogenetic tree branches (Emberger, cited by Tixier 1980) and this seems also to be true for bryophytes (Vitt 1984). Hence, we should expect that special adaptations exist.

In the tropical rainforest, epiphytism among bryophytes is probably the result of coevolution since the Cretaceous (Gradstein & Pócs 1989). Most of the foliicolous bryophytes are in the leafy liverwort family **Lejeuneaceae**, a family that is diversified most strongly in the rainforest, especially the subfamilies **Lejeuneoideae** and **Cololejeuneoideae**. The **Lejeuneaceae** has several morphological adaptations, as noted below, but its most significant evolutionary trend in the phyllosphere is its shortened life cycle. Several taxa may reach reproductive maturity in an early stage of development (**neoteny**).

Gradstein (1997b) pointed out that many epiphyllous species are **facultative** – also able to grow on bark or other substrates. He described the **typical epiphyllous species** (those growing exclusively or almost exclusively on leaves) as shade epiphytes of the understory. These are small, pale-colored, appressed (Figure 65), with rhizoids in bundles that form large adhesive discs. They sometimes are **neotenous** (condition in which juvenile characters remain in adults). Gemmae (Figure 66), used in short-distance dispersal, are common.

Morphology

There must be some advantage in being a small, flattened, leafy liverwort when inhabiting a leaf surface, as nearly all the epiphyllous bryophytes fall in this category, mostly in the family **Lejeuneaceae** (Figure 6-Figure 15). Many of these adaptations have been described for liverworts (Massart 1898; Evans 1904, 1935; Schiffner 1929; Renner 1933; Jovet-Ast 1949; Winkler 1967, 1970; Bischler 1968).

Some thallose liverworts, *e.g.* species of *Metzgeria* (Figure 67), are anchored to the leaf surface by rhizoids that arise randomly from the ventral thallus surface (Figure 67). In most of the foliicolous liverworts, these anchoring rhizoids develop at a definite place (Figure 68), such as the main axis, on the lobule in *Radula*, or at the base of underleaves in **Lejeuneaceae** (Figure 68, Figure 69).

Figure 67. *Metzgeria conjugata* ventral view showing rhizoid clusters. Photo by N. J. Stapper, with permission.

In the **Lejeuneaceae** the rhizoids are usually fused together to form an adhesive disc that enhances the attachment to the leaf surface. The attachment of rhizoids is strengthened by a glutinous mucus secreted by the rhizoid disc. Winkler (1967) tested this attachment experimentally and found that adhesion is stronger on smooth leaf surfaces than on rough ones.

Perhaps *Chiloscyphus koponenii* (see Figure 70) in the **Geocalycaceae** can provide some clues as to the important structures contributing to success in this habitat. This leafy epiphyllous liverwort from Papua New Guinea possesses many characteristics similar to those of some genera of epiphyllous **Lejeuneaceae**, including its tiny size, ability to fragment and grow from fragments, two-lobed and often toothed leaves, thin-walled cells, small **trigones** (cell wall swellings), very shallow but wide underleaves with two lobes, two teeth, and numerous rhizoids (Piippo 1998), which many times fuse into a firm rhizoid plate. It is likely that the small size, the saccate lobules, and close adherence to the leaf surface (often with aid of a hyaline margin) are especially adaptive to maintaining moisture.

Figure 70. *Chiloscyphus pallescens* branch (left) and leaf cells with small trigones (right). Photo by Paul Davison, with permission.

Bernecker-Lücking and Morales (1999) considered the flattened stem and reduced lobule of *Cololejeunea sigmoidea* (Figure 71) to be adaptations to being a closely appressed epiphyll. But Olarinmoye (1975c) considered that for western Nigerian epiphylls the small size and closely appressed shoots were a disadvantage in competition with other species not so appressed. Instead, he considered *Radula flaccida* (Figure 41) and *Caudalejeunea hanningtonii* (see Figure 42) to be at a competitive advantage due to their larger size and faster growth, while he considered the small, appressed form to have a possible advantage in competing with erect species of smaller size. Fragmentation is useful for short-distance dispersal and spreading, and Olarinmoye considered the production of "copious propagules" of more than one type to provide a competitive advantage over those with only one type. For example, *Radula flaccida* produces numerous gemmae, but it can also produce as many as 10,000 spores in a single capsule, with 90% viability in the first few hours, dropping to about 40% after three weeks out of the capsule. And these capsules are produced only occasionally. Numerous rhizoids would aid in maintaining the position on a waxy leaf surface during a torrential onslaught, and some leafy liverworts have rhizoids or other parts with adhesive secretions that aid in maintaining attachment (Winkler 1967; Berrie & Eze 1975).

Figure 71. *Cololejeunea sigmoidea* growing as an epiphyll. Photo by Yang Jia-dong, through Creative Commons.

Eze and Berrie (1977) found that under the extreme drying conditions of sodium chloride solution or silica gel, liverwort leaf cells did not plasmolyze, but instead the cell walls folded inward and became contorted. The **oil bodies** (Figure 72) lost their shape, and after rehydration they all coalesced into one, indicating that the membrane of the oil body had been destroyed. The oil body content of these liverworts is high, comprising 17% of the dry cell, whereas liverworts from more moist habitats (*Plagiochila praemorsa* and *P. integerrima*; see Figure 73) exhibit oil body contents of about 5%. Although the role of the oil bodies is still largely speculative, their large volume helps to reduce the loss of cell volume as the cell dries, thus somewhat preserving the cell shape. The oil body itself is unaffected by water loss. It could also be a potential source of energy upon rehydration.

Water Relations

Bryophytes in general act like sponges to absorb water. Epiphylls are no exception. The bryophytes are also able to

hold water for a greater period of time than the leaf surface. This moist environment permits colonization by nitrogen-fixing *Cyanobacteria* (see Figure 39).

Pócs (pers. comm. May 2019) concluded that the most effective method to ensure continuous water saturation seems to be **subcuticular growth**, a method used by about 6% of the foliicolous lichen species. Among liverworts, this method seems to be lacking. Instead, for many success seems to be a leaf lobule that retains water, as found in *Radulaceae* (Figure 74), *Jubulaceae* (Figure 75), and *Lejeuneaceae* (Figure 76). This lobule, in many cases among epiphylls, develops into a watersack, with the most sophisticated ones in *Colura* (Figure 77; *Lejeuneaceae*). This genus has a special closure apparatus. Other epiphyllous liverworts have hyaline leaf margins (e.g. species of *Cololejeunea* – Figure 78 and *Diplasiolejeunea* – Figure 11). These hyaline margins consist of dead cells, which may absorb water, adhere quite close to the substrate, and retain water below the leaf surface. They apparently form a capillary system that promotes the distribution of available water (e.g. a raindrop) along the liverwort shoot.

Dietz *et al.* (2007) examined surface wetness in an old-growth tropical montane forest in central Sulawesi, Indonesia. The canopy remained wet 25-30% of the time in the May-August study. The lower canopy surface

wetness is continuous for up to 22 hours per day or more. During dry periods, wetness is contributed by dewfall in the second half of the night, affecting primarily the uppermost canopy. This causes radiative heat loss and under-cooling of the leaves. The researchers suggest that epiphyll colonization might take advantage of this surface water.

Epiphylls may also steal water from the host leaves as drying commences. Barkman (1958) reported osmotic potentials as low as -90 bars in epiphytes, and Berrie and Eze (1975) have shown transfer of both water and phosphate from host to epiphyll. In the leafy liverwort *Radula flaccida* (Figure 41) in Nigeria, the osmotic potential can reach -30 to -35 bars while the potential in leaf cells of two species of their hosts are only down to -10 to -12 bars (Eze & Berrie 1977). This osmotic differential could facilitate transfer of host leaf water to the epiphyll.

Larson (1981) compared the morphologies of various lichens and bryophytes to determine their water relations. Water uptake to saturation required only three minutes in *Polytrichum juniperinum* (Figure 79-Figure 80) to more than 300 minutes in the lichen *Stereocaulon saxatile* (Figure 82). The large surface area to weight ratio was the major contributor to rapid uptake in *P. juniperinum* and other species with a high ratio. It is likely that the lamellae on leaves (Figure 81-Figure 80) of *P. juniperinum* contribute to this rapid uptake, but this species also has internal conduction to contribute to water movement. Nevertheless, this suggests that species with small capillary spaces have an advantage in both uptake and holding of water.

Figure 82. *Stereocaulon saxatile*, a lichen with a very slow water absorption rate. Photo by Ed Uebel, through Creative Commons.

The host may reap some advantage from the association of drying epiphylls. In some cases, the thick growth of bryophytes and other epiphylls may aid in evaporative cooling as they release the water retained during a rainstorm (Olarinmoye 1976). And this water may also be absorbed by some tracheophyte leaves, thus contributing to their health.

Nutrient Budget

The foliicolous species seem to have a low nutrient budget and are very effective at using nutrients. They depend on rainwater for most of their nutrients, including leachates from canopy throughfall. Some epiphyllous liverworts, however, are able to take up nutrients from the mesophyll tissue of the host leaves (Berrie & Eze 1975), using rhizoids that penetrate the cuticle. Water-soluble salts could pass from the host leaf tissue into the epiphylls in this way. Thus, we could consider the epiphyllous liverworts to be semiparasitic. On the other hand, the **Cyanobacteria** (Figure 39) that inhabit many of these liverworts can carry out nitrogen fixation. Harrelson (1969) and Edmisten (1970a) demonstrated that N fixation in leaves having foliicolous bryophytes was higher than that of leaves with no epiphylls. The interaction of the

epiphylls and nitrogen fixation is discussed further below under Interactions.

Life Cycles

Reproductive strategies are usually important in habitat limitation, and this appears to be true for epiphyllous liverworts as well (Zartman *et al.* 2015). Unfortunately for most vegetation studies, the life cycle is slow and makes it difficult to predict long-term survival. Epiphyllous species, on the other hand, must complete their life cycles in a relatively short period of time because their leaf substrate is short-lived. In fact, they have some of the shortest generation times known for terrestrial plants.

The most common type of life strategy among foliicolous bryophytes appears to be that of the **perennial shuttle** (During 1979). A shortened life span is characteristic, permitting them to complete the cycle before the leaf falls and the habitat becomes unfavorable. This makes us wonder if any species has taken advantage of this programmed change in the microhabitat, perhaps producing capsules or gemmae only after the leaf substrate falls to the ground.

Zartman and coworkers (2015) investigated the relationship of the leafy liverwort *Radula flaccida* (Figure 41) in a central Amazonian rainforest to the seasonal precipitation. By marking 154 colonies, the researchers followed colony growth, extinction, recolonization, and rates of sexual and asexual expression. They found that the dry season increased mortality due to both increased leaf fall and *R. flaccida* colony mortality. Asexual reproduction decreased significantly in the dry months, but sporophyte density seemed unrelated to rainy season or dry season. Sporophyte density did, however, relate to a threshold colony size.

Kraichak (2012) considered asexual propagules to be adaptive among tropical leafy liverworts in the **Lejeuneaceae** (Figure 6-Figure 15). He tested several potentially adaptive traits and only asexual reproduction seemed to be evolved in the presence of epiphyll. Other traits associated with epiphyll appeared to result from shared evolutionary history, not adaptive evolution.

Epiphyllous mosses are much rarer than epiphyllous leafy liverworts. The epiphyllous moss *Crossomitrium patrisiae* (Figure 21) is **dioicous** (having male and female organs on separate plants), presenting a particularly challenging reproductive mode for this habitat. Alvarenga *et al.* (2013) set out to determine what permitted its success as an epiphyll. To do this, they examined 797 **ramets** (**ramet** – individual in a clone) for total length, presence, number of **gametoecea** (sexual reproductive structures and surrounding bracts), and number of fertilized **perichaetia** (modified leaves enclosing female reproductive structures and later the seta). They found high rates of sexual expression (76%). They unexpectedly found a highly male-biased population (0.43 females to 1 male) at the ramet level, n=604. Despite the isolation, with only 36.7% of the shrubs and 12.8% of the colonies having co-occurring sexes, the species nevertheless has one of the highest rates of fertilization known for any dioicous bryophyte. Nearly 90% of the mixed colonies produced sporophytes, with 40% of the female-only ramets producing sporophytes. Individual female ramets exhibited

74% sporophyte production. The researchers suggested that the species invests in the success of the sporophyte rather in the number of perichaetia in a species that demonstrates low levels of abortion. To further elucidate this unusual reproductive strategy, Alvarenga *et al.* (2016) experimented with threshold colony sizes and alternative reproductive strategies. They followed growth, reproduction, and fate of 2101 colonies of *C. patrisiae* for two years and found that asexual expression, but not sexual onset, was limited by a threshold colony size. Age and threshold size did not correlate. Colonies with brood bodies survived nearly twice as long as did sterile or solely sporophytic colonies. Nevertheless, reproductive strategy had no effect on colony growth rate.

He and Zhu (2011) compared the spore output of 26 selected species, representing 11 genera in the **Lejeuneaceae**. The mean spore output for these species ranges from 257 in *Cololejeunea magnilobula* (Figure 83) to 5038 in *Ptychanthus striatus* (Figure 84). The **Lejeuneaceae** has a much lower but more stable spore output than other leafy liverwort families. However, among eight species of **Ptychanthoideae**, *Acrolejeunea pusilla* (Figure 85) is the only species with a mean spore output of less than 1000 spores per capsule.

Figure 83. *Cololejeunea magnilobula*, a species that produced a mean of only 257 spores in a Chinese population. Photo by Yang Jia-dong, through Creative Commons.

The moss *Ephemeropsis trentepohlioides* (Figure 86) has globose gemmae and spores that can germinate in the capsule, and protonemata can extend out of the capsule (Bartlett & Iwatsuki 1985). Like *E. tijbodensis*, this species can cover an entire leaf by expansion of its persistent protonemata (Figure 87). The bunches of erect filaments increase its surface area for adsorbing water. Nevertheless, this species has seldom been reported from leaves – it usually grows on twigs.

Lücking and Lücking (1998) looked for adaptations and convergences in the phyllosphere, using mosses, lichens, and insects. Sierra *et al.* (2018) looked at the mechanisms of species assembly in epiphyllous bryophytes. These small organisms have the advantage of a short period of assembly that must be completed during the life of the host leaf. Sierra and coworkers studied the frequency and distribution of 55 species of epiphyllous bryophytes inhabiting 5 leaf-age classes on the understory shrub *Piper grande* (Figure 88) in a Panama premontane tropical forest. They found that dispersal was an important contributor to the assembly pattern, particularly for early arrivals. These early arrivals also had greater probabilities of sexual and specialized asexual reproduction. They concluded that interspecific variation in dispersal capacity, combined with various indirect effects, are the prerequisites for the high **alpha diversity** (average species diversity in habitat or specific area) of these epiphyllous communities.

Neoteny

Pócs (1980) observed that young gemmalings of **Lejeuneaceae** with 2-3 pairs of leaves produced gametangia. Gemmae also apparently are important in the life cycle of foliicolous liverworts (Schiffner 1929) and gemmae production together with sexual reproduction may significantly accelerate their propagation (see also Schuster in Richards 1984b, p. 1270). In some foliicolous taxa sexual organs are produced "directly" on an expanded, persistent protonema which is thallose in *Metzgeriopsis pusilla* (see Figure 127) and *Radula yanoella* (Figure 89) (Schuster 1980) and filamentous in the moss genus *Ephemeropsis* (Figure 86-Figure 87) (Fleischer 1929; Tixier 1974). The vegetative leafy gametophore in these plants has almost completely become suppressed as the result of neotenic evolution. The neotenic life-cycle of foliicolous taxa may be seen as an adaptation to the relatively short life span of the "evergreen" host leaves and represents a striking example of an evolutionary strategy to survive the hazards of life in the tropical rainforest.

Life Strategy Types

Colonizers (primary colonists of Winkler 1967)	Adhesive apparatus or hemiepiphyllous growth, abundant gemmae and spores
temporary	Small size, short life cycle (e.g. <i>Aphanolejeunea</i>)
resistant	Appressed or subcuticular growth, or ciliae, setae, perpendicular structures, or size preventing overgrowth (<i>Cololejeunea</i> with hyaline margin, <i>Colura</i>)
Occupants (secondary colonists)	
overrunner and overgrower (see Kiss 1982)	Fast growth rate, loose, creeping habit or robust size (<i>Radula flaccida</i> , <i>Diplasiolejeunea</i> , <i>Cheilolejeunea</i> spp.)
squeezer (line contact of Kiss 1982)	Physical or chemical pressure against another species (latter by <i>Frullania</i>)
Explerents (<i>sensu</i> Ramensky 1938, tertiary colonists)	
space economizer	Utilizing space between other species, e.g. by hypophyllous growth, pendulous from leaf margin, e.g. <i>Meteoriaceae</i>)
replacer	Settling in the debris of dead, decomposing plants (e.g.

Syrrophodon on leaf surface) or occupying over-mature center of round colonies (window contact of Kiss 1982)

Accidental (non-adapted) settlers that cannot reach maturity after germination (non-epiphyllous bryophytes like *Bazzania* or *Leucoloma*)

Host Adaptations

While epiphylls are not parasitic (Olarinmoye 1976), they can reduce photosynthesis and in some cases may encourage the growth of fungi by maintaining a higher humidity on the leaf surface. They can also block stomatal openings, hampering gas exchange. Hence, we might expect some trees to have evolved adaptations that discourage the growth of epiphylls.

Drip Tips

Some leaves have special adaptations that permit them to slough off the cuticle on a regular basis, getting rid of the epiphytes at the same time (Attenborough 1995). Some tropical biologists have attributed the success of some leaves in preventing epiphyte colonization to the presence of a **drip tip** (Figure 90) that increases the flow of water from the leaf, thus making the habitat less hospitable for colonization (Briscoe 1994). For example, O'Brien (1994) asked if drip tips can affect the population dynamics of fungal pathogens and epiphyllous organisms such as bryophytes. Junger (1891) found fewer epiphylls on leaves with drip tips and believed that the tip was an adaptation to avoid interference with assimilation that could handicap the plant. He contended that taxa with rounded or cordate bases and rounded apices lacked any special adaptation for getting rid of water and appeared to support larger populations of epiphyllous plants (Junger, in Howard 1969).

Figure 90. Drip tips on sacred fig leaves. Photo by Challiyil Eswaramangalath Vipin, through Creative Commons.

However, recent experiments have shown that the tip does not increase the drying speed and thus the adaptive value in warding off epiphyllous taxa is doubtful. Monge-Nájera and Blanco (1995) noted that leaf substrates vary in both biochemistry and morphology. Using plastic ribbon

tape as artificial leaves the researchers found that the epiphyll cover differed little after nine months of exposure on five shapes and two sizes. Furthermore drip tips did not affect the epiphyll cover. But cover was four times higher in a clearing than in a shaded understory.

Panditharathna *et al.* (2008) noted that drip tip (Figure 90) lengths were greatest in seedlings and least in canopy trees, an observation that would seem to negate likely benefits for epiphylls or for preventing their establishment on leaves. Lücking and Bernecker-Lücking (2005) found no significant difference in the development of lichen colonies on leaves with drip tips and those without. On the other hand, leaves lacking drip tips accumulated more debris in the apex and concomitantly few lichens in this region. It might be the same for bryophytes. The drip tips cause a difference in accumulated drop size and residence time on the leaf. On those leaves with drip tips, the water forms smaller drops that run off more frequently.

Ivey and DeSilva (2001) experimented with drip tips (Figure 90) in Costa Rica (Figure 91) from 23 November to 2 December during the rainy season to see if having a drip tip reduces colonization. With a sample of 28 saplings and three leaves per tree for each treatment, they were unable to show any effect on the bryophytic epiphylls. However, fungi had greater cover on the leaves that were missing their drip tips. They found instead that the bryophytes tended to be on the drier parts of the leaves, away from bases, midveins, and tips. Fungi, on the other hand, tended to be in those very regions. Nonetheless, 9 days is much too short to expect much effect on colonization rate by bryophytes. Their experiment did demonstrate that the drip tip had little effect on helping the leaf to shed debris, but those with drip tips intact had significantly less water retention (about half) compared to those with the tip cut off. Ivey and DeSilva suggested that prevention of fungi might be the important adaptation and that epiphylls may not be a significant factor in reducing photosynthesis by the host leaves because of their slow growth. By the time they have achieved significant cover, the leaf is ready to senesce. But Ellenberg (1985) has argued that the tip is an environmental response to high humidity, not an adaptation to it, whereas Edmisten (1970b) has argued that it might reduce nutrient leaching. The latter might even be of some benefit to bryophytes if it means that more nutrients remain on the leaf and might help explain their greater abundance near the drier margins.

Figure 91. Montane oak forest in Costa Rica. Photo by Jorge Antonio Leoni de León, through Creative Commons.

Ellenberg (1985) discussed the drip tips found on many tropical leaves. They occur mostly in humid areas of warmer zones. The prevailing hypothesis was that these tips would facilitate drainage of water from the leaves, thus preventing growth of epiphyllic algae, lichens, and bryophytes. But this hypothesis was not supported by field observations or by experiments with leaves and leaf models. These tips typically develop before the leaf expansion and rarely develop after the leaf has expanded fully. Those tips that develop before the leaf expands expose the tips to the environment outside the buds. Their role, if any, in preventing epiphyll colonization remained a matter of conjecture.

Leaf Size and Shape

Monge-Nájera and Blanco (1995), also working in Costa Rica (Figure 91), likewise found that leaf shape had little or no influence on epiphyll cover. What did matter in their study was light. The epiphyllous cover in a clearing was four times that found in the dark understory of the tropical forest, regardless of leaf size or shape. However, in an earlier Costa Rican study, while finding a similar relationship between clearings and epiphyllous cover, Monge-Nájera (1989) found that epiphyllous cover increases more rapidly than the size of the leaves. This is somewhat offset by an increasing rate of herbivory on the epiphylls as the tree leaves increase in size.

Epiphyllic cover is generally higher on larger leaves, as demonstrated by epiphyllous liverworts in Monteverde, Costa Rica (Figure 91) (Monge-Nájera 1989). Perhaps this is because the growth of the epiphylls increases more rapidly than does the leaf area. Once again, degree of epiphyll does not correlate with leaf shape. Surprisingly, both absolute and relative epiphyllic cover are higher in the forest clearing than in the understory. Monge-Nájera attributed this to the greater light in a region with overall high atmospheric humidity.

The ratio of bryophytes to lichens in these communities depends on environmental conditions. Drier, more open habitats seem to favor lichens and are usually poor in bryophytes. The number of foliicolous species in one locality varies between 20-50 for lichens and 30-90 for bryophytes. A single leaf will average 5-25 lichen species and 3-13 bryophyte species, with a maximum of 45 and 20, respectively (Jovet-Ast 1949; Santesson 1952; Tixier 1966; Pócs 1978). The number of species increases with leaf area, to a maximum at 5-8 cm² and remains more or less constant above that (Sjögren 1975; Pócs unpublished). Leaflets of compound leaves should in this respect be treated as separate leaves because the composition of the foliicolous communities often varies among the leaflets of one leaf.

Leaf Age

The number of species and individuals is also determined by the age of the host leaves. Richards (1932) observed a decrease of species number and increase in number of individuals with leaf age. However, Olarinmoye (1975c) and Pócs (1978) observed an increase in number of both species and individuals. On *Marattia* (Figure 92) fern leaflets Pócs observed an increase of the average plantlet number from 588 to 1754 per 100 cm² within 1-2 years. One explanation for the observed differences in number of

species is that as the colonies increase in size, competition may eliminate some of the species.

Leaf Longevity

Coley *et al.* (1993) questioned whether long-lived leaves may attain a higher epiphyll cover as suggested by Richards (1954), Pócs (1982a), and Bentley (1987). This hypothesis had never been tested before. Coley and coworkers found that rather than having higher cover, these long-lived leaves actually have both lower colonization rates and lower accumulated cover throughout the life of the leaf. They suggest that characters that protect the leaves from herbivory and environmental events might also protect them from epiphylls. But they also suggest that there may also have been selection for leaf characters that specifically protect them from epiphyll colonization. They suggest that the rapid colonization on short-lived leaves would cause detrimental effects when persistent over long periods of long-lived leaves.

One of the limiting factors that prevents bryophytes from making leaves their home is that the leaf is short lived and the bryophyte is slow growing. This generally limits colonization to those leaves that endure for more than one year and that live in regions where the atmospheric moisture or frequency of rain is ample for growth on a substrate that doesn't hold water.

Leaf Chemistry

On the other side of the story is the co-adaptation of the host leaf. Coley *et al.* (1993) found that longer-lived leaves actually had greatly reduced rates of epiphyll accumulation, suggesting that these leaves have some sort of defense against the epiphylls. Liverworts colonized 45% of the leaves with one-year lifetimes, but only 5% of longer-lived leaves. If this is indeed an adaptation against epiphylls rather than just an adaptation against pathogens (longer-lived leaves are known to have good defenses against pathogens), then it implies that epiphylls present a problem for their host leaves. On the other hand, liverworts may actually protect the host leaves from herbivory – see below, and may encourage the development of nitrogen-fixing *Cyanobacteria* (Figure 39).

Voglgruber (2011) reported that up to 80% of a leaf may be covered by epiphylls, where they can have a significant effect of reducing photosynthesis of the host leaf. Voglgruber studied the relationship in the humid tropical rainforest of Piedras Blancas National Park, Costa Rica. The rates of colonization were host specific. The fastest colonization was on *Costus laevis* (Figure 93) leaves; the slowest were on *Asplundia pittieri* (Figure 94) leaves, among the six species studied. Voglgruber tested the cuticles and identified long-chained alkanes, alkanols, sterols, and unidentifiable compounds. The species and leaf ages differed in wax composition. The data support the hypothesis that epicuticular wax chemistry has an effect on the growth of the epiphylls.

Interactions

We might well ask if there is any advantage to the liverwort, or disadvantage to the host, resulting from this close association. Bentley (1987) reported that leafy liverworts, especially **Lejeuneaceae** (Figure 6-Figure 15), form dense coverage on leaves in the rainforest. Suitable leaves can be completely covered in only two years (Coley *et al.* 1993).

Cornelissen and ter Steege (1986) suggest that the ecological and evolutionary effects of epiphylls on their host leaves may be significant. Working in a rainforest of Guiana, they examined the liverworts and lichens that formed the dominant epiphylls and demonstrated both positive and negative effects by the epiphylls. They also found that host leaf characteristics can influence the colonization rates of epiphylls.

Nutrient Exchanges

Host Leaf Leachates

The role of leachates from the host leaf in the success of the epiphylls should not be ignored. Orlarinmoye (1981, 1982) found that leachates and extracts of various tracheophyte leaves greatly increase extension growth of gemmaling shoots, leaf size, and rhizoid production of the leafy liverwort ***Radula flaccida*** (Figure 41), although they have no effect on the initiation of gemma growth. Rhizoid branching differs, depending on availability of the leachate, with long, straight and little-branched rhizoids when grown in leachates, but short, much-branched, and crooked rhizoids in some extracts. Extracts from ***Averrhoa carambola*** (Figure 95) killed all the cultures within four weeks. But are the liverworts ever exposed to the cell contents? We need tracer studies to determine if these extractable substances ever contact the liverworts. The leachates are available to them and have an important role in promoting the successful establishment and growth of these epiphylls, particularly in tropical areas with abundant annual rainfall. Often they provide nearly all of the nutrient supply.

Figure 95. ***Averrhoa carambola*** leaves and fruits. Extracts from these leaves kill cultures of the leafy liverwort epiphyll ***Radula flaccida***. Photo by Dinesh Valke, through Creative Commons.

Pócs (pers. comm.) observed that leaves of planted orange trees at Amani Station (Tanzania) with mass occurrence of aphids were covered by a sticky, sugar-containing exudate that promoted copious colonization by epiphylls, mostly ***Leptolejeunea*** (Figure 14) sp. and also some specimens of ***Diplasiolejeunea cornuta***.

Bryophyte Leachates

Montagnini *et al.* (1984) gathered indirect evidence that minerals are transferred from epiphylls to host leaves. They found that the concentrations of Cd, Pb, Ni, and Cr were higher in leaves that had epiphylls than in leaves that lacked them. The tropical Amazonian bryophytes usually have lower concentrations of heavy metals than in those from temperate zones, suggesting that long-range transport of these air pollutants is limited.

It seems logical that if heavy metals in leaves increase as the result of epiphyll colonization, other nutrients might increase as well. Epiphylls live and die on the leaves where they live. Hietz *et al.* (2002) found a correlation in leaf delta ¹⁵N with that of epiphylls, suggesting that there was at least some exchange of nitrogen between the epiphylls and the host leaves (or that leaves with epiphylls might have more **Cyanobacteria**).

Jordan *et al.* (1980) examined the role of bryophytes in scavenging nutrients from rainfall and subsequent nutrients in the throughfall in Venezuela. They hypothesized that nutrients were intercepted by epiphylls in the canopy, conserving nutrients in the forest. They supported this by demonstrating that nutrient flux of calcium, sulfur, and phosphorus in rainfall was greater than that in the throughfall.

Ruinen (1965) reported that epiphylls on coffee leaves (Figure 96) can increase the coffee leaf nitrogen content by up to 60% in about one week due to the ability of the epiphylls to retain the nitrogen. These bryophyte (mostly liverwort) assemblages most likely help to maintain the necessary humidity and nutrient retention for the included micro-organisms to survive.

Figure 96. Coffee plantations with dwarf trees in the distance, in Colombia. Photo courtesy of Robbert Gradstein.

Witkamp (1970) used paired leaf discs to compare retention of added elements by epiphylls from a tropical rainforest at El Verde, in El Yunque, Puerto Rico (Figure 97). He found that the epiphylls increased ¹³⁷cesium by 6.7-20 times that of the cleaned leaf discs. For phosphorus it was 4.7-18.3, for manganese 1.7-4.7, and for strontium

1.9-2.9. These numbers indicate the significant role that epiphylls can play in mineral nutrient retention.

Figure 97. El Yunque forest, Puerto Rico. Photo by Matt Shiffle, through Creative Commons.

Volcanic activity can be a major contributor to bryophyte nutrients. Baudoin (1985) reported that epiphyllous bryophytes can be used satisfactorily as indicators of volcanic air pollution and nutrient contributions. Similarly, Witkamp (1970) used epiphyllous bryophytes in studies of irradiation at El Verde, Puerto Rico (Figure 97) by measuring mineral retention. According to Pócs (1990) near the Great African Rift Valley with active soda volcanoes, leafy epiphylls do not occur at all, even in wet rainforests, due to the alkaline-containing dust accumulated in the soil, air, and on the bryophyte substrates including leaf surfaces, and their components accumulate even in the epiphytic mosses.

Seed Beds

In some cases, old leaves have such a dense covering of bryophytes (Figure 98) that seeds of epiphytic flowering plants germinate there (Richards 1932) or spores of ferns – a disadvantage to the host plant, no doubt, but possibly an advantage to that tracheophyte.

Figure 98. Dense covering of bryophytic epiphylls on a palm in Guyana. Photo copyright Patrick Blanc, with implied online permission.

Nitrogen Fixation

Zhou *et al.* (2009) noted that epiphylls obtain their nutrients independently. However, there are indications that substances can be exchanged between epiphylls and host plants. They report that **nitrogen fixation** within the epiphyll community provides 10-25% of the nitrogen for the understory forest in tropical ecosystems. **Nitrogen fixation** is the process of converting atmospheric nitrogen into a form that is usable by plants, typically to NH_4^+ .

The most important contribution of epiphylls to leaves is most likely through the nitrogen-fixing organisms they harbor. Nitrogen-fixing **Cyanobacteria** (Figure 39), particularly *Scytonema* (Figure 39) (Basilier 1979), are often associated with the epiphyllae, and this added nitrogen could be of benefit to the host leaf as well. Bentley (1987) suggested that epiphyllous bryophytes, especially liverworts in the **Lejeuneaceae** (Figure 6-Figure 15), enhance moisture levels, permitting nitrogen-fixing bacteria to subsist. Bentley and Carpenter (1980) found that epiphyllous liverworts improve the microenvironment for **Cyanobacteria** and other nitrogen-fixing bacteria by increasing the leaf moisture. Using radioactive tracers, Bentley and Carpenter (1984) were able to show a direct transfer of fixed N from the epiphyllous micro-organisms to the host leaf on the palm *Welfia georgii* (Figure 17) and estimated that such transfer could account for 10-25% of the host leaf N content. Most of the N fixation appeared to occur among filamentous **Cyanobacteria** associated with leafy liverworts, as well as within a thick layer of coccoid **Cyanobacteria** immediately above the leaf cuticle (Carpenter 1992). Nitrogenase activity, indicating nitrogen fixation, in the *W. georgii* association produces about 270 mg N per ha daily. Furthermore, this association may benefit the forest as water dripping from these leaves is enriched in nitrogen compared to rainwater (Richards 1984a).

Bentley and Carpenter (1980) examined the effects of desiccation on nitrogen fixation rates among epiphylls. Fixation on leaves that had been dried for 12 hours was only 0.66 ng N per 10 cm² h⁻¹, whereas that on continuously hydrated leaves was 18.69 ng N per 10 cm² h⁻¹. Intermediate rates occurred after 2 and 4 hours of rehydration. The bryophytic epiphytes helped to maintain moisture on the leaf surface, prolonging the duration of fixation.

In general, **Cyanobacteria** (Figure 39) are the typical contributors of nitrogen fixation on leaves. Bentley (1987) considered glucose and mineral nutrients leached from host leaves, light intensity, and desiccation to be the major influences on the co-occurrence of the **Cyanobacteria** and epiphyllous bryophytes. Bentley found that a significant portion of the fixed nitrogen is transferred to the host leaf and may contribute 10-25% of the total nitrogen in the leaf. The bryophytes most likely contribute to the fixation rates by maintaining moisture longer than leaves with no epiphylls. Although desiccation has a dramatic effect on fixation, recovery is quite rapid, reaching the levels of moist controls within 4 hours. Berrie and Eze (1975) contend that the bryophytes are also able to draw water from the host leaves, contributing further to maintaining moisture for the fixation. Low light reduces the rate of fixation. The water flowing on a leaf actually has less

nitrogen than rainfall collected in the open, suggesting very efficient uptake mechanisms on the leaf surface. High N fixation rates are associated with dense cover of epiphyllous bryophytes, especially for leafy liverworts in the **Lejeuneaceae** (Figure 6-Figure 15). Bentley suggested that the bryophytes enhance the moisture levels on the leaf, encouraging microbial growth. One can observe that a few hours after rain, when the naked leaf surface is already dry, under the cover of epiphylls a still good amount of moisture is preserved.

Roskoski (1980) measured nitrogen fixation by epiphylls on coffee (*Coffea arabica*; Figure 99). The C_2H_2 reduction (a measure of N fixation) was similar at all sites in Vera Cruz, Mexico, despite differences in shade, averaging 3.21 nmoles C_2H_2 reduced per leaf with epiphylls per day. This suggests that the shading/light intensity within the range encountered was unimportant in the fixation rate. Furthermore, he found no correlation between percent epiphyll cover and magnitude of nitrogen-fixing activity. Roskoski concluded that the nitrogen fixation associated with epiphylls is not an important N source for that coffee ecosystem.

Figure 99. *Coffea arabica*, a species that commonly hosts bryophytic epiphytes, with fruit, in Hawaii. Photo by Forest and Kim Star, with permission.

For the epiphyllous liverworts living on leaves of the undergrowth, as opposed to higher levels of the canopy, these **Cyanobacteria** (Figure 39) may even be a necessity. Canopy leaves and epiphytes remove so much of the nutrients before the rainfall reaches the lower branches that liverworts like *Radula flaccida* (Figure 41) are likely to be nutrient limited (Olarinmoye 1975a). In support of this suggestion, Olarinmoye found that the standard bryophyte media used by other researchers (Diller *et al.* 1955; Basile 1965; Bennecke in Schuster 1966) caused aberrant plants, and he was forced to reduce the concentration to 10-20% of the standard. The greatest percent of buds producing leafy shoots occurred in the 10% solution; growth was highest in the 10 and 20% media as well. Even in distilled water the gemmalings exhibited appreciable growth extension, although they were not as healthy as in the diluted nutrient media.

Wanek and Pörtl (2005) acknowledged the role of free-living nitrogen-fixing organisms and throughfall to provide nutrients to epiphyllous bryophytes, but added that the

bryophytes also obtained nutrients from leachates of the host leaf. On the other hand, bryophytic epiphylls lose quantities of nutrients after drying events, and these can be absorbed by host leaves. However, when the researchers measured the nitrogen leachates from the epiphylls of four species in a lowland tropical wet forest in Costa Rica, they contributed less than 2.5% of the lost leaf N after 14 days. Nevertheless, 180 days of observations demonstrated that the nitrogen in the phyllosphere was highly dynamic, with the bryophytes at times being sinks and other times being sources.

Freiberg (1994, 1998, 1999) measured nitrogen fixation on leaves in a premontane rainforest in Costa Rica. He found maximum rates on 26 ng N cm⁻² leaf area h⁻¹ and determined that two species of *Scytonema* (*Sc. javanicum*, *Sc. hofmannii* – Figure 39; **Cyanobacteria**) contributed most of that. The rates of fixation correlated with the leaf area covered by *Scytonema*. This fixation was dependent on rainfall and ceased completely in 2-3 days with no precipitation. Liquid water was necessary – fog and mist were not helpful. Light and temperature both influenced the rate. In a follow-up study, Freiberg (1999) identified seven species of epiphyllous **Cyanobacteria** in a primary premontane rainforest in Costa Rica.

Harrelson (1969) further discussed the epiphyllae of tropical leaves and their relationship to nitrogen fixation, noting that nitrogen fixation was greater in leaves with epiphylls. Goosen and Lamb (1986) measured nitrogen fixation associated with leaves in one tropical and two sub-tropical rainforests.

Herbivore Protection

Coley *et al.* (1993) found that *Cololejeunea* (Figure 13), *Leptolejeunea* (Figure 14), and *Lejeunea* (Figure 3) (all **Lejeuneaceae**) were common epiphylls. They hypothesized that the liverworts might protect their host leaves from herbivores. Liverworts are known for their rich terpenoids, and experiments show that leaf cutter ants (Figure 100) prefer leaves with no epiphylls. On the other hand, the epiphylls hold moisture that may increase pathogenic infection. The epiphylls also block light, reducing photosynthesis, possibly making the leaves a less desirable food source.

Figure 100. *Atta cephalotes* carrying a cut piece of a leaf. Photo by Jim Webber, through Creative Commons.

Epiphylls have a little more direct relationship with the leafcutter ants (*Atta cephalotes*; Figure 100), albeit a

negative one. These ants are known for their attacks on leaves. When Wetterer (2003) removed the epiphylls from the base and two side branches of a grapefruit (*Citrus paradisi*; Figure 101), the ants chose to cut leaves from the cleaned branches nine out of ten times. This behavior suggests that the epiphylls provide protect the host leaves from the leafcutter ants.

Figure 101. *Citrus paradisi*, a species on which epiphylls seem to provide protection from leafcutter ants that would eat the leaves. Photo by Amada44, through Creative Commons.

For some leaves, the antiherbivore role may be significant. For example, in Costa Rica, leafcutter ants (*Atta cephalotes*; Figure 100) preferentially clipped leaves of *Citrus paradisi* (Figure 101) and *Cyclanthus bipartitus* (Figure 102) from which epiphylls had been removed (Figure 103-Figure 104) (Mueller & Wolf-Mueller 1991). This benefit may be derived from the greater processing effort required of the ants when epiphylls cover the leaves or from decreased palatability due to secondary compounds found in epiphyllous lichens and bryophytes. In particular, liverworts are rich in terpenoids that are toxic to both the leafcutter ants and the fungus they cultivate (Hubbell *et al.* 1983; Howard *et al.* 1988; Coley *et al.* 1993). Citrus leaves with epiphylls are less preferred by leaf cutter ants, most likely due to these terpenoids (Coley *et al.* 1993).

Figure 104. Leaf cutter ant damage on leaves of two species of tropical plants; leaves have epiphylls retained and epiphylls removed. Error bars represent one standard error. Modified from Mueller & Wolf-Mueller 1991.

In a southern Ecuadorian montane rainforest, Bodner *et al.* (2015) found many caterpillars (**Lepidoptera**) that were not feeding on leaves as might be expected. Instead, they feed on lichens, dead leaves, and epiphylls, including bryophytes. Bodner *et al.* (2011) conducted feeding trials with caterpillars in the Montane Forest Zone in Southern Ecuador. They found that more than 22% of the caterpillars did not eat the leaves, but rather ate dead leaves and epiphylls. In some cases, up to 80% were epiphyll consumers.

Similarly, Callaghan (1992) found that the butterfly *Pentila picena cydaria* (Figure 105) laid its eggs singly on live trees that were covered with lichens and mosses in a Nigerian cola forest. The initially white eggs soon became dark brown (within a day). The caterpillars subsequently fed on the epiphylls.

Figure 105. *Pentila picena cydaria*, a species whose caterpillars feed on epiphylls. Photo by Grose-Smith and Kirby, through public domain.

Yet another butterfly, *Sarota gyas* (Figure 106), uses the epiphylls (DeVries 1988). The larvae of this species rest on the upper surfaces of leaves and feed on the epiphylls, where they blend in. The epiphylls are primarily *Cyanobacteria* (Figure 39) and leafy liverworts in the *Lejeuneaceae* (Figure 6-Figure 15). Others (Lycaenidae: Lipteninae) in the Nigerian cola forest feed on epiphyllic lichens and fungi as larvae (Callaghan 1992).

Micro-organisms

The same lobules that hold water for the leaves of many epiphyllous liverworts also serve as the habitat for some species of protozoa (Barthlott *et al.* 2000). In the liverworts *Pleurozia* (Figure 107) and *Colura* (Figure 108), the openings of these sacs can be closed by a movable lid. This caused some researchers to hypothesize that sacs could trap small animals, a theory that they supported by finding ciliate protozoa in them. These protozoa feed on bacteria on the surface of the plants, but there seems to be no evidence that there is any mechanism to attract the protozoa to the liverwort. Hence, there is thus far no evidence that the protozoa provide any useful function for the liverwort leaves.

Epiphyllous bryophytes can provide a suitable habitat for a number of kinds of micro-organisms, and the role of these micro-organisms in affecting the health of the host is largely unknown. Leafy liverworts in Ecuador, Costa Rica, and Puerto Rico support the growth of at least eleven species of slime molds (*Myxomycetes*), especially in lowland rainforests with high annual rainfall (Schnittler 2001). Among these, *Arcyria cinerea* (Figure 109), *Didymium iridis* (Figure 110), and *D. squamulosum* (Figure 111) have the most common (frequency of 59-66%). While these produce visible sporocarps in culture, it is likely that they exist in their amoeboid stage among the epiphylls, in which case they may contribute to controlling bacteria.

A number of ascomycetous fungi parasitize epiphyllous liverworts. According to Döbbeler (1997) and Döbbeler and Hertel (2013) more than 400 known fruit-body-forming species of *Ascomycetes* (Figure 41) occur obligately on the gametophytes of mosses and hepatics. A good portion of them is specialized to epiphyllous liverwort hosts.

Küttner (2005) used 4x4 cm leaf squares to investigate parameters that controlled epiphyllous micro-organisms in a tropical humid lowland rainforest in Costa Rica. The size of these microbial communities was influenced by both species and leaf age of the host leaf. On the other hand, site had little or no effect on the composition or size of the epiphyllous microbial community. This microbial

community has experienced few studies, and more information is needed to assess how it affects the epiphyllous bryophytes and *vice versa*.

Negative Impacts on Leaves

Most of the impacts of epiphylls on their host leaves seem to be positive. However, epiphyll rhizoids may actually penetrate the epidermal cells of the host, presumably serving as a means of anchorage (Berrie & Eze 1975). This can result in the death of some leaf epidermal cells, permitting more rhizoids to enter. It appears that this penetration contributes to water loss, as leaves with extensive epiphyllous colonies and those stripped of their epiphyllae both have a high evaporative loss compared to uninhabited leaves of the same age. Further detriment to the leaf may occur if the sites of penetration serve as entry points for leaf pathogens. So far, this has not been demonstrated, except for senescent leaves. (But could it be that the penetration has contributed to the senescence?)

Light Interference

In some areas, the bryophytes become so abundant that they can seriously interfere with photosynthesis by intercepting the light (Attenborough 1995). In other cases, light interference is scant; Eze and Berrie (1977) found that even under the heaviest colonization of *Radula flaccida* (Figure 41), only 2% of the light was intercepted by that liverwort. They found no difference in the chlorophyll content of colonized and uncolonized parts of the host leaf. Furthermore, they found no loss of photosynthetic product from the host to the epiphyll, or from epiphyll to host. Coley *et al.* (1993) found that epiphyllous liverworts in several locations in Panama transmitted 44% of the light through liverworts in a single layer and that transmission did not differ between saturated and blotted dry liverworts.

Conflicting reports on the effects of epiphylls on *Cacao* trees have been discussed above. Roskoski (1981) found that the number of leaves with epiphylls is lowest on *Coffea arabica* (Figure 99) in a shadeless site. The percent cover of epiphylls is inversely related to the number of young coffee leaves, making them highest in February and lowest in May. Height strata have no significant effects on number of leaves with epiphylls. Epiphylls do affect the host leaves by reducing the photosynthetic area of the trees, with shading ranging 0.5-19.7%. Nevertheless, the epiphylls do not seem to cause any detrimental effects on the coffee productivity.

Zhou *et al.* (2014) compared the effects of lichens vs liverworts on host leaf traits in the tropical montane rainforest, Hainan Island, China. They studied effects of epiphyllous lichens, liverworts, and uncolonized leaves on leaf characters of *Photinia prunifolia* (Figure 112). Colonization by lichens significantly decreases leaf water content, chlorophyll *a* and *a + b* content, whereas liverworts have no effect on these. Furthermore, lichens have more effect on net photosynthesis than do liverworts. Lichens caused an increase in leaf light compensation point by 21% and a decrease of the light saturation point by 54%, whereas liverworts exhibited contrary effects. This study suggests that the type of epiphyll is important in assessing potential decreases in productivity of the host plant.

Composition and Distribution of Communities

Based on studies through the 20th century, Pócs (unpublished) considered indications that some genera or species are typical for certain geographic or vegetational units or altitudinal belts. In Africa, for example, *Radula flaccida* (Figure 41), *Cololejeunea auriculata*, *C. jonesii*, and all species of *Leptolejeunea* (Figure 14) seem to be typical of lowland rainforest, whereas *Radula stenocalyx*, *Cololejeunea jamesii*, *C. malanjae*, *C. tanzaniae*, *C. zenkeri*, and all species of *Drepanolejeunea* (Figure 9) seem to be restricted to submontane and montane forest habitats. Ericaceous heaths have endemic species of *Colura* (*C. berghenii*, *C. hedbergiana*, *C. ornithocephala*, and *C. saroltiae*) that are apparently restricted to ericaceous leaves and twigs.

Within the montane rainforest habitat Tixier (1966) was able to distinguish the lower and upper strata by their characteristic foliicolous communities. Winkler (1970) found a significant correlation between certain groups of species within the same geographic area. Host preference allows two different foliicolous communities to occur at close distances, e.g. on evergreen shrubs and on filmy ferns within the same forest habitat (Pócs 1978).

Species Richness

As already noted, the most common of the epiphyllous species are in the leafy liverwort family **Lejeuneaceae** (Figure 6-Figure 15), a dominant member of the epiphyllous bryophyte flora in lowland rainforests (Piippo 1994). Many of these species are endemic, for example 20.5% in Western Melanesia [Papua New Guinea, Papua (West Irian), and the Solomon Islands].

The family **Lejeuneaceae** (Figure 6-Figure 15) is repeatedly considered the most diverse and abundant family among the epiphylls. However, the species and even the tribes differ by continent and between the Old World and Neotropics. Many of the epiphyllous species extend outside the tropics into the Macaronesian Azores, Madeira, and the Canary Islands. Even in these sub-tropical locations, several of the species belong to typical tropical families of **Lejeuneaceae** and **Radulaceae** (Figure 16) (Sjögren 1997). These islands had 89 epiphyllous

species reported, 14 of which were endemic to the Azores or to Macaronesia. Nan and Zhu (2007) reported a much smaller number of species (19 epiphyllous liverworts) in the Maoershan Nature Reserve, Guangxi, China. Boecker *et al.* (1993) reported on epiphylls of the Canary Islands.

Table 1. Number of epiphyllous liverwort species known in genera having pantropical distribution, based on Pócs 1978. These constitute 60% of the ~1000 foliicolous liverwort species described at the time. Revisions have eliminated some of these species.

	Neotropics	Africa incl islands	Asia, Oceania, Australia
<i>Aphanolejeunea</i>	24	9	8
<i>Cololejeunea</i>	40	72	41
<i>Colura</i>	14	18	41
<i>Diplasiolejeunea</i>	19	28	8
<i>Drepanolejeunea</i>	34	18	37
<i>Leptolejeunea</i>	11	5	24
<i>Microlejeunea</i>	12	6	11
<i>Radula</i>			
<i>sec epiphyllae</i>	6	5	8

The epiphyll richness varies with altitude differently in the different parts of continents or islands. In continental East Africa the highest epiphyllous diversity occurs at 1500-1800 m near the coast and at 1800-2500 m inside the continent (Pócs 1978, 1994), while in more oceanic conditions, like in the Indian Ocean islands (Mascarenes, Seychelles) we can observe the highest epiphyllous diversity already from 600 m above the sea level.

Asia

In India, the epiphyllous species of liverworts are restricted to the Eastern Himalayas, South India, and Andaman and Nicobar Islands (Lal 2003). By 2003, only a small number of epiphyllous species were known; 39 species in 14 genera were all that had been identified. These were in only three families: **Lejeuneaceae** *s.l.* (Figure 6-Figure 15), **Radulaceae** (Figure 16), and **Metzgeriaceae** (Figure 19). But Dey and Singh (2012) soon reported 89 taxa of epiphyllous liverworts from the Eastern Himalayas, of which 66 species belong to **Lejeuneaceae**.

Gao and Be (1988) identified 12 species of epiphyllous liverworts from Daiwa Shan, Jiulong, China. Despite the small number of species, these represented 10 genera and 5 families, occurring at 650 m asl. As has been common when exploring these small organisms, these researchers found that five of the genera and six of the species were new to China.

Ji and Wu (1996) reported only 10 species in 1 family and 4 genera from Jinggangshan Nature Reservation, Jiangxi Province. Nevertheless, one species was new for China.

When Li and Wu (1992) assessed epiphyllous liverworts from Heishiding Natural Reserve, Guangdong Province, China, they reported only 13 species in two families and 7 genera. The most common species among these were *Leptolejeunea elliptica* (Figure 14) and *Radula acuminata* (Figure 35). *Leptolejeunea hainanensis* and *Cololejeunea floccosa* (Figure 113) occur in the broad-leaved forests in ravines at 350-600 m asl.

Figure 113. *Cololejeunea floccosa*, an epiphyllous liverwort species that occurs in the broad-leaved forests in ravines at 350-600 m asl in Guangdong Province, China. Photo by Yang Jia-dong, through Creative Commons.

Liu *et al.* (1988) found slightly more species (17 species) when investigating the epiphyllous liverworts from southern parts of Anhui Province, East China. Nevertheless, these occurred in only 10 genera and 4 families. Not surprisingly, 11 of these species were new for the province. Only one was new for China. The researchers were unable to show any obligate relationship between the epiphyllous liverworts and the host species. They did determine that leaves that were thin, soft, and/or rough were less suitable for these liverworts than those that were thick, rigid, and smooth. They surmised that the distribution of these liverworts is currently much narrower than it was in the distant past.

Zhu *et al.* (1994) found a greater species richness at the Fengyangshan Nature Reserve, Zhejiang Province, China. They identified 33 species of epiphyllous liverworts. These researchers found two species new to China.

Among the more diverse assemblages of epiphyllous bryophytes in China, the Wuyanling of Zhejiang Province supports 18 species, in 3 families and 13 genera (Zhang & Hu 1991). *Rhaphidolejeunea foliicola* (Figure 114) and *Leptolejeunea elliptica* (Figure 14) are the dominant epiphyllous liverworts in the region. Most of the epiphyllous species occur on leaves of *Ilex latifolia* (Figure 115), *Symplocos sumuntia* (see Figure 116), *Trachelospermum jasminoides* (Figure 117), and *Rhododendron ovatum* (Figure 118).

Ji *et al.* (2001) found 14 epiphyllous species in the Matoushan Nature reserve of Jiangxi Province, China. These occur at 450-950 m asl in evergreen broad-leaved forests. They are distributed in 5 families and 10 genera. *Leptolejeunea elliptica* (Figure 14) and *Lejeunea flava* (Figure 119) are the most common of these species.

Figure 119. *Lejeunea flava*, a common facultative epiphyllous species in the evergreen broad-leaved forest of Jiangxi Province, China. Photo by Scott Zona, with permission.

Zhu *et al.* (1992) found 27 epiphyllous liverworts in Babaoshan, Guangdong, China. Even this larger number is only distributed in 6 families. The dominant epiphyllous species are *Radula acuminata* (Figure 35), *Leptolejeunea elliptica* (Figure 14), and *Cololejeunea spinosa* (Figure 120).

Figure 120. *Cololejeunea spinosa* epiphyllous on a fern. Photo by Ying Jia-dong, through Creative Commons.

But *et al.* (2000) examined the epiphyllous liverworts on rosette leaves of *Ardisia* (Figure 121) species in China. This species in China, including Hong Kong, hosts only 12 species of epiphyllous liverworts, but these include 9 genera. There is no apparent species-specific relationship to the hosts.

Figure 121. *Ardisia crenata*. In China members of this species host only 12 species of epiphyllous liverworts. Photo by Kenpei, through Creative Commons.

But and Gao (1991) identified 28 species of epiphyllous liverworts from 25 sites in the Kowloon Peninsula, Hong Kong. These are mostly located at 30-200 m asl.

Summarizing the epiphyllous liverworts known in China up to the year 1990, Luo reported 102 species, in 11 families and 32 genera (Luo 1990). Of these, the largest family is the *Lejeuneaceae* (Figure 6-Figure 15) with 21 genera and 85 species. *Cololejeunea* (Figure 6, Figure 13, Figure 113) is the largest genus, which has altogether 48 epiphyllous species in China according to Zhu and So (2001).

Some of the Chinese epiphyllous liverworts are **facultative**, occurring on soil rocks, and tree trunks. These include *Calypogeia* (Figure 122), *Cephaloziella* (Figure 123), *Frullania* (Figure 20), *Lepidozia* (Figure 124), *Metzgeria* (Figure 19, Figure 127), *Plagiochila* (Figure 73), *Porella* (Figure 125), and *Radula* (Figure 16, Figure 35). In China, the epiphyllous species extend to 31° N. Most of the Chinese species occur in the South Yangtzi River areas at 200-2,800 m asl, where warm, moist air currents come from the Pacific and Indian Oceans, there is considerable geographical relief, and several large rivers add to the moisture.

More recently, Zhu and So (2001) studied the epiphyllous liverworts of China, recording 168 species. Of these, 14 are endemic. They recognize obligate, common facultative, and occasional epiphylls. In China, the epiphylls prefer tropical and subtropical forests with evergreen, thick, hard, smooth leaves. These epiphylls are most common in Yunnan, Hainan, and Taiwan, where they are highly frequent in the cloud-zone forests at 800-1500 m asl.

Jiang *et al.* (2014) identified six core distribution areas for the epiphyllous liverworts of China, concluding that it was the macrohabitat factors that most affected their distribution.

The genera of Chinese epiphylls tend to be pantropical in their distribution. In subtropical evergreen forests of southeast China, Wu *et al.* (1987) found four leafy liverworts to be dominant, each in a genus that is common throughout the tropics [*Leptolejeunea* (Figure 14), *Radula* (Figure 16), *Cololejeunea* (Figure 6), and *Frullania* (Figure 20)].

The genus *Cololejeunea* (Figure 6, Figure 13, Figure 113) preferentially lives on leaf surfaces or other aerial parts of tracheophytes in wet forests (Yu *et al.* 2014). Among 70 species of *Cololejeunea* in their study, Yu and coworkers found that there were only weak correlations between morphological variations and species diversity. These differences were not linked to epiphytism, although some characters did show positive or negative relationships. *Cololejeunea* is described by its small gametophyte size and the occurrence of adaptive features such as compressed, thin stems, lack of underleaves, inflated lobules, and asexual propagules (Gradstein 1997b; Gradstein *et al.* 2006; Kraichak 2012). It is able to live on substrates that are extremely ephemeral, smooth, have limited access to nutrients and water, and may have exposure to light (Yu *et al.* 2014).

Diplasiolejeunea (Figure 11, Figure 23, Figure 126) is an epiphyllous genus with a pantropical distribution (Dong *et al.* 2012). It ranges from lowlands to more than 4,000 m asl. In contrast to *Cololejeunea* (Figure 6), these species prefer to live on leathery, harder leaves. Their morphological diversity hides their genetic diversity, with four morphologically semi-cryptic species. Based on

molecular data, the genus exhibits a deep split into a **Palaeotropical** (relating to phytogeographical kingdom comprising Africa, tropical Asia, New Guinea, and many Pacific islands, excluding Australia and New Zealand; Old World tropics) clade and a Neotropical (North, South, and Central American tropics) clade. Nevertheless, *D. cavifolia* (Figure 11) and *D. rudolphiana* (Figure 126) remain valid pantropical species, providing evidence for transcontinental dispersal from the Neotropics to the Palaeotropics. The molecular data support the subgenus *Physolejeunea* (Figure 23) as Palaeotropical and the subgenera *Austrolejeuneopsis* (Figure 126) and *Diplasiolejeunea* (Figure 11) as Neotropical. The subgenus *Physolejeunea* is primarily epiphytic, whereas *Austrolejeuneopsis* and *Diplasiolejeunea* are primarily epiphyllous. But these disjunct subgenera also separate on ocelli, which are present in *Diplasiolejeunea* and absent in *Physolejeunea* and *Austrolejeuneopsis*.

Figure 126. *Diplasiolejeunia rudolphiana* (subgenus *Austrolejeuneopsis*) from the Neotropics. Photo by Michael Lüth, with permission.

A number of other Chinese studies on epiphylls have been published: Chen & Wu 1964; Wu & Lou 1978; Wu *et al.* 1983; Wu & Guo 1986; Dengke & Wu 1988; Li & Wu 1988; Li 1990, 1997; Ji & Liu 1998; Ji *et al.* 1998a, b, 1999, 2001; Peng *et al.* 2002.

Asia and the Pacific are home to the epiphyllous liverwort *Metzgeriopsis* (Figure 127). One unusual epiphyllous moss species, *Ephemeropsis tjibodensis* (Figure 128), forms horizontal protonemata on monocots, whereas it grows on lawyer vines and broad-leaved trees in Malaya and Queensland, Australia (Goebel 1888; Györfy 1916; Richardson 1981). These protonemata have photosynthetic side branches that grow upwards and end in long bristles. The basal protonemata have holdfasts that attach the moss to the leaf surface. The leafy gametophore and capsule, on the other hand, are both quite small (Bower 1935). Meijer (1972) found only one location in West Sumatra where the moss had capsules, and suggested that we need to include studies on all the epiphyllous liverworts associated with this moss to get clues as to the long-distance recent dispersal versus the ancient distribution of this unusual moss.

Figure 128. *Ephemeropsis tjibodensis* protonematal mat on a palm leaf in Fiji. Photo by Tamás Pócs, with permission.

In southern Thailand, the most recent study reports that epiphylls number 54 liverwort species and 1 moss species (Pócs & Podani 2015).

Additional studies on epiphylls include those of Japanese researchers Horikawa (1932, 1939, 1948), Kamimura (1939), Tixier (1966), and Mizutani (1966, 1975).

South Pacific Islands

Kraichak (2013) studied the epiphyllous bryophytes on the island of Moorea, French Polynesia (Figure 129). As leaves age and epiphyll succession occurs, there are significant changes in abundance, species richness, and composition. These successional changes in epiphylls on *Inocarpus fagifer* (Figure 130) do not follow any single trajectory, causing older leaves to have divergent communities.

Figure 129. Polynesia – Moorea Island. Photo by Anne Caillaud, through Creative Commons.

Figure 130. *Inocarpus edulis*, an epiphyll host. Photo by Tau'olunga, through Creative Commons.

Piippo (1994) found that 20.5% of the western Melanesian and Malaysian **Lejeuneaceae** (Figure 6-Figure 15) were endemic, but this is actually somewhat lower than the figure for liverworts in general (38.2%). She attributed the smaller number of endemic **Lejeuneaceae** to the many epiphyllous taxa. The epiphyllous taxa tend to be particularly widespread in the lowland rainforests.

Eggers and Pócs (2010) added 13 new epiphyllous liverwort species new to the flora of Samoa (Figure 131) in the South Pacific islands. Söderström *et al.* (2011) reported more than 70 epiphyllous liverwort and hornwort species from Fiji Islands. Our understanding of dispersal patterns and mechanisms, as well as the ecology, will remain poor until we have a better understanding of the distribution of the species in these poorly studied areas.

Figure 131. American Samoa forest. Photo from US Department of Agriculture, through public domain.

Africa

In Africa, epiphyllous bryophytes have not been studied in many areas. Busse (1905) was among the first to become intrigued with identifying these bryophytes in Africa. He wrote eight pages on the occurrence of these epiphylls in the rainforest of Cameroon.

Pócs has been one of the early explorers of the African epiphylls (*e.g.* Pócs 1975). In 1978 Pócs reported 185 species of epiphyllous bryophytes for the entire continent of Africa. In a country where many areas have not been explored, this number is likely to be a very low estimate. Pócs and Tóthmérész (1997) found an average of 8-9 species per leaf in epiphyllous communities in East Africa (Figure 132) and the nearby Indian Ocean islands. Degraded habitats are more likely to have only 3-4 species. The number of species within habitats varies from 14 to 25. Nevertheless, this total number does not correlate with habitat degradation due to increased **beta diversity** (ratio between regional and local species diversity).

Figure 132. Uganda – Murchison Falls, Nile River, in East Africa. Photo by Rod Waddington, through Creative Commons.

On Bioko Island in Equatorial Guinea, Müller and Pócs (2007) found 57 species of epiphyllous bryophytes, of which 55 were liverworts and 2 were mosses. One of these, *Cololejeunea papilliloba* (Figure 133) was new to Africa. Only 24 of the liverworts were previously known to the island.

Figure 133. *Cololejeunea papilliloba*, a species unknown in Africa until 2007. Photo by Barbara Thiers, NY Botanical Garden, through Creative Commons.

As in most of the tropics, in Malawi (Figure 134) the **Lejeuneaceae** (Figure 6-Figure 15) are abundant, with 64 taxa found during a single collecting trip of the BBS (Wigginton 2001) of which 45 were epiphylls. As has been common in tropical collecting trips, 51 species of the 64 taxa were new to the Malawi bryoflora.

Figure 134. Nyika miombo, Malawi, showing diminishing forests in the background. Photo by Dr. Thomas Wagner, through Creative Commons.

Host leaf size, age, and texture play important roles in the distribution of East African (Figure 132) epiphylls (Pócs 1978). Pessin (1922) found that some types of leaves are preferred and others avoided. Host specificity may play a role based on longevity of the leaf, water-holding capacity, overgrowth by mold, and other factors. Wetability is important – essential – but it is the **glabrous** (smooth) and leathery leaves that are usually colonized. This most likely is because these are the persistent leaves, and that longevity is necessary for the bryophytes to become established. But in many rainforests, it seems that host specificity is of little importance. Olarinmoye (1971, 1975a) found similar growth of *Radula flaccida* (Figure 41) on leaves of eight different taxa in a laboratory experiment. And in western Nigeria (Olarinmoye 1975b), he found no specificity among the bryophytes for any particular tree species.

Neotropics

Central America

Like Olarinmoye (1975b) in Africa, Marino and Salazar Allen (1991) likewise found that it is light and microsite, not shrub species, that determines the epiphyllous communities on *Hybanthus* (Figure 37) and *Psychotria* (Figure 38) in the Neotropics. In this case, the epiphylls grow poorly in the shade but as expected are very sensitive to quite small differences in moisture. For example, *Cololejeunea sicifolia* (see Figure 13) dominates communities in dry microsities but is rare in wet microsities, whereas *Leptolejeunea elliptica* (Figure 14) dominates in wet microsities and is relatively rare in dry microsities. When the two shrubs grow together in the same microsities, their epiphyllous communities are similar.

Equihua and Pócs (1999) reported 26 liverwort and 1 moss species growing as epiphylls in the Lacandon Forest in Chiapas, Mexico. Nine were new for the country, all members of the **Lejeuneaceae** (Figure 6-Figure 15).

It is interesting that the epiphylls worldwide are nearly all liverworts, especially in the family **Lejeuneaceae** (Figure 6-Figure 15), suggesting that this family has some special adaptations for this habitat. For example, in El Salvador Winkler (1967) found 66 species of liverworts, but only 12 species of mosses on leaves, a number that is actually quite high. In the rainforest on Bioko Island of

Guinea, Müller and Pócs (2007) found 57 species of epiphyllous bryophytes, of which only two were mosses and the remainder were liverworts.

Dauphin (1999) reported 98 liverwort, 54 moss, and 1 hornwort species among epiphytes from Cocos Island, Costa Rica (Figure 135). In this study, more than 60% of the species have a Neotropical or Pantropical distribution. Less than 5% are endemic. The **Lejeuneaceae** (Figure 6-Figure 15; many as epiphylls) and **Lepidoziaceae** (Figure 136) comprised most of the taxa. Few thallose liverworts or moss taxa were found. Dauphin attributed the greater bryophyte species count in the Galapagos Archipelago to greater habitat variety, particularly wet and dry habitats. But most of the bryophytes in this Cocos Island study area are corticolous (46%), with only 25% epiphyllous.

Figure 136. *Lepidozia cupressina* (**Lepidoziaceae**) from the Neotropics where this family is occasionally one of the epiphylls. Photo by Michael Lüth, with permission.

By contrast, Bernecker-Lücking (2000) reported 56 mosses and 106 liverworts growing on Cocos Island, Costa Rica. Of these, 45 were epiphyllous. Like the study of Lücking (1997) and Dauphin (1999), these had primarily Neotropical affinities. One surprising result of their study was the discovery of epiphylls growing on the undersides of leaves in the mountainous area, perhaps due to the high light intensity there. Most of the epiphyllous species are in

the liverwort family **Lejeuneaceae** (Figure 6-Figure 15). Other epiphyllous liverworts include *Metzgeria* (Figure 19, Figure 127) and *Radula* (Figure 16). Of the few species of mosses, most are in the genus *Crossomitrium* (Figure 21). In this study, the diversity, distribution, and density were related to microclimate, especially humidity, but they also related to differences in the vegetation.

South America

In a superhumid tropical lowland forest of Chocó, Colombia, epiphyllous bryophytes have had little study, leading to an assumption of rarity that might not be justified (Benavides & Sastre de Jesús 2011). Among these poorly known or rare species are *Cololejeunea gracilis* (Figure 137), *Leptolejeunea tridentata* (see Figure 14), and *Otolejeunea schnellii*. The researchers found that the diversity and composition of epiphyll species differs little between the palm and non-palm leaves. Disturbance affects epiphyll cover, species richness, and diversity of rare species negatively. The rare species do not agree well with the global or national red lists, again reinforcing the need for more studies.

Figure 137. *Cololejeunea gracilis* var. *linearifolia* on leaf. Photo courtesy of Tamás Pócs.

In the Colombian Amazonia, Benavides *et al.* (2004) found a total of 109 bryophyte species in a non-flooded and a floodplain forest. The life forms differed little in the two forest types, but the species of mosses and liverworts were different. On the other hand, the floodplain had more fan and mat species, whereas the non-floodplain had more epiphytic liverworts. The epiphyll species seemed to differ little between the habitats. Benavides and coworkers suggested that the epiphyll habitat is stressful enough that the habitat differences have little effect.

One of the common genera of leafy liverworts among the epiphylls is *Frullania* (Figure 20), although none of its species is typically epiphyllous. Von Konrat and Braggins (1999) reported eleven epiphyllous species in New Zealand, New Caledonia, and Colombia, with 29 more that had been listed previously as epiphylls in other regions of the world. Epiphyllous species of *Frullania* range from sea level to 2,500 m and can be considered facultative or accidental on the leaf substrate. The genus also occurs on rocks and bark. The largest number of epiphyllous *Frullania* species occurs in the floristic regions of New Zealand, New Caledonia, Macaronesia, and Madagascar (Braggins & von Konrat 1999).

Pócs (2002) explored the Neotropical species of *Cololejeunea* (Figure 6) from Ecuador and Brazil and found two new species: *Cololejeunea ecuadoriensis* and *C. schusteri*. In fact, it is unusual to find a tropical study that does not include new species. In 2018, Pócs found the epiphyllous liverwort *Reinerantha foliicola* (*Lejeuneaceae*; Figure 138) in Venezuela, in a genus previously described from Ecuador by Gradstein *et al.* (2018) as a new genus.

Figure 138. *Reinerantha foliicola*, an epiphyllous leafy liverwort from Ecuador and Venezuela. Photo modified from Gradstein *et al.* 2018, with permission.

Campelo and Pôrto (2007) provided a checklist including both epiphyllous and epiphytic bryophytes of Frei Caneca RPPN, Jaqueira, Pernambuco State, Northeastern Brazil. This was a remnant Atlantic forest at 750 m alt. They found 21 families, with the liverworts in *Lejeuneaceae* (Figure 6-Figure 15; 31 species) and the mosses in *Calymperaceae* (Figure 139-Figure 142; 7 species) predominating in species number. Most of the species (67%) are Neotropical, but 15% are pantropical. Orbán (1997) has shown that different genera of *Calymperaceae* prefer to colonize different parts of the leaves, like *Mitthyridium* (Figure 139) mostly the petiole, *Calymperes* (Figure 140), *Leucophanes* (Figure 141), and some *Syrrophodon* (Figure 142) the midrib, while other *Syrrophodon* species grow on the margin.

Zartman and Ilkiu-Borges (2007) have provided a key, descriptions, and illustrations for the epiphyllous bryophytes of Central Amazonia. To facilitate bryological work in both English and Spanish, the keys and descriptions are provided in both languages.

Bromeliad Basins

Some bryophytes live on bromeliad leaves (Figure 143) and in the basins of water provided by them. *Bromeliophila helenae* and *B. natans* (Figure 144) grow exclusively in the leaf axils of bromeliads (Gradstein 1997a; Gradstein *et al.* 2001; Benavides & Callejas 2004; Heinrichs *et al.* 2014). *Bromeliophila natans*, which like its sister species is barely distinguishable from *Lejeunea* (Figure 3), is apparently endemic to southeastern Brazil (Gradstein 1997a). It occurs, often submerged, in terrestrial bromeliads such as *Vriesea glutinosa* (Figure 145), *Aechmea nudicaulis* (Figure 146), and *Quesnelia arvensis* (Figure 147), mostly on open sites in the coastal rainforest. *Bromeliophila helenae*, a montane species, is known from the Guayana Highland of Venezuela and on the island of Dominica in the central Lesser Antilles. It grows in the basins of both terrestrial and epiphytic bromeliads such as the terrestrial *Brocchinia hechtiioides* (see Figure 148-Figure 149).

In Puerto Rico, 13 out of 65 bromeliads sampled near the radiation center in 1965 had bryophytes in their basins (Maguire 1970). Mosses in these aerial basins are rare, with the only known species being *Philophyllum tenuifolium* in the *Leucomiaceae*, occurring submerged or emergent in *Vriesia* (Figure 145) and *Nidularium* (Figure 150) of Guatemala, SE Brazil, and Peru (Gradstein *et al.* 2001). The basin of water created in the middle of the youngest leaves is available to keep the bromeliad hydrated and thus provides an aquatic habitat for bryophytes.

Fragmented Habitats

Deforestation is creating forest fragments in many areas of the tropics. Oliveira *et al.* (2011) reported that they could detect no edge effect on epiphytic bryophytes in a fragmented landscape of an Atlantic forest in northeast Brazil. Furthermore, canopy openness was not correlated with bryophyte richness. Here we explore if this absence of edge effect holds as well for the epiphyllous bryophytes in the Neotropics.

Zartman (2003) discussed the effects of this habitat fragmentation on epiphyllous bryophyte communities in central Amazonia. He found that regionally common taxa were often reduced in epiphyll diversity in small forest fragments. On the other hand, rare taxa were often more abundant in fragments than in continuous forest habitat. Larger fragments (100 ha) exhibited higher species richness, abundance, and among-site variation than did the smaller fragments (1 & 10 ha).

Like Daniels (1998), Zartman and Nascimento (2006) took advantage of the accelerated life cycles, high rates of local extinction, and naturally patchy substrates of epiphyllous bryophytes to look at the effects of habitat fragmentation. They examined both local abundance and regional distribution of 67 epiphyllous bryophyte species in Amazonia. The landscape was experimentally fragmented and demonstrated that changes in local abundance caused by habitat fragmentation can be explained by fragment size rather than nearness to the forest edge. The simultaneous inter-specific decline in epiphyll local abundance and regional distribution in small (1-10 ha) forest fragments support metapopulation predictions of the importance of immigration in ameliorating risk of patch extinction (*i.e.*

the **rescue effect**). They concluded that their results provide indirect evidence that dispersal limitation, not compromised habitat quality due to edge effects, can account for species loss from small tropical forest fragments. They further concluded that preservations of rainforest areas of at least 100 ha are necessary for the long-term persistence of these epiphyllous communities.

Alvarenga and Pôrto (2007) explored eight Atlantic forest fragments in Pernambuco, Brazil, ranging in size from 7 to 500 ha to determine the effects on epiphytes and epiphylls. Habitat fragmentation existed in the lowland and submontane forests (Alvarenga & Pôrto 2007). Despite the increase in richness, diversity, and abundance with altitude, clear evidence exists that fragment size and isolation are more important as determinants of these community parameters. Isolation is the most important factor, emphasizing the importance of dispersal. Furthermore, the greatest proportion of shade species occurs in larger fragments with lower degrees of isolation. Fragments also increase the number of species with larger niches (**generalists**) while decreasing the number with smaller niches that were likely to specialize on shady or sunny areas.

In the Eastern Arc Mountains of Kenya, Malombe *et al.* (2016a) investigated fragmentation and its effect on the sensitive epiphylls. Using a disturbance gradient up to 200 m from the forest edge in three moist forest fragments, they collected at least four leaves from each host species. They found 96 epiphyllous bryophyte species. No correlation was evident between the environmental variables (relative humidity, temperature) and the forest edge gradient. Nevertheless, epiphyll diversity differs with site-specific characteristics. Forest edge distance does not have a significant influence on richness or distribution of the epiphyllous bryophyte species. Instead, these parameters depend on microhabitat variables such as tree species composition, sunlight exposure, and spatial and dimensional canopy structure.

Malombe *et al.* (2016b) also examined fragmentation effects on the composition, abundance, and species richness of epiphyllous bryophytes in fragments of tropical cloud forests in the Eastern Arc Mountains of Kenya. Again using a disturbance gradient extending 200 m out from the forest edge, they collected four leaves from each phorophyte at three sites, totalling 1,387 leaves from 489 phorophytes. This revealed 95 species of bryophytic epiphylls. Once again, richness did not change with distance from the forest edge. And as in their moist forest fragment study, richness depended on the tree species composition and microhabitat, including exposure to sunlight and canopy structure.

Hylander *et al.* (2013) studied fragmentation effects in the moist Afromontane forests of Ethiopia. This study differed from most in that the forest margins were still in heavy use by local farmers, creating a mosaic landscape. Going into the forest instead of away from it, they found strong edge effects on canopy cover and number of stumps. Heavy usage by humans was indicated by paths, beehives in trees, and timber harvesting, and perennial crops such as coffee and spices. The number of epiphyllous bryophytes increased from 20 m to 75 m inward from the edge. They concluded that the edge effects on epiphyllous bryophytes do not get worse over time.

Silva and Pôrto (2010) similarly studied the species richness and diversity of both epiphytic and epiphyllous bryophytes on an edge to interior gradient in a large remnant of the Atlantic forest in Northeast Brazil. The researchers estimated light differences using hemispherical photographs. They found no significant difference in species richness or diversity based on distance from forest edge up to 1084 m inside. Altitude, however, causes an increase in bryophyte diversity, especially for epiphylls and shade-tolerant bryophytes. Canopy cover is somewhat less important than altitude. Differences within the forests are more important than distance from the edge.

Alvarenga *et al.* (2009) also studied bryophytic epiphylls in fragmented forests of northeastern Brazil, from forest edge to 100 m within the fragment. They found decreasing abundance both locally and regionally resulting from habitat loss. They concluded that this is related to both sexual and asexual expression. Frequently-fertile species are more frequent in forest fragments than infertile species. Nevertheless, the landscape and habitat quality are more important in epiphyll richness and presence than distance from forest edge. As in the above studies, habitat modification is less important than forest characteristics, but they nevertheless play a role. They concluded that fragmentation results in negative and long-term effects in fragmented landscapes. Connectivity between patches is important in successful conservation.

Zartman *et al.* (2012) experimented with recolonization rates by stripping bryophytes from their branches. When both local and neighboring phorophytes within 400 m² plots were experimentally denuded, the extinction events increased, along with a reduction in colonization. When no denuding occurred, losses of the epiphylls were subject to rescue effects from neighboring leaves. The researchers suggest that negative density-dependent growth in within-leaf populations indicates resource limitation or intraspecific competition.

Zartman and Shaw (2006) considered the demographic mechanisms causing species loss in the tropics to be greatly underexplored. To contribute to the understanding of the impact of fragmentation, they chose the epiphyllic leafy liverworts *Radula flaccida* (Figure 41) and *Cololejeunea surinamensis* (see Figure 71). They transplanted these two species to study sites with areas ranging 1, 10, 100, up to 110,000 ha. All the transplants exhibited significantly positive local growth with a nearly constant per-generation extinction probability of 15%. In reserves of 100 ha or greater, the colonization rate nearly doubled (to 48%) compared to small reserves (27%). They considered this an indication that epiphyll loss in small fragments was due to reduced colonization.

Pócs (1996) emphasized that conservation of epiphytes "can only be achieved through the rigorous protection of the forests."

Sampling Epiphylls

Collection of the epiphyllous bryophytes requires the same techniques as for bryophytes on branches at the same level in the forest, including use of ropes, bow and arrow, or climbing. Ecological methods, however, may be somewhat different.

In a study of epiphylls in Colombia, Benavides and Sastre de Jesús (2011) used 10 x 10 cm quadrats in 30

plots, totalling 240 samples. They recommend the Floristic Habitat Sampling, a method that focuses on mesohabitats as the sampling unit. Unfortunately, that does not provide the randomness required for statistical comparisons. They therefore recommend a combination of a systematic grid of 1-several km² with Floristic Habitat Sampling within the plots.

Vanderpoorten *et al.* (2010) emphasized that many bryophytes are annual or identifiable during only part of the year. They claimed that completely random plot sampling or systematic sampling are both likely to miss species and variation within the sampling area unless the sampling effort is very high (number of plots, large number of sampling dates).

The IUCN uses the Area of Occupancy for recording rare species. This is defined as the area calculated by summing all 2x2 km grid squares that actually have the taxon. But Vanderpoorten and coworkers recommend reducing the mesh size because the Area of Occupancy values decline sharply with a reduction in scale. This occurs because the bryophyte species have a more linear and fragmented distribution.

Collection is necessary to identify or verify most bryophytes and to permit DNA analysis now or later. For epiphyllous bryophytes, it is necessary to collect entire leaves that host them and to put them in new papers in a plant press so that the host leaf remains flat. They should be lightly pressed until they are dry.

Bryophytes living on leaves are typically collected by collecting host leaves. These are preserved by pressing and drying. Pócs and coworkers (Pócs 1978; Pócs & Podani 2015) found that 30 (50 preferred) randomly collected leaves from a hectare are usually representative of most species occurring there. Each leaf can be considered as a separate stand which can be studied and compared by the methods generally used in phytosociology. These should be examined microscopically. Pócs (1978, 1982b) counted the number of foliicolous plantlets on each leaf and related that number to leaf area. Frequency is used to represent the presence of a certain species on different leaves among the samples collected.

To determine cover values, one can use a celluloidin film solution spread over the leaf (Tamás Pócs, unpublished). Once this has hardened, it can be removed, together with the foliicolous community, and examined under a microscope at low magnification using a square grid ocular micrometer. This can provide the data to determine cover values.

Carroll (1979) developed another method when surveying the epiphyllous organisms on Douglas fir needles (*Pseudotsuga menziesii*). He used photographs of random sections of needles and extrapolated these to total needle area. This method is especially useful where collecting is not allowed or sampling would be too destructive.

Benavides and Sastre de Jesús (2009) similarly used digitized images for estimating bryophyte cover. They compared accuracy, efficiency, and objectivity among three methods: Braun-Blanquet cover classes, grid percentage, and digital image processing. Two observers used clay tiles that had been planted with *Neckeropsis disticha* (Figure 151) and estimated cover by the three methods. Accuracy was determined by comparing cover values with the dry weights. Efficiency was a measure of time and data

variability. Objectivity was compared between observers. The digital method was the most efficient in time in the field ($p < 0.001$) and furthermore had the least variation among the data ($p = 0.01$). This method is especially useful when repeated measures through time are needed and is more accurate when the cover is small, as in epiphylls.

Figure 151. *Neckeropsis disticha*, an epiphyll. Photo by Jan-Peter Frahm, with permission.

Epiphylls typically have associated **Cyanobacteria** that fix nitrogen, benefitting both the epiphylls and the leaf. Some leaf leachates benefit the epiphylls. Bryophytes may accumulate heavy metals, causing the host leaf to have greater concentrations of these. The epiphylls also seem to protect the host leaves from at least some kinds of herbivory. But sometimes rhizoids penetrate the epidermal cells, permitting the entry of leaf pathogens. They can also interfere with light, but the leaves seem to be able to compensate for this. Bromeliads growing in the trees can provide a unique habitat for bryophytes.

Species richness varies with habitat, but not as much as one might expect. Moisture is the main limiting factor, with light and temperature also being important. Disturbance and pollution decrease species richness. Comparison of geographic areas is still in its infancy, with many undescribed species and nomenclatural problems. Nevertheless, it is clear that the family **Lejeuneaceae** is the most species rich family of epiphylls.

Fragmented habitats may limit dispersal, thus reducing frequency and diversity.

Sampling requires some of the sampling techniques for epiphytes in general. They can be quantified using quadrats. Digitized images of marked quadrats are useful for quantifying growth.

Summary

Bryophytic epiphylls are almost entirely leafy liverworts. Epiphylls are common on leathery, persistent leaves, but colonize more rapidly on short-lived leaves, most likely due to antibiotic compounds in the persistent leaves. Close adherence to the leaf, numerous rhizoids, adhesive secretions, sacs and grooves to hold and transport water all help epiphylls survive on the alternately wet and dry leaves of their hosts. Crustose lichens often colonize as epiphylls first, then liverworts, then foliose lichens that may overgrow the liverworts. In other cases, the liverworts are first to colonize.

Liverworts hold water on the leaf surface and may make it more suitable for fungi. On the other hand, they might provide secondary compounds that inhibit fungal growth. The bryophytes can provide evaporative cooling as they lose water over a longer period of time than do the uncolonized leaves.

Epiphylls necessarily have short life cycles that can be completed before the leaf falls. Epiphyllous **Lejeuneaceae** have protonematal spores that adhere to the leaf surface and are able to germinate quickly. Asexual reproduction is particularly common but is limited by colony size. Asexual reproduction may decrease in dry months, whereas sporophyte density may be unrelated to the rainy season.

Host leaves may have drip tips, but their role is controversial. Leaf longevity is important, and evergreen leaves may even have epiphylls in moist forests outside the tropics. Epicuticular wax chemistry seems to affect epiphyll growth.

Acknowledgments

My appreciation goes to Noris Salazar Allen for her efforts to make this chapter reliable and up-to-date. Her helpful discussions kept me going on this part of the world I know so little about.

CHAPTER 8-7

TROPICS: LOWLAND RAINFORESTS

Figure 1. Amazon rainforest near Manaus, Brazil aerial view. Photo by Neil Palmer, through Creative Commons.

Lowland Rainforests

Undeveloped areas of the humid tropics are characterized by tropical rainforest. As shown by Frahm and Gradstein (1991) there are five tropical rainforest belts and their elevational limits are higher on continents than on islands due to the "mass elevation effect." On the continent the forest line is normally ca. 4,000 m asl but has been lowered to ca. 3,200 m in many places due to human impact, reaching as high as 1,500 m asl near the Equator and up to 700 m at the upper and lower tropical borders (Pócs 1982). The area covered, originally at 12% of Earth's surface, is estimated at only about 5% of Earth's surface now (Butler 2006), and it is still rapidly diminishing.

The lowland tropical rainforests (up to 500 m asl) are characterized by their great height, up to 60 m tall (Pócs 1982), with many evergreen species, particularly in areas that have a dry season. With annual rainfall greater than 1500 mm and an average temperature of 20-27°C (Pócs 1982), with little seasonal change, the trees flourish and the canopy is dense. Thus, the forest floor is characterized by limited light, even for a bryophyte. This unfavorable light level, in particular in the lowland rainforest, is made more unfavorable to bryophytes by the heavy leaf litter

(Gradstein 1992; Delgadillo & Cardenas 2002). The result is that the tropical rainforest floor has lower moss species diversity than in temperate regions (Hallingbäck 1992).

Richards (1954) was among the first to attempt a description of these lowland forests. He recognized four main bryophyte synusia in the Moraballi Creek rainforest of British Guiana: high epiphytes, shade epiphytes, epiphyllae, and dead wood, noting their distinctness in both structure and floristic composition. Nevertheless, few species are very frequent. Exceptions to this are *Calymperes lonchophyllum* (see Figure 2) and *Octoblepharum albidum* (Figure 3); with the exception of the epiphyllous habitat, these two species occur in all the other synusia. The epiphylls are almost entirely highly specialized species exclusive to the phyllosphere. Richards noted that growth/life forms differ among the synusia. He further remarked on the absence of bryophyte synusia on the ground at Moraballi Creek, the presence of an epiphyllous community, and the distinct dominance of liverworts, especially *Lejeuneaceae* (Figure 62-Figure 64). Although he noted that the forest was probably poorer in species than many temperate forests, his basis for this statement did not include knowledge of the diverse canopy bryophytes. Richards further claimed that these

comparisons would likewise apply to the lowland rainforests in Africa or the Indo-Malayan region. They would not, however, apply to the montane forests.

Figure 2, *Calymperes* sp.; *C. lonchophyllum* is a species found in all synusia except epiphyllous at Moraballi Creek rainforest of British Guiana. Photo by Niels Klazenga, with permission.

Figure 3. *Octoblepharum albidum*, a species found in all synusia except epiphyllous at Moraballi Creek rainforest of British Guiana. Photo by Portioid, through Creative Commons.

In lower elevations, below 1500 m, the forest typically has a complex canopy. Trees have a variety of heights, some of which may reach 50-60 m tall. Levels in these forests can be classified as emergent, canopy, understory, and forest floor. This provides a variety of conditions for bryophytes, and often the within-tree diversity is greater than that between trees.

The canopy buffers and protects the lower strata of the forest. It reduces turbulence by absorbing wind energy; in one Costa Rican study, canopy (10 m) wind speeds were 11.3 m sec^{-1} while those on the forest floor (2 m) were 4.0 m sec^{-1} (Lawton 1980). The canopy modifies the temperature by absorbing heat and radiation (Nadkarni 1994). Its leaf surfaces absorb CO_2 and emit water vapor.

It modifies the light quality by absorbing red and transmitting green, and it can reduce light intensity by as much as 98% before it reaches the forest floor (Cachan 1963). But for the canopy dwellers, being near the upper surface means intense sunlight, more temperature and humidity extremes, higher water stress, and a nutrient supply dependent on that in rainfall (Nadkarni 1994).

Although irradiation and desiccation are high in the canopy, the inner canopy affords some protection (Gradstein & Pócs 1989). Hence, dense mats or cushions are able to develop here, including the liverwort *Frullania* (Figure 4) and the moss *Macromitrium* (Figure 5). When it is very humid, **pendent** bryophytes and epiphyllous lichens and liverworts become established. In Bolivia (Figure 6), Acebey *et al.* (2003) found that rough mats appeared almost exclusively in the canopy, apparently requiring the high light intensity. This same restriction of rough mats to the high light zone of the upper canopy occurs in Guyana (Cornelissen & ter Steege 1989), and undoubtedly other areas of the tropics.

Figure 4. *Frullania* sp. in the Neotropics, where it can form dense cushions in the lowland rainforest inner canopy. Photo by Michael Lüth, with permission.

Costa (1999) studied the rainforest epiphytes in six forest types in the lowland rainforest of Rio de Janeiro, southeastern Brazil (Figure 7). She found 39 moss species and 36 liverwort species. The highest species richness occurred in the mature secondary hillside rainforest (43 species) whereas the lowest diversity was in the highly degraded hillside rainforest (6 species) and hillside secondary rainforest (5 species). As in Guyana (Cornelissen & Gradstein 1990), Costa found that the **Lejeuneaceae** (Figure 62-Figure 64) was one of the most important families (30% of species), with the moss family **Sematophyllaceae** (Figure 41) being second with 7 species (10%). In this case, 45% of the species were exclusively in the canopy. Mats were the most common life form of the six found there. Shade epiphytes are more susceptible to deforestation damage than are sun epiphytes, with many species not returning after 20-45 years. However, after 80 years, the bryophyte flora has recovered to that of the primary forest.

Figure 7. Rainforest canopy, Brazil. Photo by Ben Sutherland, through Creative Commons.

The Tropical Atlantic Rainforest in southeastern Brazil (Figure 7) has the high diversity of 338 taxa, with 49 families and 129 genera represented, with the altitudinal zones accounting for the richness (Costa & Lima 2005).

As expected, the lowest diversity was in the Lowland Atlantic Rainforest; the highest was in the Montane Atlantic Rainforest. The moss family **Sematophyllaceae** (Figure 41) had 19% of the taxa in the lowland forest, **Meteoriaceae** (Figure 8) had 10% in the montane forests, and **Dicranaceae** (Figure 9) had 18% in the upper montane forests. Taxa with wide distributions in the Neotropics accounted for 40% of the total taxa and were important in all the forests. The taxa restricted to Brazil were second most important in the upper montane and montane forests.

Figure 9. *Campylopus pilifer* (**Dicranaceae**), a family having 18% of the taxa in the upper montane forests of southern Brazil. Photo by Michael Lüth, with permission.

In Australian rainforests (Figure 10), liverworts usually dominate the bryophytes in lowland vine forests (Ramsay *et al.* 1987). Mosses are the more common bryophytes in wet higher altitudes or valley forests. Such bryophytes as *Chandonanthus* (Figure 11), *Dicnemon* (Figure 12), and *Leptostomum* (Figure 13) can be so heavy when they are wet that they become important in pruning the upper and dead branches.

In Australia, members of the epiphytic and saxicolous (growing on or among rocks) moss genus *Macromitrium* (Figure 5) are found primarily in the rainforest (Figure 10) (Ramsay *et al.* 1987). These reach their greatest diversity in the lower elevation ravine rainforests. These habitats form an archipelago of refugia where the remnant patches of forest occur along the eastern and northern coast of the continent.

Streams often create a habitat suitable for a rich bryophyte flora (Dixon 1935; Shevock *et al.* 2017). At Tenompok in Borneo, smaller shrub and tree vegetation is adorned with thin pendulous mosses and liverworts. Tree trunks are thinly covered, but cushions are nearly absent. However, on the more exposed steeper slopes the small trees have moss and liverwort cushions. At higher elevations, these cushions are dominated by liverworts. Above ~2,000 m, up to ~3,000 m asl, the liverwort *Mastigophora* (Figure 14) and other liverworts provide most of the ground cover in the open ridge forest. In more sheltered places, different liverworts occur. Mosses, while present, are not abundant in the ridge forest. *Sphagnum* (Figure 15) cushions can be found, but not abundantly.

Figure 14. *Mastigophora diclados*; in Borneo, this genus, along with other liverworts, provides most of the ground cover in the open ridge forest. Photo by Cesar Garcia, through Creative Commons.

Figure 15. *Sphagnum junghuhnianum*; *Sphagnum* cushions are present but uncommon in the ridge forests of Borneo. Photo from Taibif, through Creative Commons.

In the Guianas, Pardow *et al.* (2012) described a new type of tropical lowland forest, the tropical lowland cloud forest. This forest type has a high epiphytic bryophyte

species richness. This diversity is facilitated by frequent early morning fog in valley locations. Lowland cloud forests and lowland rainforests differed in the functional composition of bryophytes in the canopy, especially the mid and outer canopy. The cloud forest reached a higher biomass and cover of both bryophytic and tracheophytic epiphytes. It similarly had a greater diversity of bryophyte life forms. the typical cloud forest life forms of **tail**, **weft** and **pendants** were almost completely absent in the lowland rainforests, making life forms an easy way to characterize differences in these two forest types.

Figure 16. Top of lowland rainforest canopy in French Guiana. Photo by Renske Ek, courtesy of Robbert Gradstein.

Obregón *et al.* (2011) studied the fog frequency in tropical lowland forests. Its occurrence is frequent in the lowland valleys of central French Guiana (Figure 17). It reaches its maximum before sunrise, with a duration of about 4.6 hours. This fog forms when rain saturates the soil, creating greater evapotranspiration. This morning fog follows an increase in temperature differences between the valleys and hill sites after the sun sets. This increase in fog provides an early morning moisture that provides suitable conditions for photosynthesis while the day is still somewhat cooler, supporting a higher epiphyte diversity in the lowland cloud forest compared to the hills. This fog even makes photosynthesis possible in the early mornings of the dry season.

Amazonia Lowlands

Prance (1980) decried the mixed terminology being used to describe the Amazonian floodlands. Hence, reading older literature and comparing vegetation types can be challenging and lead to misconceptions. Prance recommended creating terminology based on vegetation cover type, water type, and duration of flooding.

The Amazonian lowlands (Figure 1, Figure 18) include both the dry land (**terra firme**) and the wetlands, including mangrove (Figure 19) forests and estuaries. The latter two are saltwater habitats that are not hospitable for bryophytes. Kürschner and Parolly (1998) reported on the shade epiphytes of the Amazonian lowlands of Peru. Since then a number of studies have contributed to our understanding of the bryoflora of Amazonia.

Figure 18. Canopy of lowland rainforest in Colombian Amazon. Photo by Laura Campos, courtesy Robbert Gradstein.

Figure 19. Mangroves in Dominican Republic. Photo by Rachel Doherty, through Creative Commons.

In 1985, Amazonia occupied nearly 6,000,000 km² of South America (Pires & Prance 1985). Since then, deforestation for agriculture, cattle ranching, and logging has greatly reduced its size (Fearnside 2005; Heckenberger *et al.* 2007; Nepstad *et al.* 2008; Clement *et al.* 2015; Butler 2017). Some of the sub-basins have lost up to 33% since 1970 (RAISG 2015). In 2018, the Amazon Basin of 7,000,000 km² had only 5,500,000 km² covered by the rainforest (Wikipedia 2018). Although these numbers do not seem to agree, they nevertheless indicate that considerable loss of Amazonian lowland rainforest is disappearing.

The Amazonian lowland occurs mostly below 100 m asl and rarely rises above 200 m asl. Classification of the vegetation is based primarily on the topography. Two main types of forest vegetation occur: the **terra firme** (dry land) and the inundated formations [**igapó** (Figure 20) and **várzea** (Figure 21)], terms exclusive to Amazonia and all of which are primarily forest land. In addition, some areas have savannah vegetation, but this is a much smaller percentage of the land. Additional more specialized wetland vegetation types are mangrove swamps, **restinga** (spit and distinct type of coastal tropical and subtropical moist broadleaf forest in eastern Brazil), **buritizal** (periodically inundated palm thicket characterized by buriti – the palm *Mauritia flexuosa*), and **pirizal** (cariacal – extensive, emergent vegetation of small, stagnant lakes and puddles). The terra firme forest occupies the largest percentage of the area in Amazonia.

Figure 21. Várzea forest, Marajó, Brazil. Photo by Dayse Ferreira, through Creative Commons.

The lowland forests typically have a strong gradient of humidity and light, with humidity decreasing and light intensity increasing from the ground to the upper canopy (Figure 22-Figure 23) (Leon-Vargas 2001).

Figure 22. Humidity in ascending heights in the Amazon lowland forest. Modified from Leon-Vargas 2001.

Figure 23. Light intensity at ascending heights in a Neotropical lowland forest. Modified from Leon-Vargas 2001.

Amorim *et al.* (2017) compared bryophyte distribution in southeastern Brazil. They considered two distinct groupings, the inland areas and the coastal areas, with

annual precipitation and temperature influencing the floristic similarity among the coastal areas. Distance from the ocean and altitude were the dominant factors influencing the bryophyte composition of the inland areas.

Lisboa (1976) characterized the Amazonian plain as having poor soil nutrients. Unlike many rainforests, the light intensity can in some areas be very high, resulting in high air (38°C) and soil (42.3°C) temperatures. This combination of high light and high temperatures restricts the bryophyte community. Nevertheless, they found 34 bryophyte species, representing the moss families **Calymperaceae** (Figure 2), **Leucobryaceae** (Figure 40), **Leucodontaceae** (Figure 24), **Plagiotheciaceae** (Figure 25), **Sematophyllaceae** (Figure 41), and liverwort families **Frullaniaceae** (Figure 4, Figure 26), **Lepidoziaceae** (Figure 53), **Lejeuneaceae** (Figure 62-Figure 64), **Odontoschismaceae** (currently included in **Cephaloziaceae**; Figure 27), **Plagiochilaceae** (Figure 28), **Radulaceae** (Figure 73), and **Zoopsidaceae** (currently included in **Lepidoziaceae**; Figure 29). The liverwort *Frullania nodulosa* (Figure 26) stood out as the most frequent species, a species with wide ecological amplitude. Bark of the tree *Aldina heterophylla* (**Rubiaceae**) proved to be a preferred substrate, providing old age, thick bark, and otherwise good conditions for bryophyte community development.

Benavides *et al.* (2006) claimed the first bryophyte surveys from the Colombian Amazon. They divided the bryophytes into mosses and liverworts and into four life-form classes to describe floodplains, swamps, terra firme forests, and white-sand areas. They identified 50, 45, 45, and 32 species respectively. The higher number of species in the floodplains and swamps suggested the importance of moisture in delimiting communities. **Fan** life forms in the floodplains (Figure 30) further attested to the higher humidity there. Liverworts were more likely to form **mats** in both floodplain and terra firme habitats. And liverworts had greater species richness in the white-sand plots, suggesting a greater importance of light intensity than humidity for these species. Tree bark was the most important substrate for both bryophytes and liverworts in both floodplain and terra firme (Figure 31) (Benavides *et al.* 2004). The floodplain (várzea – Figure 21) differed markedly in species from the other three habitats.

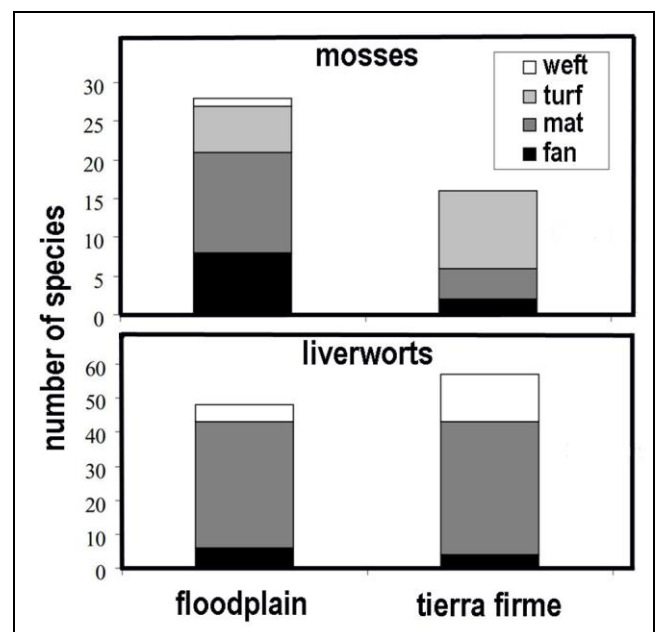

Figure 30. Bryophyte life forms in Terra Firme vs Floodplain. Modified from Benavides *et al.* 2004.

Figure 31. Bryophyte substrates in terra firme vs floodplain. Modified from Benavides *et al.* 2004.

Leal *et al.* (2010) considered the possibility of using bryophytes (and other taxa groups) as surrogate taxa to indicate species richness in the Brazilian Atlantic forest and caatinga. But they did not include the bryophytes in their sampling of the caatinga. They found that the species richness of the various taxa groups (bryophytes, pteridophytes, trees, ants, euglossine bees, birds, and mammals; total of 768 species) were significantly correlated with each other. Only two taxa (trees and ants) were required to have excellent surrogacy for species richness of all groups. Bryophytes did not seem to be good surrogates for the richness of the other taxa groupings.

Valente *et al.* (2009) described the mosses in a segment of the Atlantic forest in Bahia State, Brazil. They found 61 moss species, distributed in 23 families. The most species-rich family was **Sematophyllaceae** (7 spp.; Figure 41), followed by **Orthotrichaceae** (6 spp.; Figure 5), **Pilotrichaceae** (5 spp.; Figure 32), **Calymperaceae** (5 spp.; e.g. Figure 2), **Leucobryaceae** (5 spp.; e.g. Figure 40), and **Meteoriaceae** (4 spp.; Figure 8). Corticolous species predominated, with 70% of the species, followed by **epixylous** (on wood with no bark) having 23% of the species. The area was species-rich, with 24% of the bryophytes in the Bahia State represented there.

Epixylic bryophytes (living on logs with no bark) in the Atlantic forest of Brazil supported 35 species of bryophytes, not counting the **Lejeuneaceae** (Figure 62-Figure 64) (Germano & Pôrto 1996, 1997). These comprise 11 families of mosses: **Calymperaceae** (Figure 2), **Pilotrichaceae** (Figure 32), **Fissidentaceae** (Figure 71, Figure 91-Figure 93), **Hookeriaceae** (Figure 33), **Hypnaceae** (Figure 34), **Leucobryaceae** (Figure 40), **Leucomiaceae** (Figure 35), **Orthotrichaceae** (Figure 5), **Plagiotheciaceae** (Figure 28), **Sematophyllaceae** (Figure 41), and **Thuidiaceae** (Figure 36), and 5 families of liverworts: **Aneuraceae** (Figure 55), **Frullaniaceae** (Figure 4), **Geocalycaceae** (Figure 37), **Plagiochilaceae** (Figure 28), and **Radulaceae** (Figure 73). These included 8 species new for northeastern Brazil.

Pires and Prance (1985) considered the dense tropical forests of the Amazon to be fireproof. These dense forests create many niches, permitting the occurrence of many

species. Costa (2003) reported 514 species in the Amazonian rainforest. Nevertheless, only 106 species are known from the state of Acre, Brazil, suggesting that the area has been understudied. After only two field trips, Costa was able to increase the known flora by 50%. These trips yielded 50 species that were new for the state and 10 more that were "interesting." In an earlier study, Vital and Visnadi (1994) reported only 76 species, and at that time 66 were new records for the state of Acre. This report included one hornwort, *Notothylas vitalii* (see Figure 38).

Figure 38. *Notothylas orbicularis*; *Notothylas vitalii* is the only species of *Notothylas* known to Costa in 1985 for the Amazonian lowland rainforest. Michael Lüth, with permission.

New species most likely await us in these forests. Moura *et al.* (2012) noted the abundance of *Lejeunea* (Figure 39) species in the low várzea (Figure 21) forest in lower Amazon, Pará, Brazil, and reported the new species *Lejeunea combuensis*.

Terra Firme

Oliveira and ter Steege (2013) used standardized sampling methods for epiphytic bryophytes in nine localities in the Amazon basin terra firme forests. They sampled five height zones from forest floor to canopy on

eight canopy trees at each locality, generating 3,014 records and 222 species plus 39 morphospecies. As is typical in the tropics, the most common family was **Lejeuneaceae** (Figure 62-Figure 64) (55% frequency), along with the mosses **Calymperaceae** (Figure 2) (8%), **Leucobryaceae** (Figure 40) (4%), and **Sematophyllaceae** (Figure 41) (4%). No geographical gradient was evident in species richness or composition. Nevertheless, richness differences were evident, with the greatest richness in Saül of French Guiana and Tiputini of Ecuador, compared to other localities. Of the 155 species occurring in more than one locality, 57 were specialists. A total of 29 species were found only in the canopy.

Figure 40. *Leucobryum martianum*. Members of its family, **Leucobryaceae**, are common on trees in the Amazon basin. Photo by Jan-Peter Frahm, with permission.

Figure 41. *Sematophyllum* sp. (**Sematophyllaceae**), a well-represented family from the Amazon lowlands. Photo by Michael Lüth, with permission.

Alvarenga and Lisboa (2009) reported 120 species of bryophytes from the Amazon lowlands. Among these, the **Lejeuneaceae** (Figure 62-Figure 64) species are by far the most abundant with 58 species, followed by **Calymperaceae** (Figure 2) (13 spp.), **Sematophyllaceae** (Figure 41) (9 spp.), and **Plagiochilaceae** (Figure 42). Of these 120 species, 97 are epiphytic; 65 are **epixylic** (growing on wood that has lost its bark). Only 27 species are epiphyllous and only 15 occur on the ground. The most diverse ecosystem is the terra firme forest. The liverworts are strong dominants on leaves, with dominance gradually shifting among the habitats. Liverworts are only slightly dominant on live and dead trunks, and mosses are dominant on the other substrates.

Figure 42. *Plagiochila* sp. from the Neotropics; **Plagiochilaceae** is a common family in the Amazon lowlands. Photo by Michael Lüth, with permission.

Sierra *et al.* (2018) provided a more comprehensive study on the Amazon lowlands, listing 150 species from 712 collections. These were comprised of 109 liverworts and 41 mosses. Of these 104 species lived as epiphytes and 38 as **epiphylls** (species living on leaves). Another 31 species occurred on decaying logs, 16 on rocks, and 24 on soil. But of these species, 68 occurred in only one or two samples. As is obvious from the numbers in each habitat, many were not exclusive to one habitat.

As in many other communities, the most species-rich liverwort families in the studied Amazon lowlands were **Lejeuneaceae** (81 species) and **Lepidoziaceae** (11 species) (Sierra *et al.* 2018). The three most species-rich genera were *Cheilolejeunea* (15 spp.; Figure 43), *Cololejeunea* (12 spp.; Figure 60-Figure 61), and *Ceratolejeunea* (6 spp.; Figure 63), all in the **Lejeuneaceae**. The most common liverwort species were *Cheilolejeunea aneogyna* (see Figure 43), *Pycnolejeunea contigua* (see Figure 44), *Cheilolejeunea neblinensis*, *Cololejeunea surinamensis* (see Figure 60-Figure 61), *Archilejeunea fuscescens* (see Figure 45), *Acrolejeunea torulosa* (see Figure 46), and *Vitalianthus aphanellus*, all in the **Lejeuneaceae**.

Figure 43. *Cheilolejeunea* sp., a species-rich genus in the Amazon lowlands. Photo by Michael Lüth, with permission.

Figure 46. *Acrolejeunea* sp.; *Acrolejeunea torulosa* is one of the common species in Amazonian lowlands. Photo by Peter de Lange, through Creative Commons.

The most species-rich moss families in the studied Amazon lowlands were **Calymperaceae** (16 species), and **Sematophyllaceae** (9 species), again being common families throughout the Neotropics (Sierra *et al.* 2018). The most species-rich genus of mosses was *Syrrhopodon* (12 spp.) in the **Calymperaceae**. The most common moss species were *Leucobryum martianum* (**Leucobryaceae**; Figure 40) and *Syrrhopodon xanthophyllus* (see Figure 47).

Figure 47. *Syrrhopodon lycopodioides* from the Neotropics; *Syrrhopodon xanthophyllus* is one of the two most common moss species in the Amazon lowlands. Photo by Michael Lüth, with permission.

Benavides *et al.* (2006) suggested that the periodic flooding added nutrients to the tree trunks, possibly contributing to the high diversity of bryophytes there compared to the swamps, terra firme forests, and white-sand habitats.

Most of the studies in the Amazon lowlands seem to be floristic with little ecological information on bryophytes. The following habitats can be identified, but few seem to have been described bryophytically, giving us little or no information on dominant species.

Dense Forest

This forest has the greatest biomass of the terra firme forests (Pires & Prance 1985). The understory is distinct, occurring where environmental conditions are optimal. Water is not limiting, having neither too much nor too little.

Open Forest without Palms

This forest has considerably less biomass and trees typically have a basal area of only slightly more than 20 m² per hectare (Pires & Prance 1985). The trees are lower, permitting a greater penetration of light. This allows shrubs and lianas to develop well. Large trees are only occasional. This vegetation type may be limited by a lower water table, impermeability of the soil, poor drainage, poor root penetration, somewhat long dry seasons, or lower relative humidity. Epiphytes are fewer due to the drier habitat. This forest type is not affected by fire and is predominantly not deciduous.

Open Forest with Palms

This forest has a similar physiognomy to that of the open forest without palms, but it has palm trees, especially *Attalea maripa* (Figure 48), *Attalea speciosa* (Figure 49), *Euterpe precatoria* (Figure 50), *Jessenia bataua* (Figure 51), and *Oenocarpus distichus* (Figure 52) (Pires & Prance 1985).

Figure 51. *Jessenia bataua*, a palm of the open forest in the Amazonian lowland. Photo by Jean-Christophe Pintaud, through Creative Commons.

Figure 52. *Oenocarpus* sp., one of the palms found in the open forest of the Amazonian lowlands. Photo from Kew.org, through Creative Commons.

Van Dunne *et al.* (2001) sampled the epiphytes on the palm *Jessenia bataua* (Figure 51) at 1, 3, and 5 m heights. They found greater similarity among species of bryophytes on the same trunks than they did between palms. Of the 42 species identified, only 3 showed a spatial dependence.

The biomass ratio of mosses to liverworts increased with height on the tree, but total bryophyte biomass showed no significant differences with height. The number of species increased with height sampled. They concluded that short-distance dispersal was less important than long-distance dispersal in determining the species composition. The most abundant families in this palm tree trunk habitat were **Lejeuneaceae** (Figure 62-Figure 64) (13 spp.) and **Lepidoziaceae** (Figure 53) (9 spp.), both leafy liverwort families. The moss family **Leucobryaceae** (Figure 40) was represented by 6 species. The lower and middle tiers of the trunk had mosses in addition to the leafy liverwort families **Calypogeiaceae** (Figure 54) and **Lepidoziaceae**. Only the family **Lejeuneaceae** was typically higher in the higher tiers. In addition, the only other families represented on this palm species were the mosses **Calymperaceae** (Figure 2) and **Sematophyllaceae** (Figure 41) and the thallose liverworts **Aneuraceae** (Figure 55) and **Pallaviciniaceae** (Figure 56).

Liana Forest

Lianas occur in the open forest where one might typically find Brazil nut trees (*Bertholletia excelsa*; Figure 57) and *Attalea speciosa* (Figure 49) (Pires & Prance 1985). These forests are usually discontinuous, intermeshed with dense forests lacking lianas. These forests usually are somewhat elevated and have rich deposits of such minerals as iron, aluminium, manganese, nickel, gold, and others. Some bryophytes are able to live on these woody lianas.

Figure 57. *Bertholletia excelsa*, a dominant tree in the liana forest of Amazonian lowlands. Photo by Vihelik, through public domain.

Dry Forest

The **dry forests** (Figure 58) are transitional forests and are seasonal and drier than rainforests (Pires & Prance 1985). The trees are at least partially deciduous except along the rivers and streams where flooding occurs. These forests do not occupy large areas.

Figure 58. Caatinga rich dry forest. Photo by Duarte, through Creative Commons.

Restinga

The **restinga** is the vegetation of coastal sand dunes. This vegetation type has few species in Amazonia.

Figure 59. Restinga forest at Itaguare beach in Bertioga State Park, Brazil. Photo by Miguel Rangel Jr., through Creative Commons.

The restinga has received at least some attention regarding its bryophytes. Working in the Setiba State Park, Espírito Santo, Brazil, Visnadi and Vital (1995) found 25 liverwort and 9 moss species, reporting the fewest species in the low and sparse restinga, with the most in the high and sandy restinga. Some of the bryophytes are specific, with the liverworts *Cololejeunea* (syn.=*Aphanolejeunea*) *subdiaphana* (see Figure 60), *Chonecolea doellingeri*, and *Cololejeunea cardiocarpa* (Figure 61) occurring only in the low and sparse restinga. *Leucolejeunea conchifolia* (Figure 62) occurs only in the medium restinga. *Ceratolejeunea laete-fusca* (see Figure 63) was only found in the high restinga; *Taxilejeunea pterigonia* (see Figure 64) only appeared in the high and sandy restinga. The mosses *Bryum capillare* (Figure 65) and *Campylopus pilifer* (Figure 9) only occur in low and sparse restinga; *Groutiella apiculata* (Figure 66) and *Schlotheimia rugifolia* (Figure 67) occur only in the high restinga. In other areas, the restinga bryophyte vegetation can be very different, with few species in common with this one. This is especially true when comparing the northwestern Amazonian restinga bryophyte vegetation with that in the southern Amazonian lowlands.

Figure 60. *Cololejeunea microscopica*; *C. subdiaphana* is found only in the low and sparse restinga in Setiba State Park, Espírito Santo, Brazil. Photo by Stan Phillips, through public domain.

Figure 68. *Jubula hutchinsiae* in Jubulaceae, one of the families with high species richness in Parque Nacional da Restinga de Jurubatiba, RJ, Brazil. Photo by Stan Phillips, through public domain.

In the Parque Nacional da Restinga de Jurubatiba, RJ, Brazil, Imbassahy *et al.* (2009) reported 61 taxa. As is typical in the tropics, the **Lejeuneaceae** (Figure 62-Figure 64) had the most species (25), greatly exceeding other high-species families of **Jubulaceae** (Figure 68-Figure 69) (7), **Calymperaceae** (Figure 2) (4), and **Sphagnaceae** (Figure 70) (4). Most of the taxa are **corticolous** (on bark) and most are of Neotropical distribution (35%). The most common life form is the **mat**.

Figure 69. *Jubula hutchinsiae*, representing the **Jubulaceae**, one of the families with high species richness in Parque Nacional da Restinga de Jurubatiba, RJ, Brazil. Photo by Jonathan Sleath, with permission.

Figure 70. *Sphagnum* sp. from the Neotropics, one of the families with high species richness in Parque Nacional da Restinga de Jurubatiba, Brazil. Photo by Michael Lüth, with permission.

In the restingas of Northeastern Brazil, the soils have a low capacity to retain water, a low nutrient content, and a high salt concentration, coupled with occasions of high temperatures (Silva *et al.* 2016). In the seven areas studied, 55 species were identified. These exhibit intermediate desiccation tolerance and occupy corticolous and ground habitats. This number of species is low compared to other Brazilian restingas. The dominant families are **Lejeuneaceae** (Figure 62-Figure 64) (24 spp.), **Fissidentaceae** (Figure 71) (8 spp.), and **Calymperaceae** (Figure 2) (6 spp.). The families **Metzgeriaceae** (Figure 72), **Plagiochilaceae** (Figure 42), and **Radulaceae** (Figure 73) are absent, whereas they are common in the southeastern restingas. Life forms facilitate their success, with high (**tuft** and **cushion**) or intermediate (**mat** and **carpet**) tolerance to desiccation; the former colonize soil or live trunks, and the latter colonize live trunks and/or, more rarely, decaying trunks. Sun-tolerant species are mostly those with intermediate desiccation that colonize live trunks and decayed logs. There are fewer shade-tolerant species and these are represented by *Fissidens* spp. (Figure

71), which form tufts and have a terrestrial habitat, and by the **pendent** and corticolous *Squamidium nigricans* (Figure 74).

Caatinga

This vegetation type of **caatinga** (shrubland; Figure 75) is also known as **campina**, **campinarana**, **chavascal**, and **charravascal** (Pires & Prance 1985). The vegetation grouping grows over leached white sand. This habitat is suitable for forest vegetation, but is limited by the nutrient-poor soil and seasonality of flooding and extreme drought due to the soil (sand) porosity. Diversity is low in a given area, but great variability exists between areas, making the caatingas overall rich in diversity. The caatinga vegetation is **xeromorphic** (having forms adapted to dry habitats). This is exhibited in thick leaves and thick bark. Nevertheless, lichens and mosses are abundant on the branches and soil surface.

Figure 75. Caatinga Biosphere Reserve, Brazil. Photo by Diego Rego Monteiro, through Creative Commons.

When comparing the elevational zones of the **caatinga** (Figure 75) biome in Brazil, Valente *et al.* (2013) found the highest numbers of exclusive bryophyte taxa in the forests and **campos rupestres** (dry, rocky grasslands; Figure 76), accounting for 51% and 40% of the taxa, respectively. The caatinga and cerrado (savanna) had only 5% and 4% respectively. The lower and upper montane zones had the highest species richness and numbers of exclusive taxa. The number of disjunct species was significant between Brazil and the Andes.

Figure 76. Campos rupestres, Brazil, showing dry, rocky grassland. Photo by Antonio José Maia Guimarães, through Creative Commons.

The low elevation Amazon caatinga forest (Figure 77) is an evergreen sclerophyllous forest (Klinge & Herrera 1983). It forms small "islands" in the tall Amazon caatinga. These "islands" are surrounded by a 20-m wide band of vegetation with trees over 10 m tall (**tall bana**). This band resembles the vegetation of the **tall Amazon caatinga**. The low Amazon caatinga is known as **bana**. Klinge and Herrera describe it as an evergreen sclerophyllous woodland with bleached quartz sands in the lowlands of southwestern Venezuela. It occurs as small islands within the tall Amazon caatinga. The outer vegetation belt is about 20 m wide with trees over 10 m tall and this is known as the **tall bana**. Its floristic composition is similar to that of the tall Amazon caatinga. The **low bana** has a maximum tree height that is typically less than 5 m. The central part is occupied by **open bana** where trees are even shorter and very widely spaced.

Figure 77. Caatinga in Brazil. Photo by Glauco Umbelino, through Creative Commons.

Bastos *et al.* (2000) found 65 taxa in the campos rupestres at Estado da Bahia, Brazil. Of these, 41 were mosses and 24 genera were liverworts. Six of the moss species were *Sphagnum* (Figure 70). Consistent with the argument for the need of more studies, 23 of these species are new records for this state.

The first study of bryophytes in Bahia, Brazil, was as recent as 1998 (Bastos *et al.* 1998). In this initial study in the state of Bahia, only 18 species were discovered, 15 mosses and 3 liverworts. These are mainly generalists and **xerophilous** (preferring dry habitat conditions). However, some **hygrophilous** (preferring moist habitats) species occur here. The generalists are represented by *Hyophiladelphus agrarius* (Figure 78-Figure 79), *Hyophila involuta* (Figure 80-Figure 81), *Calymperes palisotii* subsp. *richardii* (Figure 82), *Bryum argenteum* (Figure 83), *Entodontopsis leucostega* (see Figure 84), *Octoblepharum albidum* (Figure 3), *Frullania ericoides* (Figure 85). *Helicophyllum torquatum* (Figure 86-Figure 87) and *Riccia vitalii* (Figure 88) and others are restricted to this type of vegetation. Unlike most of the epiphytic flora, most of these species are erect, acrocarpous species with **short turf** life forms. The leafy liverworts present are **incubous** (leaves overlap from base of stem to tip like shingles of a roof from peak to edge).

Silva and Pôrto (2016) used mosses to determine if stem growth can be used to indicate changes in local climate change in the caatinga. But the gametophyte length is highly variable in the test moss, *Campylopus pilifer*. They concluded that stem length in this species is a poor indicator of local conditions in harsh environments. On the other hand, soil islands seemed to account for longer stems than typical values for this species.

Savannah Vegetation

Non-forested vegetation in Amazonian Brazil is also known as **campo** (Pires & Prance 1985). These savannahs may have trees or be treeless and are dominated by grasses. The savannahs on terra firme occupy 3-4% of Brazilian Amazonia. The littoral savannahs occur on coastal areas and have frequent lakes. The most common grass is *Paratheria prostrata* (Figure 89). **Roraima savannahs** (Figure 90) are usually open with few trees. **Campos rupestres** (Figure 76) are open formations on rocks and are often confused with open savannahs. These formations suffer drought and are unable to retain water. Lichens are common on the rocks.

Some savannahs are inundated. These are created where sediments are deposited by muddy rivers. Grasses colonize these areas as the rivers recede.

South Atlantic Islands

The most recent studies describe the small Brazilian islands in the South Atlantic, Fernando de Noronha and Trindade (Câmara & Carvalho-Silva 2018; Costa *et al.* 2018). Noronha is primarily a caatinga vegetation, but presents some interesting differences in species composition (Costa *et al.* 2018). Like the island of Trindade, there is a lack of endemism on Fernando de Noronha, compared to St. Helena (29 of 110 species), Tristan da Cunha (18 of 160 species), and Ascension (16 of 87 species). Nevertheless, *Riccia ridleyi*, which occurred at just one location, is critically endangered, but during the

rainy season, extensive populations can appear (Pereira & Câmara 2015). *Fissidens* (Figure 91-Figure 93) is the most species-rich genus with 12 species. On the other hand, the only member of the **Lejeuneaceae** present is *Lejeunea laetevirens* (Figure 94)! On Trindade, there are 11 species of **Lejeuneaceae**, with a total of 33 bryophyte species. Fernando de Noronha also has more species of mosses (23) compared to liverworts (3) (Costa *et al.* 2018), whereas Trindade has more liverworts (20) compared to mosses (12). Fernando de Noronha island has **Notothyladaceae** (Figure 95), **Ricciaceae** (Figure 88), **Bryaceae** (Figure 96), **Dicranaceae** (*Dicranella varia*; Figure 97), **Fissidentaceae** (Figure 91-Figure 93), **Pottiaceae** (Figure 79), **Splachnobryaceae** (*Splachnobryum obtusum*; Figure 98), with very low numbers of corticolous species [*Calymperes palisotii* (Figure 82), *Frullania ericoides* (Figure 85), and *Lejeunea laetevirens*]. Many (39%) of the species on this island have worldwide distribution, including *Bryum coronatum* (Figure 96), *Entodontopsis leucostega* (see Figure 84; the only pleurocarpous moss on the island), and *Hyophiladelphus agrarius* (Figure 79). But be careful what you do to preserve species. It is only on a disturbed site with engineering activity that one can find new populations of *Notothylas* (Figure 95), *Fissidens* spp. (e.g. Figure 91-Figure 93), and *Philonotis cernua* (see Figure 99), with the most extensive populations of *Notothylas* occurring there.

Summary

Many names are used for lowland rainforests and Amazon rainforests. Some are local names, whereas others are general. Terra (tierra) firme refers to the dryland habitats, thus not including mangroves and other wetlands. It includes dense forest, open forest without palms, open forest with palms, liana forest, dry forest, restinga, caatinga, and savannah, with classification based primarily on topography.

High light intensity and high temperatures limit the bryophyte vegetation in parts of terra firme, but it includes some members of the moss families **Calymperaceae**, **Leucobryaceae**, **Leucodontaceae**, **Plagiotheciaceae**, and **Sematophyllaceae**, and liverwort families **Frullaniaceae**, **Lepidoziaceae**, **Lejeuneaceae**, **Odontoschismaceae** (currently included in **Cephaloziaceae**), **Plagiochilaceae**, **Radulaceae**, and **Zoopsidaceae** (currently included in **Lepidoziaceae**). Logs are an important substrate on terra firme. Otherwise, the most common bryophyte families on terra firme are **Lejeuneaceae**, along with mosses **Calymperaceae**, **Leucobryaceae**, and **Sematophyllaceae**. Other important families are **Calypogeiaceae** and **Lepidoziaceae**, both leafy liverworts. In the drier restinga, the **Lejeuneaceae** predominates among the liverworts, with *Bryum argenteum* and *Campylopus pilifer* among the mosses. In the caatinga, erect generalist, acrocarpous species forming **short turfs** are the most common.

In places with a protracted dry season, like the South Atlantic Islands, **Ricciaceae** are common, going dormant and all but disappearing in the dry season.

Acknowledgments

My appreciation goes to Noris Salazar Allen for her efforts to make this chapter reliable and up-to-date. Her helpful discussions kept me going on this part of the world I know so little about. Tatiany Oliveira da Silva was a tremendous help on this subchapter, providing me with

references and constructive feedback and helping me to understand the various habitats. S. Robbert Gradstein was invaluable in providing me with papers, images, and constructive criticism.

CHAPTER 8-8

TROPICS: ELEVATION

Figure 1. Elevational vegetation differences at Tangkoko National Park, North Sulawesi, Indonesia. Photo by Lip Kee Yap, through Creative Commons.

Elevation

First, a definition. Merriam-Webster defines elevation as "the vertical elevation of an object above a surface (such as sea level or land) of a planet."

Although most of us use altitude and elevation interchangeably, for clarity in science we need to be precise and consistent. In fact, in Italian, they have the opposite meanings from usage in English. Hence, I shall try to use them based on the publication in *Oecologia* by McVicar and Körner (2013). "**Elevation** is the vertical distance between a point on the land surface and a reference point, usually taken to be the mean sea level. **Altitude** is the vertical distance between an object (e.g., a bird, aircraft, or parcel of air) and a reference point or stratum, where the object is not in direct contact with the reference point/stratum. The reference point/stratum is usually either the mean sea level (e.g., as often used by commercial airlines) or the land surface (at whatever elevation), which

is often used when describing the altitude of a parcel of air, for example. **Height** is the vertical distance between (usually) the top of an object (e.g., a tree, building, person, or Stevenson screen) and the land surface, where the object is in direct contact with the ground. It is therefore a measure of how far something vertically protrudes above the land surface."

The changes with elevation are multifold (Figure 1, leading to various hypotheses on the identity of the controlling factors for vegetation. These differences include distinct elevational thermal zones, differences in floristic composition and functional forms with both elevation and windward versus leeward slopes, differences in seasonal monsoon wind systems, and isolation of montane forests that cause them to behave like islands (Ohsawa 1995). In addition to these, we will soon see that available moisture is a significant factor. Troll (1948) diagrammed the vegetation zones as they relate to latitude and elevation (Figure 2).

Figure 2. Elevation vs. latitude of vegetational zones. Modified from Troll 1948.

Santos *et al.* (2014) considered the possibility of using liverworts to indicate elevational zonation in the Brazilian Atlantic Forest. Among those species found, 34 appeared to be good indicators of the Atlantic Forest groups. Among the 26 localities in the study, the **beta diversity** [ratio between gamma (regional) and alpha (local) diversities, *i.e.* effective number of distinct compositional units in the region] shows a deterministic distribution along the Atlantic coast in southeastern Brazil. Elevation has a significant role in determining the species, with five floristic groups emerging. The important variables are elevation, temperature, and precipitation. But in regions such as oceanic islands and coastal mountains, geographic distance is important.

Santos *et al.* (2017) used a short elevational gradient from 10 m to 1170 m asl in southeastern Brazil to assess changes in bryophyte communities. Using six elevational belts, they sampled ten 10 x 10 m subplots located randomly in a 1-ha forest plot at each elevation in the survey. This revealed 253 species. Richness did not vary significantly with elevation and floristic similarities among the elevations were all greater than 50% except the mountaintop forest, which had a similarity of less than 35%. **Endemism** (ecological state of species being unique to defined geographic location) increased with elevation and amplitudes of the phytogeographical patterns of species decreased as the elevation increased. It is interesting that **dioicous** (sexes on separate plants) species predominated in all elevations sampled and that the smallest dioicous:monoicous ratio was at mid elevations.

At an early date, Seifrizz (1924) showed differences in elevational distributions of mosses on Mt. Gede, Java (Figure 3). Frahm *et al.* (2003) contended that bryophytes were good indicators of elevational zones in rainforests. Based on the reaction of bryophytes to climatic factors, Frahm and coworkers considered the bryophytes to be especially good as indicators of climatic changes. In the tropical rainforests, they have several advantages over flowering plants. The bryophytes are less numerous, have considerably fewer species worldwide, with no more than 5000 species in the Neotropics. Many of the species occur throughout the Neotropics. Recent studies verify the

latitudinal diversity gradient in liverworts and hornworts (Figure 4) (Wang *et al.* 2016).

We find that at greater latitudes the bryophyte communities become more like those at greater elevations near the Equator (Gradstein & Pócs 1989). Comparing high mountains in Colombia, Peru, Borneo, and Papua New Guinea, Gradstein and Frahm (Gradstein & Frahm 1987; Frahm 1990c, d; Frahm & Gradstein 1991) identified similar elevational zonations of bryophytes indicating **lowland forest** (Figure 5), **submontane forest**, **upper lower montane forest**, **montane forest** (Figure 6), and **subalpine forest**. These zones seem to be correlated primarily with climate (precipitation, air temperature), rather than with substrate (van Reenen & Gradstein 1983). Bryophyte diversity and abundance both increase from lowlands to montane regions (Figure 7) (van Reenen & Gradstein 1983; Gradstein & Pócs 1989; Frahm 1990b). A similar pattern occurs in Madagascar (Figure 8) (Lewis *et al.* 1996) and Brazil (Pôrto 1992), with an increase in bryophyte and lichen cover and diversity as elevation increases. The distribution patterns of bryophytes through the elevational zones of the humid tropics mimics that of the ferns, which similarly have their highest species numbers in the lower montane forests (Kessler 2000 – Andes, Bolivia & Colombia; Hemp 2002 – Mt. Kilimanjaro, Tanzania).

Another important observation for the tropical distributions of species with elevation is that for most species the habitat preferences are comparable to those at higher latitudes (Gradstein & Vána 1987). Nevertheless, some occupy quite different habitats in the tropics, such as *Diplophyllum obtusatum* (Figure 9), *Solenostoma sphaerocarpum* (Figure 10), and *Schistochilopsis incisa* (Figure 11). Whereas these may be found in pristine habitats at higher latitudes, they are colonizers of man-made habitats in the tropics. Some species that are especially common (and typically have relatively wide niches and/or distributions) extend from tropical elevations to northern habitats. From peat bogs, *Sphagnum magellanicum* (Figure 12) and *S. cuspidatum* (Figure 13) fit this description. Rock outcrops in both latitudinal and elevational extremes can have *Racomitrium lanuginosum* (Figure 14) and *Andreaea rupestris* (Figure 15) as well as *Racomitrium crispulum* (Figure 16) and *Rhacocarpus purpurascens* (Figure 17) from southern latitudes. Mires typically have *Calliergonella cuspidata* (Figure 18), and *Scorpidium scorpioides* (Figure 19), whereas less boggy ground may have *Pleurozium schreberi* (Figure 20). Tropical roadsides often have *Schistochilopsis incisa* and *Solenostoma sphaerocarpum*. On periodically submerged rocks one can find the ubiquitous *Platyhypnidium riparioides* (Figure 21), *Brachythecium plumosum* (Figure 22), and *Schistidium rivulare* (Figure 23), along with the southern latitude *Clasmatocolea vermicularis* (Figure 24) and *Cryptochila grandiflora* (Figure 25).

Ah-Peng *et al.* (2007) demonstrated elevational gradients in bryophyte diversity on a 19-year-old lava flow in La Réunion. Because the lava flow is a uniform substrate, it provides an ideal opportunity for studying elevational effects without interference by substrate differences. Using quadrats in the range of 250-850 m asl, they determined that diversity increases with elevation, a pattern that occurs in many studies cited in this chapter. Nevertheless, a variety of available host plants seems to be important in fostering diversity (70 species) of epiphytic bryophytes on the lava flow.

In the Andes of Peru and Colombia, Kessler (2000) found floristically discrete communities that corresponded with elevational belts. He found that the floristic boundaries related to strong changes in **orography** (topographic relief of hills and mountains). These included the transition from the hilly lowland to the steep mountains, a co-occurring change in geological substrate at 400 m, a strong humidity gradient at 1,000 m on the Bolivian transect and at 1,250-1,980 on the Colombian transect, and the transition from mixed cloud forests to forests

dominated by *Polylepis* (Rosaceae; Figure 26) or *Podocarpus* (a broad-leaved evergreen conifer; Figure 27). In relatively species-poor forest communities, the presence or absence of a few tree species influences the whole ecosystem. By contrast, in species-rich communities such as the forests at low to mid elevations, the elevational belts are ill-defined.

In 2017, von Konrat stated that his study of elevational bryophyte communities in the Fiji Islands was the first of its kind for Fiji. Von Konrat assessed presence/absence on the lower stems of the *Calophyllum* spp. (Figure 28) trees and on tree ferns at three elevations (~160 m, 590 m, and 1,260 m). Unlike the Uganda study of Tusiime *et al.* (2007 – see below), this one revealed a hump-shaped diversity distribution (Figure 7), with the greatest species richness in the mid elevation or upland forest. Liverworts dominated at all three elevations. The bryophyte communities were distinctly different at both the host tree level and among the three elevations.

Churchill *et al.* (1995) reported a moss diversity for the tropical Andes of 2,058 species comprised of 343 genera and 75 families. However, they considered that once the systematics are understood, and superfluous species are reduced to synonymy, this number is likely to drop to 1,500-1,700. The tropical Andes have a moss flora that is approximately eight times as rich in species as that of the Amazon basin. While **α diversity** (site diversity) may be similar, **β diversity** (differences in species composition among sites) and **γ diversity** (landscape diversity) in the Andes are much greater. These differences are largely due to **orographic** factors (relating to mountains, especially regarding position and form) (see also Pócs 1976). Nevertheless, the mosses do not seem to follow the latitudinal species gradient shown by other species groups. That is, there is no increase in number of species from the poles to the equator.

Despite these high numbers, one habitat had typically been overlooked in the early studies: the canopy. Particularly in the lowland rainforest, the canopy (Figure 29) houses a rich diversity with many species that are unique to the high canopy (Gradstein *et al.* 1990). In fact, these canopies can house more than 50% of the local species, as discussed in the sub-chapter on epiphytes.

Campylopus pilifer (Figure 30) is broadly distributed and drought-tolerant and is found at high elevations in the tropics (Gradstein & Sipman 1978; Stech & Wagner 2005).

Westerners tend to think of Africa as the land of elephants and camels. But Africa has a remarkable topography and wide diversity of habitats. Tusiime *et al.* (2007) compared species richness among the habitats along an elevational range as well as along streamsides and trails in the forests of Bwindi Impenetrable National Park,

Uganda, using 1000-m transects with 1x1 m quadrats at 50 m intervals. In contrast with some of the Neotropical studies, richness of bryophyte species was negatively correlated with elevation. The exception to this was the thalloid liverworts, which increased with elevation. Streamside diversity was the highest, compared to that along trails. The evergreen forest had the greatest bryophyte richness, followed by the mature mixed and bamboo forests.

Additional studies discuss the effects of elevation on the bryophyte vegetation. Hedberg (1951) examined bryophytes in vegetation belts in the East African mountains and Pócs (1984) on Kilimanjaro. Bryant *et al.* (1973) demonstrated habitat differences among liverworts in ten areas of the Luquillo Mountains of Puerto Rico. Van Reenen and Gradstein (1983, 1984) investigated distribution and ecology on an elevational gradient in the Andes and on the Sierra Nevada de Santa Marta of Colombia; van Reenen (1987) reported on elevational zonation. Wolf (1989) reported on abundance of epiphytic communities along an elevational transect in the Cordillera Central, Colombia.

In some cases, soils may play a role in determining differences in bryophyte communities. Grieve *et al.* (1990) compared soils in six primary forest plots at 100 m, 500 m, 1,000 m, 1,500 m, 2,000 m, and 2,600 m asl on Volcán Barva, Costa Rica. As elevation increased, there was less evidence of intensity of weathering and organic matter decomposition. Simultaneously, subsoil clay content decreased from 80% at 100 m to less than 10% at 2000 m. Other soil factors likewise changed, with the ratio of free to total iron decreasing while surface organic matter increased. In fact, most nutrients at high elevations did not seem to be less than at low elevations.

On Mt. Kinabalu and the Himalaya of Bhutan, Ashton (2003) considered the floristic relationships to be complicated. He observed that the elevational level at which changes occur has only minor differences between the Equator and the tropical area. Rather, Ashton concluded that soil changes may play a more direct and important role than previously considered. The important soil factors are the increase in organic content in lower montane soils when compared to those of the lowland. This is accompanied by a change from termite-dominance to earthworm-dominance and frequency of dense moss layers and mor humus in the upper montane soils. But the question remains, do these soil differences make any differences in the composition of bryophyte communities?

Defining Zones

Enroth (1990) recognized five elevational zones in Papua New Guinea: 0-300 m, 300-1,200 m, 1,200-2,200(-2,300) m, 2,200(-2,300)-2,800(-2,900) m, and 2,800(-2,900)-3400 m asl. These zones are recognized by their distinct changes in the bryophyte flora. These zones also correspond well with previous studies on seed-plant flora. At the highest elevations, species from the Northern Hemisphere occur. The high elevations generally have New Guinean or Western Melanesian and Malesian endemics. At low to moderate elevations, the flora is representative of Asian-Oceanian and Asian-Oceanian-Australian taxa, particularly among the mosses.

Cosmopolitan species have either wide vertical ranges or occur only at high elevations.

Van Reenen and Gradstein (1983) recognized five elevational bryophyte zones in the Sierra Nevadas of Colombia in the range of 500-4,100 m asl. Four zones are forest zones and one is **páramo** (high treeless plateau). They based their classification of these zones on relevés that included species presence, substrate preference, and percentage cover of bryophytes. The zones are correlated with precipitation and air temperature. Species presence and percent cover seem to be of equal importance in distinguishing the bryophyte zones in the forests. These are highest in the **condensation zones** (zones where water vapor in atmosphere condenses and becomes liquid).

Frahm and Gradstein (1991) examined the cover, biomass, and turnover rates of bryophytes in rainforests of Colombia, Peru, Borneo, and Papua New Guinea. From these, they concluded that elevational zonation is similar in different parts of the humid tropics.

In Hawaii, Kitayama and Mueller-Dombois (1992) studied the community organization on the windward slope of Haleakala. On a transect from 350 m asl to the summit at 3,055 m asl they used a Braun-Blanquet approach to record species. They found hierarchical arrangements that were correlated with elevation. The low to mid-elevational climate is wet, changing abruptly to an arid high-elevation climate. This climatic distinction created three broad zones with elevation: lowland, montane, and high-elevation zones. Further distinctions partitioned these into seven plant communities, six based on elevation and one dieback zone.

Zone Limitations

In Ecuador, the montane and lowland rainforests both have a cooler, wetter season from April to July (Grubb & Whitmore 1966). The montane site has fog-bound and fog-free days. On the fog-free days, sunshine may be present for a prolonged period. These sunny periods are longest in the dry season, lasting 1-2 weeks. On fog-bound days, there is little diel (within a period of 24 hours) temperature change and the relative humidity typically remains at 95% or higher. On fog-free days, the temperature range and minimum relative humidity are similar to those on an average day in the lowland forest. These fog conditions are absent in the lowland rainforest. Nevertheless, on the fog-bound days in the montane forests, the conditions are similar to those of the lowland forests in the wet season. The forest types correlate with the frequency of fog, not the temperature regime. The success and greater abundance of epiphytes in the montane forest compared to the lowland forest seems to result from the frequency of wetting by fog, not to a constantly higher humidity.

On a worldwide basis, Ashton (2003) is right; the causes of zonation with elevation are complicated. In Costa Rica, Kluge *et al.* (2006) studied the pteridophyte richness at 10-2800 m asl and at 2,700-3,400 m on the Atlantic slope of Costa Rica. They analyzed species richness in 156 plots of 20x20 m. They regressed species richness against temperature, humidity, precipitation, and actual evapotranspiration. As in many other studies, the species richness distribution of the 484 species was a hump-shaped one (Figure 7) typical of many elevational distributions in the tropics. And as is typical, it peaked at

the mid-elevations. Nonetheless, the distribution correlated with the climatic variables of humidity and temperature. The mid-elevations have the highest humidity and offer moderate temperatures; high elevations have a reduced richness that the researchers attribute to the low temperatures. At low elevations, reduced water availability, coupled with high temperatures, reduce the species richness.

Low elevation bryophytes are limited by high temperatures and low light intensity (Richards 1984a; Frahm 1990a). In fact, the light intensity barely exceeds the **light compensation point** (intensity at which CO₂ lost by respiration = that fixed by photosynthesis). By contrast, montane bryophytes experience low temperatures and higher light intensities, with nearly horizontal rainfall and constant humidity, providing "suitable" conditions for a rich bryophyte flora (Pócs 1982; Richards 1984a; Stadtmüller 1987). The characteristics of the host plant for the predominantly epiphytic flora seem to be of minor importance.

Traditional assumptions have been that temperature, light intensity, and water availability determine the distribution of tropical bryophytes. Chantanaorrapint (2010) determined that in a slightly disturbed tropical forest in Thailand (Figure 31), it was a complex set of factors that affected the distributions of the epiphytic bryophytes. These related to these same elevational gradient factors of light intensity, air temperatures, and relative humidity working together.

Figure 31. Thailand rainforest. Photo courtesy of Ochir Nuchitprasitchai.

Kürschner (1995) demonstrated a strong correlation between known elevational zonation, forest zones, and plant sociological units in the tropics of the Democratic Republic of Congo and Rwanda (Figure 32). Because of their broad geographic distribution, relatively small number of species (compared to seed plants), sensitivity to climate, and prominence in tropical rainforests, bryophytes are good indicators of the elevational zonation pattern that is characteristic of the humid tropics.

There are a number of changes in the environment from lowland to montane, and these may work in consort, as noted by Chantanaorrapint (2010), to provide more favorable habitats in the mountains. Richards (1984b) suggested that lowland temperatures are too hot for most

bryophytes. We can expect that these C_3 plants generally have their photosynthetic optimum around 20°C; mean annual temperatures in the montane rainforests are generally 10-20°C (Gradstein & Pócs 1989). As already noted, Frahm (1990b) found that the rate of net assimilation of tropical montane bryophytes decreases radically above 25°C. Biebl (1964) showed that most of the bryophytes of the montane forest at El Yunque, Puerto Rico, could not survive at temperatures above 35°C. Light intensity in the lowlands is low, respiration (including photorespiration) is high, and moisture is often limiting, making it difficult for lowland bryophytes to assimilate more by photosynthesis than they lose to respiration. In fact, Frahm (1987) experimented in the laboratory with montane rainforest bryophytes from Peru and demonstrated just that – they cannot photosynthesize enough under the conditions of the tropical lowland rainforest. In such lowlands, one is most likely to find pantropical families such as **Calymperaceae** (Figure 134), **Hookeriaceae** (Figure 33), and **Lejeuneaceae** (Figure 76-Figure 94) (Gradstein & Pócs 1989).

Figure 33. *Hookeria acutifolia* (Hookeriaceae); Hookeriaceae is a pantropical family found in Peruvian lowlands. Photo by John Game, through Creative Commons.

These dry conditions of the lowlands, however, do not persist throughout the other climatic zones of the tropics. In the lower montane rainforest in Panama (Figure 34), the daily water content of liverwort thalli is pronounced, and both the low and the high water content place considerable limitation on the CO_2 exchange (Zotz *et al.* 1997). However, between those values is a range where a net carbon gain is possible. Even so, half of the mean daytime carbon gain is lost during the night due to respiration at the relatively high temperatures. Enough carbon is stored and not subsequently released to account for a net annual gain of approximately 45% of the initial carbon content of the thallus.

Figure 34. Panamanian montane forests. Photo by S. B. Matherson, through Creative Commons.

Additional studies include those by Grubb (1974) on the factors that control the distribution of forest types on tropical mountains in Malesia. Frahm (1990c) examined the elevational zonation of bryophytes on Mt. Kinabalu, Malaysia.

Transplant Studies

Experimental studies are few, but can provide a clearer picture of elevational relationships. Stam *et al.* (2017) transplanted 558 pendent epiphytes in the Afromontane forests of Taita Hills, Kenya (Figure 35). Several of the four pendent mosses grew very well in the upper montane forest where it was cool and humid, more than doubling their biomass in the year of study. By contrast, all of the transplanted mosses performed poorly in the humidity, heat, and low light of the lower canopy in the dense lower montane forests.

Latitude vs Elevation

Delgadillo and Cardenas (1989) found that the highlands in the Chiapas of Mexico have moss floras similar to those of temperate regions. Truly tropical taxa are mostly confined to the lowland moist sites. The Meso-American species and species with wide distributions are the most numerous in species.

Churchill (1991) suggested that latitude does not play a major role in distinguishing moss diversity from high to low latitudes in the temperate and tropical regions. Rather, in Colombia (Figure 36), bryophyte species richness increases with elevation up to treeline (Figure 37). It is on

the high mountains that the tropical bryophytes reach their zenith in diversity. A similar curve is seen for Yunnan, China (Figure 38) (Song *et al.* 2015). The hump shape (Figure 37-Figure 38) is typical of the diversity distribution.

Figure 38. Mean (\pm SE) species richness for bole bryophytic epiphytes along elevational gradients in Yunnan, China. Modified from Song *et al.* 2015.

Churchill (1991) reported that ~93% of total species richness for mosses (900 spp.) in Colombia occurs within the 20-25% of land surface occupied by the Andes. Within that area, ~50% of diversity occurs at 2,600-3,300 m asl, the high montane zone. Among tropical bryophyte families, 60% are primarily montane while less than 5% are primarily lowland taxa. Freiberg and Freiberg (2000) also found higher bryophyte biomass in the montane zone of Ecuador (Figure 39) compared to the lowland forests, with a corresponding increase in dead organic matter. Similarly, in the Andes of Colombia (Figure 40), montane areas may produce at least ten times the epiphytic bryophyte biomass of lowland forests (van Reenen & Gradstein 1983). Frahm (1987) obtained similar biomass relationships in Peru (Figure 41). Lowlands and submontane regions also are deprived of endemics, sporting a number of transoceanic and pantropical taxa, especially liverworts in *Lejeuneaceae* (Figure 76-Figure 94) and mosses *Fissidens asplenoides* (Figure 42), *Floribundaria floribunda* (Figure 43), and *Neckeropsis disticha* (Figure 44), whereas endemics increase in number in alpine areas, causing the tropics to have a high number of endemic bryophytes (Gradstein *et al.* 2001a). Nöske *et al.* (2003) reported that in Ecuadorian Andes species range sizes decrease toward higher elevations, refuting **Rapoport's elevational rule** (prediction of trends of increased elevational ranges of plants with increase in elevation). It does suggest that more endemics might be expected at higher elevations. Nevertheless, endemism overall was very low (1%).

Using only bole bryophytes to assess elevational differences eliminates most of the soil influences. Song *et*

al. (2015) compared bryophyte species in three protected forest areas in tropical sub-montane (800-1400 m asl), montane (2000-2600 m asl) and sub-alpine (3200-3800 m asl) in Yunnan, SW China (Figure 45). They used 60 20x20 sampling plots, with five plots at each of 12 elevations with 200 m elevational intervals. They used 540 subplots, each with an area of 400 cm². These revealed 226 epiphytic bryophyte species. Life forms included smooth mat, fan, and turf as dominants in the sub-montane, montane, and sub-alpine forests, respectively (Figure 46). The sub-montane forest had significantly lower bryophyte species richness, a response they attributed to higher temperature, limited water availability, and more frequent human disturbance. As in many other studies cited here, the distribution of species richness was a hump-shaped curve with elevation (Figure 7), reaching its highest richness where the moisture levels were highest at ~2,600 m asl. Liverworts had the greatest species richness at all three sites (Figure 47).

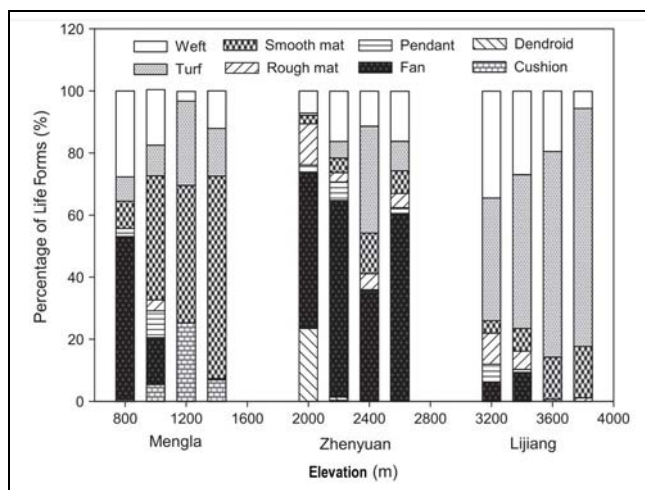

Figure 46. Comparison of life forms on three mountains in Yunnan, China. Modified from Song *et al.* 2015.

Figure 47. Species richness of mosses vs liverworts on three elevational transects in Yunnan, China. Species richness represents twenty 20 x 20 m plots on each mountain. Modified from Song *et al.* 2015.

Using data on more than 840 mosses and liverworts from the Himalayas in Nepal (actually subtropics; Figure 48), Grau *et al.* (2007) determined the known maximum and minimum elevations of the species. They found strong correlations in species richness among the ferns, flowering plants, mosses, and liverworts and elevational relationships. Maximum richness of liverworts occurred at 2,800 m, for mosses at 2,500 m asl. The endemic liverworts reached maximum richness at 3300 m; non-endemic liverworts at 2,700 m. Nevertheless, the mosses again did not support **Rapoport's elevational rule** (prediction of trends of increased elevational ranges of plants with increase in elevation). For liverworts, the relationship is not clear. Grau and coworkers (2007) suggest that differences in importance of climatic variables such as available energy and water might explain the differences among the four plant groups.

Records of Elevation

One might expect the highest known elevation for bryophytes to be in the tropics, where the climate will be the warmest at high elevations compared to the same elevation elsewhere. Grolle (1966) reported records up to 5100-5200 m asl in Nepal (subtropics). Alexey Potemkin (Bryonet 11 February 2016) noted that these were liverworts from a wide variety of genera: *Scapania*

ornithopodioides (Figure 49), *Lophozia incisa* (Figure 50), *Chandonanthus filiformis* (see Figure 51), *Gymnomitrium sinense* (see Figure 52), *Marsupella commutata* (Figure 53), *M. revoluta* (Figure 54), *Plagiochila carringtonii* subsp. *lobuchensis* (Figure 55), *Herbertus sendtneri* (Figure 56), *Anthelia julacea* (Figure 57), *Bazzania tricrenata* (Figure 58), *Metacalypogeia alternifolia* (Figure 59).

Schiavone and Suárez (2009) reported the moss *Globulinella halloyi* (Pottiaceae; see Figure 60) as a new species from Volcán Socompa, Argentina. It has the distinction of occurring at 6,000 m asl, 280-590 m higher than any known record for a bryophyte. It forms large, dense patches in communities with dense clumps of *Pohlia papillosa* (see Figure 63-Figure 64) on warm soil with moist conditions.

Figure 60. *Globulinella globulifera*; *G. halloyi* is a new species that occurs at 6000 m asl in Volcán Socompa, Argentina, making it the bryophyte at the highest elevation on the planet. Photo by Claudio Delgadillo Moya, with permission.

Volcanoes are particularly likely to have high-elevation bryophytes. Areas near geothermal vents have heated soil and sufficient moisture to maintain a suitable bryophyte habitat. Potemkin *et al.* (2018) reported two liverwort and two moss species from the top of Elbrus (5,590 m asl) in the Caucasus. They occupied an area free of snow and ice. The liverworts are *Marsupella boeckii* (see Figure 61) and *M. cf. funckii* (Figure 61). The mosses are *Atrichum cf. angustatum* (Figure 62) and *Pohlia nutans* (Figure 63-Figure 64), both widespread species. These are not tropical locations, and thus the high elevation is more remarkable, but the heat and moisture from the geothermal vent makes this habitat livable for these species. *Pohlia nutans* is also recorded from 3,000-4,000 m asl in China (Zhang *et al.* 2007). *Atrichum angustatum* is reported in Europe, Macaronesia, Turkey, Iran, eastern and central North America, and China. *Marsupella boeckii* is an infrequent Holarctic species; *M. funckii* is a European species.

Rodriguez (2015) reports the first known symbiosis in a high elevation (6480 m asl, Mt. Everest) population of mosses. The moss *Gymnostomum aeruginosum* (Figure 65) has a symbiotic fungus living completely within the tissues, making it the first documentation of a high elevation symbiosis. Rodriguez has continued testing to see if fungi confer any low temperature or high UV tolerance on the moss. Potemkin *et al.* (2018) have reported the Mt. Everest location of this species, based on a photograph, as hidden in a crevice in cold snow.

Figure 65. *Gymnostomum aeruginosum*, a moss with a symbiotic fungus at 6,480 m on Mt. Everest, possibly the highest elevation for a bryophyte. Photo by Hermann Schachner, through Wikipedia Commons.

Frey *et al.* (2012) listed the highest records for bryophytes in the Cordillera Real in Bolivia. The liverworts *Stephaniella paraphyllina* (Figure 66) and *Gymnocoleopsis multiflora* occur at 5,000 m asl. The moss *Grimmia longirostris* (Figure 67) occurs at 5,800 m asl. Thus it appears that the highest elevation record thus far goes to *Gymnostomum aeruginosum* on Mt. Everest.

Diversity-Richness Changes

Early studies recognized differences in the bands of vegetation as elevation increased. Bryologists naturally became curious about the co-occurring changes in the bryophyte vegetation.

Pócs (1984) used four transects on the SSW slope of Mt. Kilimanjaro to show bryophyte species changes in each 100-m elevational section. On this mountain they found that the number of species increased "rapidly" from 1,800 m asl upward. They found two peaks in species diversity, one at 2,200 m, where the structure of the montane rainforest is most complex, and one at 2,700 m in the cloud belt, where the precipitation is greatest. At timberline (3,000 m), there is a rapid decrease in species diversity, but this remains relatively constant until 3,800 m, where the vegetation is subalpine heath and it is more open and dry

with less rainfall. Above this level, the number of bryophyte species reach their minimum level on the mountain. The uppermost known species occurs at 5,050 m asl. These conditions created six bryophyte zones, each with characteristic species combinations, and these parallel the established zones of tracheophyte vegetation.

In Southwest Nigeria, Oyesiku (2013) conducted one of the rare ecological studies in a tropical rainforest biome in Africa. He found 138 bryophyte species, with 70% mosses and 30% liverworts. Unlike other studies, this one found the species distribution to be relatively homogeneous along the elevational trail (**Gini coefficient**=2.54%). A Gini coefficient of zero expresses perfect equality, where all values (species) are the same; 100% indicates that all values (species) are different. Nevertheless, there was a significant correlation between number of bryophyte species (for both mosses and liverworts separately) and elevation.

Frahm (1990c) investigated the elevational zonation of Bryophytes on Mt. Kinabalu in Borneo. Later, Frahm (1994a) summarized the results of the BRYOTROP Expedition to the Democratic Republic of Congo (previously Zaire) and Rwanda, which examined the elevational zonation of bryophytes on Mt. Kahuzi in the Democratic Republic of Congo. Based on bryophyte parameters such as species per hectare plot and elevational ranges of species, they identified four bryophyte vegetation zones: submontane forest (<1,500 m), lower tropical montane forest (1,500-2,000 m), upper tropical montane forest (2,100-2,800 m), and subalpine forest (2,900-3,200 m). These zones correlate with those previously named for the general tracheophyte vegetation.

Gradstein *et al.* (1983) compared liverworts between the Neotropics and Africa to determine the level of disjunction. Early researchers tended to name species on a new continent as new, but as more in-depth studies occur, many of these emerge as synonyms. Among 35 known Afro-American species, there are three distribution types one can recognize. These are Tropical Afro-American (lowland, montane, and the alpine element), Subtropical-Mediterranean (southern, wide element) and Temperate-SubAntarctic (southern, wide element). Most of these disjuncts occur in the leafy liverwort order **Jungermanniales** (Figure 10). The subtropical disjuncts are an exception, being thallose liverworts. The researchers suggest that the species disjunctions are due to long-distance dispersal, but experimental evidence to support this is totally lacking. On the other hand, it is possible that generic disjunctions and species vicariance might be the result of ancient land connections through Gondwanaland.

Although the bamboo forest (Figure 68) is low in bryophyte species diversity, it nevertheless exclusively hosted 17.6% of the collected bryophytes in the Bwindi Impenetrable National Park, Uganda (Tusiime *et al.* 2007).

Zhang (2001) demonstrated that the number of species per plot increases linearly with elevation in Hong Kong. Sun *et al.* (2013) found that the species richness of ground bryophytes on Gongga Mountain, China, shows no elevational trend. Cover, on the other hand, increases with elevation, with the maximum occurring at ~3,758 m asl,

with biomass averaging 700 g m^{-2} and maximum thickness reaching 8 cm. For these ground dwellers, litter, air temperature, and precipitation seem to control distribution.

Figure 68. Uganda bamboo forest. Photo by A. M. Doughty, through Creative Commons.

Nekesa (2015) used a transect from 2,400 m to 4,800 m asl, sampling at 200-m intervals to examine the distribution of both bryophytes and tracheophytes on Mt. Kenya. Tracheophytes were sampled in $10 \times 10 \text{ m}$ quadrats with $10 \times 5 \text{ cm}$ bryophyte quadrats nested within them. Bryophytes had the highest diversity, followed by flowering plants. Diversity overall decreased from 2400 m asl to 460 m asl, with the optimum occurring at 2400 and 3000 m asl (over 350 species each). The most diverse bryophytes were humicolous and corticolous (80%) with only 0.001% in the aquatic habitat. Nekesa concluded that elevation is the major factor affecting the distribution of both groups, with microhabitats of bogs, rocks, and tracheophytes themselves being the secondary factors.

Glime *et al.* (1990) demonstrated a change in associations among *Frullania* (Figure 72) species with elevation on Mount Albert Edward, Papua New Guinea (Figure 69). The species diversity of this genus is greatest in the middle elevations, least in the dry lowlands. Sibling taxa show elevational differences within pairs, thus occupying different niches. It is likely that we will find multiple environmental races among at least some species when we compare them among elevations.

Figure 69. Mount Albert Edward, Papua New Guinea. Satellite image through Creative Commons.

On Mount Albert Edward, Papua New Guinea (Figure 69), there are more than 50 taxa of the leafy liverwort genus *Frullania* (Figure 72) (Glime *et al.* 1990). These taxa form many associations, often with other members of the same genus. The associations and the major taxa differ with elevation, and the species richness likewise differs. The most taxa occur at the middle elevations, especially the cloud forests, and the least in the dry lowlands and high alpine areas. Furthermore, many clumps of single *Frullania* species occur in the latter two regions, whereas at the other elevations collections are rarely pure. In fact, at 2,000-2,500 m asl associations between *Frullania* taxa are so common between repeating species pairs or groups (*i.e.* high fidelity) that we (Glime *et al.* 1990) suggested that some benefit might be derived from the association. We suggested that these untested benefits might include:

1. high light intensity protection for small liverworts that live among larger ones in the forest canopy or in exposed alpine areas
2. protection from drying out by reducing the amount of free space among the branches and leaves
3. gain in water availability by species that have a poor ability to move water from the substrate or surface of the clump to their own branches but that can take advantage of the water moved by an associated species.

Although few authors describe such commensal water relationships in plants, except by use of mycorrhizae, Rydin (1985) has suggested that they exist among *Sphagnum* (Figure 70) species with differential abilities to absorb water in one circumstance and to retain it in another. His conclusions are further supported by the experimental studies of Li *et al.* (1992) on two additional species of *Sphagnum*.

Figure 70. *Sphagnum capillifolium* with capsules, in Chile. Photo by Juan Larrain, with permission.

Ah-Peng *et al.* (2012) compared elevational bryophyte species variation on the Reunion Island (summit 2,069 m asl) to that of the Colombia high volcano (5,321 m asl) on

the South American continent. Species richness was similar between the two locations, with 265 on Reunion Island and 295 on the Colombian volcano. On Reunion Island, species with small range sizes dominated, with mean elevational range increasing with elevation (perhaps Rapoport's elevational rule is right for bryophytes sometimes), and with species richness decreasing with elevation. The island's cloud forest has a high bryophyte species richness as well as a large number of rare species. The continental elevational gradient, by contrast, was dominated by large-ranged species.

The elevational gradient seems also to be reflected in the niche width (Figure 71) of the *Frullania* (Figure 72) taxa (Glime *et al* 1990). At both the low and the high elevations, the niche widths are narrower (not supporting Rapoport's elevation rule), at least for the parameters tested, further restricting the taxa that are there to well-defined habitats. For example, *Frullania papillata* has 95% of its observations expected between 2,368 and 2,575 m asl and occurs only between 2,500 and 3,500 m. Similarly restricted taxa, elevationally, include *F. apiculata*, *F. attenuata*, *F. gracilis* (Figure 72), *F. ornithocephala*, and *F. ornithocephala* var. *intermedia*. On the other hand, the middle elevations have the highest number of species pairs with non-overlapping distributions (Figure 73).

Figure 72. *Frullania gracilis*. Photo from Bryophyte Flora of Doi Suthep-Pui National Park, Chiang Mai, Thailand, through Creative Commons.

Figure 73. Elevational distribution of species richness of *Frullania* on Mount Albert Edward, Papua New Guinea. Redrawn from Glime *et al.* 1990.

Four sibling taxa pairs of *Frullania* occur (Figure 71, but among the ones examined, each member of the pair exhibits distinct elevational niches, suggesting that while they may have remained morphologically similar, they may have diverged physiologically (Glime *et al.* 1990).

The canopy typically has more species than the ground in a lowland rainforest. Cornelissen and Gradstein (1990), working in Guyana, reported that 50% of the species were restricted to the canopy; only 14% corticolous species were restricted to the understory. However, in Monteverde, Costa Rica (Figure 74), when rotten logs and living leaves are added to the understory percentage, about 20% of the species are exclusive to the understory (Figure 75) (Gradstein *et al.* 2001b). Gradstein and coworkers suggested that the percentage of species restricted to the canopy may be the same in lowland and montane rainforests, despite large differences in both species abundance and composition (see also Gradstein 1995).

In Panama, Gradstein and Salazar Allen (1992) assessed the bryophytes along an elevational gradient on Cerro Pirre (1,200 m asl). As shown in the other studies above, they found very different species assemblages along the gradient from inundated lowland, to hillside lowland, to submontane, to montane elfin forest. Among these, they found the greatest species richness in the submontane forest. The greatest number of exclusive species, however, occurred in the montane elfin (cloud) forest, along with the greatest bryophyte biomass. The mountain proved to have a number of rare liverworts, and this one study produced 40 liverwort species new for Panama.

Wolf (1989, 1992) elaborated on the species richness of epiphytic bryophytes on an elevational gradient in the northern Andes (Figure 95). This study included 187 liverworts and 108 mosses. Wolf (1993a, b) also examined the diversity patterns and biomass of epiphytic bryophytes along this gradient in the Central Cordillera of Colombia

(Figure 96) from 1,000 to 4,130 m asl. Elevation emerged as a complex factor in explaining the variation in species composition. Species area curves for each sampling site indicated that sampling was adequate. α and β diversity patterns along the elevational gradient differed between mosses and liverworts. Liverwort richness was maximum (~100 taxa) in the range of 2,550-3,100 m. This high level corresponds with the contact transition zone between vegetation zones. This supports the prediction that the highest species diversity will occur in a transition zone, indicating that between community interactions are more important in determining diversity than within community relationships (*i.e.* niche relationships). This is further supported by the fact that only 20.5% of the liverwort taxa are exclusive to this belt of greatest richness. Humidity appears to be an important limiting factor, with biomass increase of bryophytes corresponding with a humidity increase with elevation. Bryophyte species turnover also appears to be greater in this mountain system than that known for the temperate mountains in North America.

Figure 95. Nevado del Ruiz, northern Andes, Colombia. Photo by Edgar, through Creative Commons.

Figure 96. Western Cordillera of Colombia bordering Chocó, very rich montane cloud forests on a sunny day at 1,600 m in 1992. Photo courtesy of S. Robbert Gradstein.

The ECOANDES project has contributed greatly to our understanding of Neotropical elevational effects on bryophytes (Gradstein *et al.* 1989). Gradstein and coworkers compared the wet, foggy western slope (1,000-4,500 m) with the drier eastern slope (500-4,500 m) of the Colombian Central Cordillera at the Parque de los

Nevados. Again, the species richness increases with elevation to the upper montane forest, where the greatest bryophyte diversity occurs. Liverworts demonstrate their greater preference for moisture by outnumbering mosses in the upper submontane and montane forests on the wet western slope, but in the drier environments they are less diverse than the mosses. At lower elevations (<3000 m), the species are wide-ranging tropical species, whereas in the higher elevations the species are those with narrow ranges (Andean and endemics). Few temperate species occur, with less than 10% in the upper montane forest and ~20% in the páramo. We can assume they have arrived in Colombia relatively recently (last 5 million years) after the Cordilleras arose.

Germano and Pôrto (2006) reported on bryophyte communities in the remnant Atlantic forests in Pernambuco, Brazil. In the Atlantic Forest of Rio de Janeiro, southeastern Brazil, Santos and Costa (2010) reported 360 liverwort taxa. In addition to having floristic differences among the different formations, there were elevational differences. The montane forest has the highest species richness (238) with 63 exclusive taxa and 27 endemics, as of the year 2010. The upper montane is next with 173 species, 58 exclusive taxa, and 21 endemics. The leafy liverwort family **Lejeuneaceae** (Figure 76-Figure 94) is the most species-rich family in all formations, whereas other families may be restricted to certain formations.

In the Itatiaia National Park (Figure 6) of Brazil, three vegetation zones are clearly defined: montane forest (Figure 97), upper montane forest (Figure 97), and high-elevation fields (Figure 98) (Costa *et al.* 2015). Sampling at 10 representative elevations revealed 519 taxa, 57% of the total known bryophyte flora in the Rio de Janeiro State and 34% of that of Brazil. The montane forest had the highest species richness (296). The most endemic species (47) occurred in the upper montane zone. The researchers attributed the richness in these locations to their diversity of climate, soil, and physiographic parameters. As is typical in the tropics, especially the Neotropics, the highest diversity occurs at the mid-elevational range of 2,100-2,200 m asl. As the elevation increases, so does the number of threatened species.

On Mt. Kitanglad (up to 2,938 m asl) in the Philippines (Figure 99), Azuelo *et al.* (2010) examined the diversity and ecology of bryophytes. They report 428 species, with mosses predominating. Of these, 326 species are mosses; only 98 of these species are liverworts and 4 are hornworts. The mosses occur in 70 genera and 29 families. The highest diversity occurs in the lower montane forest (112 species), followed by the mossy (cloud) forest (108 species) and upper montane forest (87 species). Nevertheless, the highest bryophyte cover occurs in the mossy forest. A major substrate choice is epiphytic (40% of mosses, 15% of liverworts, and 1 hornwort). But, the highest richness is on the rotten logs and decaying litter, with 43% of the mosses and 42% of the liverwort species occurring there, including **Lepidoziaceae** (Figure 100), **Plagiochilaceae** (Figure 55), **Schistochilaceae** (Figure 11), and **Trichocoleaceae** (Figure 101). The moss families **Meteoriaceae** (44 species; Figure 43) and **Dicranaceae** (43 species; Figure 30) are the most species-rich families, contrasting with the prominence of the liverwort family **Lejeuneaceae** (Figure 76-Figure 94) in most areas of the tropics. Rather, the **Plagiochilaceae** (26 species) and **Lepidoziaceae** (20 species) are the most species-rich liverwort families. Among the species on the mountain, 11 moss and 6 liverwort species are considered to be medicinal.

Santos *et al.* (2017) compared the numbers of species in families at six elevations at the Serra do Mar State Park, Brazil (Figure 102)

In an attempt to determine the usefulness of liverworts as bioindicators, Santos *et al.* (2014) sampled 26 localities to determine β diversity relationships. They found a significant association of the first CCA axis with a floristic gradient from lowland forests to high montane forests. They found 34 species that could serve as bioindicators. The species groupings could be explained by elevation, temperature, and precipitation.

Churchill (pers. comm. 29 November 2011) has observed that diversity relationships with elevation are basically true throughout the tropical Andes.

Dominance Changes

As the elevation increases, the dominant species change. Santos *et al.* (2017) illustrated this clearly in the Atlantic Forest in Serra do Mar State Park, Brazil (Table 1).

Productivity

Zotz (1999) found a distinct increase in abundance of mosses and liverworts with elevation. They are especially important in tree crowns in montane regions and are inconspicuous in the lowlands. This study demonstrates that drying in the daytime in the lowlands limits photosynthesis, whereas hot, moist nights cause excessive respiration that exceeds photosynthetic gain.

Based on studies in Borneo, Tanzania, Transvaal, Venezuela, and Peru, Frahm (1990b) concluded that the biomass of epiphytic bryophytes in the tropics increases from the lowlands to the **treeline** (elevation above which trees cannot grow). Like the conclusions of Zotz (1999), he attributed this gradient to combinations of precipitation, humidity, temperature, and desiccation. This was supported by experiments showing that net assimilation decreases rapidly above 25°C. The high temperatures and low light result in higher respiratory losses compared to photosynthetic gains. This problem is further exacerbated by problems of desiccation in lowlands. At higher elevations, on the other hand, the abundant precipitation carrying a relatively high nutrient supply enhances growth in the tropical montane forests.

In this study, Frahm (1990b) compared the monthly and yearly production and chlorophyll content of the perennial moss *Hydrogonium* (Figure 125) and the seasonal moss *Physcomitrium* (Figure 126) and their associated communities in 10 x 10 cm quadrats. For *Hydrogonium*, the mean biomass was 95 g m⁻² and for *Physcomitrium* 11 g m⁻². These values are both lower than many measures of bryophytic biomass in temperate forests.

Bader *et al.* (2013) found a similar increase in biomass from lowlands to highlands in Panama, with increases to "extreme richness" in some montane cloud forests. Using gas-exchange measurements before and after transplanting bryophytes to lower elevations, these researchers determined that temperature alone could not explain the lack of success of high elevation species in the lowlands. Nevertheless, a few samples of nearly every species survived for at least 20 months. Hydration patterns proved to be important in the survival. Sunny mornings cause rapid desiccation, a regime that can be deadly to many species. This is further complicated by afternoon rains that hydrate the mosses, renewing their activity and causing high respiratory losses at night.

Figure 126. *Physcomitrium eurystomum*; the genus *Physcomitrium* in the tropics seems to have lower productivity than populations in the temperate zone. Photo by Show-Ryu, through Creative Commons.

Wagner *et al.* (2012) noted that **poikilohydric** organisms (those with predominantly external control over water content, including bryophytes) increase with elevation in the tropics. In the lowlands, low light and high temperatures cause a high respiration to photosynthesis ratio, often causing bryophytes to have negative net productivity. Among 18 tropical bryophytes in the study, from three elevations (sea level, 500 m, 1,200 m) in Panama, the optimum temperatures of net photosynthesis closely matched the mean temperatures of the habitats where the species grew. This adaptation resulted in a lack of differences in the ratio of dark respiration to net photosynthesis with elevation. As one might surmise from this, responses of individual species to water, light, and CO₂ did differ, but not systematically with elevation. Water relations seemed to be important, with higher temperatures increasing the evaporation rates. This, in turn, decreased the time available for photosynthesis each day, while nighttime respiration rates did not necessarily increase.

Chantanaorrapint (2010) compared biomass of epiphytes along three elevational transects in southern Thailand, ranging from 25 m asl to 1,500 m asl. The dry weight of epiphytic bryophytes increased with elevation, with 1.15 g m⁻² in the lowland to 199 g m⁻² in the montane forests. The dry weight increased with elevation from 2.4 kg per hectare to 620 kg per hectare. These bryophytes were important in water storage, holding 1.2 to 2.4 times their dry weight. This storage was typically higher in the montane region (up to 1,500 L ha⁻¹) than in the lowland forests. Bark pH also varies with elevation, ranging from 3.19 to 6.84, decreasing with elevation. Air temperature decreases about 0.6°C per 100 m increase in elevation.

Zotz *et al.* (1997) measured CO₂ exchange in six tropical bryophytes in a lower montane forest in Panama. The **diel** water content varied greatly. Both low and high water content were severely limiting for photosynthesis. Low photon flux density (a measure of light intensity), as occurs during rain storms, was less limiting for CO₂ exchange than water availability. More than half of the daily carbon gain of 2.9 mg C g⁻¹ was lost at night to respiration. This suggests an estimate of 45% carbon gain for the bryophytes per year.

Adaptations

There appear to be distinct adaptations that characterize forest epiphytes in elevational zones throughout the tropical regions of Southeast Asia, Africa, and South America (Kürschner *et al.* 1999). In the tropical lowlands and submontane regions, **perennial stayer** and **perennial shuttle** species dominate the life forms. In the cooler and more humid montane rainforests, **fan** and **weft** forms of **perennial stayers** and **perennial shuttle** species are prominent, relying on propagules and clonal growth to achieve the large biomass found there. These **fan**-forms and other structures such as ciliate leaves are effective at trapping fog water through rapid condensation and facilitating conduction and storage. In the upper montane forests, conditions are more open and xeric and the diurnal fluctuations are more extreme. Here the bryophytes tend to form **cushions** or **short** and **tall turfs** of **perennial stayers** and **perennial shuttle** species. They often conserve water through an abundant rhizoid tomentum and a more developed central strand in the stem.

Frahm (1994b), as part of the BRYOTROP Expedition, reported on life forms from various elevations on Mt. Kahuzi (Democratic Republic of the Congo), using a transect from 900 to 3,300 m asl. From 900 to 2,300 m elevation, the **dendroid** life form is characteristic. He interprets this as an adaptation for better gas exchange in conditions of low light and high air humidity. **Cushions** predominate above 2,500 m asl. These are typically 2-5 cm high, but some reach 50 cm at treeline. **Moss balls** can form, reaching up to 1 m in diameter. Bryophyte cover on soil is less than 5% below 2,700 m asl, but in the subalpine ericaceous belt it is 90%. Similarly, cover on bark is as low as 5% or less in the low elevations, increasing to 80% at high elevations. This gradation corresponds with light intensities from <1% to up to 50%. Temperature, on the other hand, decreases from 10.6°C at 900 m to 1.5°C at 4,500 m. The bark pH is in a relatively narrow range of 4.1-6.2.

In the Amazonian Andes in northern Peru (Figure 127), Kürschner and Parolly (1998a, b) were able to define apparent adaptations based on relative biomass of morphological types. They found three dominant life strategy categories: **colonists**, **perennial shuttle species**, and **perennial stayers**. However, the **colonists** were confined to disturbed sites and were not typical of the elevational zones. Lowland bryophytes exhibit **mat** forms with water lobules, water sacs, and rhizoid discs. The balance of high temperatures with the humidity of both the lowlands and submontane belt seem to favor the passive reproduction (having low or moderately low sexual and asexual reproduction) of **perennial shuttle** and **perennial stayer species**. In the more humid and often foggy montane zone, the **mat** forms of the lowlands disappear and **dendroid** and **pendent** forms join the more universal **fan** and **weft** forms – all forms that are able to condense water from the fog and mist (**fog-stripping**). The leaves are often ciliate or deeply fissured and frequently have a **rill-like** arrangement (like series of small, narrow valleys), all characteristics that facilitate water uptake, conduction, and storage. High vegetative reproduction through propagules and clonal growth predominates here. In the upper montane zone near timberline, the bryophytes of the

Peruvian Andes likewise exhibit **short** and **tall turfs** of other upper montane forests but also "**tails**." They retain the rill-like leaf arrangement seen in the humid montane zone and commonly have a central strand, as seen in bryophytes of other upper montane forests. These bryophytes put forth a high sexual reproductive effort, producing numerous sporophytes on a regular basis, a pattern of change toward timberline also seen in Southeast Asia and Central Africa.

Figure 127. Andes at Huandoy, Peru. Photo by Clarquitecto, through Creative Commons.

It is noteworthy that the development of **anisospory** (in bryophytes refers to a bimodal size difference between spores produced in the same sporangium) and **heterospory** (having spores of two sizes) occurs within the tropical Andean forests (Figure 128) (Kürschner & Parolly 1998a), although it can be argued that bryophytes lack true heterospory (see Volume 1, Chapter 3-3 on Sexuality: Size and Sex Differences). Anisoporous bryophytes in the **perennial shuttle** category exhibit the development of **dwarf males** (small males epiphytic on females) with no size differentiation visible among the spores. In other cases, true size differences occur, where small male spores and large female spores occur in the same capsule, for example, in *Macromitrium* spp. (Figure 129) and *Phyllogonium fulgens* (Figure 130). *Leptodontium viticulosoides* (Figure 131) exhibits a functional heterospory in which small spores are able to travel long distances, whereas the larger spores are more adaptive for short distances and a quick start for the protonema upon germination – an ideal shuttle strategy.

Physiological adaptations necessarily include tolerance to desiccation and in some cases resistance to drying. Akande (1985) found that the corticolous liverworts *Frullania spongiosa* (see Figure 72) and *Mastigolejeunea*

florea (see Figure 132) had higher osmotic potentials than the mosses *Stereophyllum nitens* (see Figure 133) and *Calymperes palisotii* (Figure 134) in his Nigerian study. This potential increased from wet to dry season, presumably making it easier for them to extract water from dew and fog.

Life Cycle Strategies

Understanding the climate and soil parameters that define the bryophyte distributions is just a beginning of our understanding of the limitations of distribution. The physiology and reproductive biology of the bryophytes are likely to be major factors in their distribution. Maciel-Silva *et al.* (2012) examined reproductive performance as influenced by elevation in both monoicous and dioicous bryophytes in the Brazilian Atlantic rainforest. They sought to separate effects of reproductive strategy from effects of habitat. Using 11 species of bryophytes, they measured reproductive performance of sexual branches, sex organs, fertilization, and sporophyte production at sites from sea level to the montane region during 15 months. As is typical, monoicous bryophytes had the highest reproductive performance, with more sexual branches, fertilized eggs, and capsule production. At sea level, bryophytes produced more sexual branches and had more female-biased sex ratios than did those in the montane site. Nevertheless, the sporophyte frequency was similar between sea level and montane zones. Fertilization occurred mostly during periods of heavy rains (October to December). But habitat is also important in influencing life-history differences. The high production of reproductive structures early in the reproductive phase seems to compensate for the female-biased sex ratios and low fertilization rates. Maciel-Silva and Valio (2011) found similar phenological characteristics in the reproduction of bryophytes from sea level and the montane region of Brazil.

Santos *et al.* compared monoicous vs dioicous species numbers at five elevations at Serra do Mar State Park, Brazil. The pattern is interesting because the ratio of dioicous to monoicous is highest at sea level, then drops, and again rises at 1200 m. This ratio is even more pronounced for liverworts than for mosses. The monoicous condition increased with elevation except on the mountaintop (1200 m). The researchers suggested that asexual reproduction may permit species to live in conditions that are unfavorable to fertilization, particularly for dioicous taxa.

Figure 135. Dioicous-monoicous comparison for bryophytes at five elevations at Serra do Mar State Park, Brazil. Modified from Santos *et al.* 2017.

Frey *et al.* (1995) examined the life strategies of epiphytic bryophytes on an elevational gradient from tropical lowland and montane forest, ericaceous woodlands, and the *Dendrosenecio* (Figure 136-Figure 137) subpáramo of the eastern Congo basin and adjacent mountains as part of the BRYOTROP expedition. They identified three strategies: **colonists**, **perennial shuttle species**, and **perennial stayers**. But only the **perennial stayers** seem to be important, an indication of the more constant ecological conditions and long-lasting microsites for epiphytes. These conclusions were based on both sociological investigations and determination of mean percentage cover values in each of the life strategy categories. In the tropical lowland and lower montane zone forests the **perennial shuttle** species and **perennial stayers** with moderately low or low sexual and asexual reproductive effort are most common. This strategy is suitable for the high temperatures and humidity levels in these zones. In the montane rainforests and cloud forests of the upper montane zone, the **perennial shuttle** species is still dominant, but has high asexual reproductive activity using propagules and clonal growth. In the secondary forests of this zone and in the ericaceous woodlands and subpáramo of African volcanoes (Figure 138), the **perennial shuttle** and **perennial stayers** are dominant, using high levels of sexual reproduction and producing sporophytes regularly here and in the subalpine-alpine zone. Such a strategy is typical for epiphytes under xeric conditions. Thus, life cycle strategy seems to be important as an adaptation to the changing conditions that arise with elevational change.

Figure 136. *Dendrosenecio*, a genus typical of the subpáramo of the eastern Congo basin, Rwenzori Mountains National Park, Africa. Photo by Agripio, through Creative Commons.

In the Neotropics, Batista *et al.* (2018) studied life forms in the humid forest of Chapada do Araripe, Ceará State, Brazil. This region experiences seasonal rainfall. The predominant life forms are the desiccation-tolerant **turfs** and intermediate **mat** and **weft** (67%) life forms (Figure 139). Few low-tolerance species (3%) were present. Turfs were further divided into **turf** and **sparse turf**. **Mats** also included **thallose mats**. The monoicous life strategy predominated (67%), with 75 % of those with asexual reproductive means (gemmae, regenerating fragments, and caducous leaves) being dioicous species (Figure 140).

Figure 138. Páramo on Mt. Cameroon old lava flows. Photo by Amcaja, through Creative Commons.

Figure 139. Number of species in the represented life forms in the humid portion of northeastern Brazil. Modified from Batista *et al.* 2018.

Figure 140. Sexual vs asexual reproductive strategies in the humid portion of northeastern Brazil. Modified from Batista *et al.* 2018.

Batista *et al.* (2018) also examined substrate preferences. Bark epiphytes were by far the most species rich (Figure 141). Some preferred rocks or soil, but the number without any substrate preference was large, exceeded only by bark species.

Figure 141. Numbers of species **with** substrate preferences, on tree bark, rocks, soil, leaves, and on decaying tree trunks in the humid portion of northeastern Brazil. Species that colonize more than one type of substrate (two types) and those that do not demonstrate any preference (**without**). Modified from Batista *et al.* 2018.

Silva *et al.* (2014) found that mean diurnal temperature range explained habitat suitability for 9 of the 10 indicator species they used from the Brazilian Atlantic Forest. This can explain the elevational distribution of bryophytes.

Summary

High elevations near the equator have similar bryophytes to those at lower elevations farther from the equator. Tropical bryophyte diversity and abundance both increase from lowlands to montane regions. Bryophytes throughout most of the humid tropics have the same elevational zonation patterns: lowland forest,

submontane forest, upper lower montane forest, montane forest, and subalpine forest, mimicking the zonation patterns of tracheophytes and correlating with temperature and available moisture. Bryophytes, therefore, serve as good indicators of the zones.

In southeastern Brazil, **dioicous** species predominate in all elevations, with the smallest dioicous:monoicous ratio at mid elevations. **Endemism** increases with elevation, but in some locations, endemism can be very low. The highest elevation records of bryophytes are mostly in the tropics. The greatest species richness typically occurs below the alpine zone. The **α diversity** in the Andes is typically similar, but **β diversity** and **γ diversity** in the Andes are much greater.

Species presence and percent cover seem to be of equal importance in distinguishing bryophyte zones. These are highest in the **condensation zones**. Higher elevations tend to have more moisture and greater species richness. At low elevations, light intensity barely exceeds the **light compensation point**, greatly limiting productivity. This problem is exacerbated by the high temperatures, as supported by transplant studies. Mosses do not support **Rapport's elevational rule** (prediction of trends of increased elevational ranges of plants with increase in elevation). It is likely that genetic races will emerge as we examine molecular data for the species that occur in multiple zones.

Both abundance and biomass of epiphytic bryophytes increase from the lowlands to the **treeline**. Both low and high water content severely limit photosynthesis. **Perennial stayers** and **perennial shuttle species** predominate throughout the elevations, but life forms change from **mat** forms of the lowlands to **dendroid**, **pendent**, **fan**, and **weft** forms that can extract moisture from fog in higher elevations of the montane. **Cushions** become common in the alpine zone. Sea level bryophytes may produce more sexual branches and have more female-biased sex ratios than do those in the montane zone. The **perennial shuttle** species is still dominant in the montane zone, but has high asexual reproductive activity using propagules and clonal growth.

Acknowledgments

S. Robbert Gradstein was invaluable in providing me with papers, images, and constructive criticism on this subchapter. Thank you to Terry McIntosh for alerting me to the elevation-altitude distinction and to Daniel Spitale for sending me the paper on it by McVicar and Körner.

CHAPTER 8-9

TROPICS: SUBMONTANE AND MONTANE

Figure 1. Ecuadorian mountains and cloud forest. Photo by Arthur Anker, with permission.

Altitudinal zonation of bryophytes in the humid tropics are similar throughout the world (Frahm & Gradstein 1991). This subchapter will discuss zonation of the submontane and montane zones.

Submontane

The submontane region in Dominica are influenced primarily by the presence or absence of the canopy tree *Amanoa caribaea* (DeWalt *et al.* 2016). But in addition to that, hurricane disturbance is a major factor.

Aceby *et al.* (2003) compared bryophyte species richness in the submontane rainforest and fallows of Bolivia. The fallows exhibited a significantly decreased diversity of moss species, but the liverwort diversity showed little reduction in species except in the very young fallows. **Smooth mats** were significantly greater in presence in the fallows (72%), probably due to the warmer, drier climate there. Generalists and sun species were the more common members of the fallow communities, with about half of the submontane species occurring there. The specialists are slower to become re-established. The submontane exhibits the highest species richness in the

canopy, whereas the fallows reaches its highest diversity in the understory. This was in part due to the shifting of typical **rough mats, fans, and tails** to the lower heights in the fallows where the air temperature and humidity were more similar to those of the montane forest.

In central Sulawesi (Figure 2), Sporn *et al.* (2010) found 146 epiphytic species. They noted that this was among the highest number of epiphytic bryophyte species reported for any tropical forests, suggesting that the Malesian region is a global biodiversity hotspot. Among these bryophytes, 45% of the species were restricted to the tree crowns. The **dendroid** and **fan**-like species were in the understory; **tufts** dominated in the tree crowns.

Valdevino *et al.* (2002) reported on the pleurocarpous mosses (*e.g.* Figure 21-Figure 22) from a submontane rainforest in Pernambuco State, Brazil. They found only 23 pleurocarpous moss species in the 700 ha of their study of valleys and hills at 900-1,120 m asl.

Sonnleitner *et al.* (2009) found that even the smallest disturbance of the forest canopy could alter the microclimate and have a negative impact on the epiphyll community in the tropical lowland rainforest in Costa Rica (Figure 3).

Figure 2. Rice field with coffee and cacao plantations and submontane rainforest in the background, Sulawesi. Photo courtesy of S. Robbert Gradstein.

Figure 3. Submontane rainforest Costa Rica. Photo courtesy of S. Robbert Gradstein.

The strong response of epiphyllous (Figure 4) bryophytes to even subtle microclimatic variations suggests that undisturbed forest canopies and their control on microclimate may be essential for the development of epiphyll communities.

Figure 4. Epiphylls on a leaf. Photo by Rafael Medina, with online permission.

In a submontane tropical rainforest in Panama (Figure 5), Zotz *et al.* (1997) found that water relations were important. Both low and high water contents reduced carbon gain. Low light levels such as those found during a rainstorm were less important. They found a net carbon gain for the year for the mosses and liverworts to be 45%.

Figure 5. Panamanian sub-montane and montane rainforests. Photo by S. B. Matherson, through Creative Commons.

One of the factors that can affect productivity is nitrogen availability. Bryophytes can't use atmospheric nitrogen, but nitrogen fixation by associated organisms contributes to their nitrogen supply. Matzek and Vitousek (2003) found that when leaves had low N:P ratios, the N fixation was greater.

In the Colombian Andes (Figure 6), Gradstein *et al.* (1989) found that liverworts outnumber the mosses in both upper submontane and montane forests on the western slopes, but in drier environments their species numbers are lower than those of mosses. Species richness increases with altitude to the upper montane forest. Furthermore, at the lower altitudes, the wide-ranging tropical species are most prevalent.

Figure 6. Ritacuba Blanco, in the Andes of Colombia. Photo by 2005biggar, through Creative Commons.

Kürschner *et al.* (1999) described, for the first time, the pantropical patterns of life forms, life strategies, and ecomorphological structures of bryophytes inhabiting tree trunks. These represented altitudinal variations in transects in Southeast Asia, Africa, and South America. They considered the **mat-forming perennial stayers** and **perennial shuttle** species to characterize the tropical lowlands and submontane belt. In Ecuador, Kürschner and Parolly (2005) compared life forms in submontane and montane epiphytic bryophyte communities. The life forms are actually functional types and can provide considerable information (humidity, water supply, desiccation risk, light climate) about an ecosystem without necessitating species identification. In the submontane region, **mat-forming perennial stayers** and **perennial shuttle species** are the dominant forms, forming the *Symbiezidium transversalis* (Figure 7)-*Ceratolejeunea cubensis* (Figure 8) alliance. These are replaced by **fan** and **weft** life forms of **perennial stayers** and **perennial shuttle species** in the more montane regions, where they can take advantage of the cooler, more humid climate.

Figure 7. *Symbiezidium* sp.; *S. transversalis* is a species indicative of the submontane zone. Photo by Hermann Schachner, through Creative Commons.

Parolly and Kürschner (2004) found that bryophytes in the submontane and montane regions of southern Ecuador fall into two zonal groups. The submontane *Symbiezidium transversalis* (Figure 7)-*Ceratolejeunea cubensis* (Figure 8) has two communities, whereas the montane *Omphalantho filiformis* (*Cheilolejeunea filiformis*; see

Figure 9)-*Plagiochilion apicedentis* (*Plagiochila longiramea*; see Figure 10) has six. There is a slight deviation from the species in these associations in Peru (Figure 11). The epiphytic bryophyte communities correspond "perfectly to the supporting forest types" and thus are useful in defining the vegetation zones.

Montane Forests

Even countries like Ethiopia (Figure 12) and Kenya (Figure 13) that we picture as dry can have distinctive montane bryophyte communities (Hylander *et al.* 2010). In their first collecting trip to the southwestern Ethiopian montane forests (Figure 12), Hylander and coworkers recorded 89 species of liverworts, with 51 of these species new for Ethiopia.

Figure 12. Haremma Forest and Bale Mountains, southeastern Ethiopia. Photo by Sabine's Sunbird, through Creative Commons.

Figure 13. Montane rainforest around Mt Kenya. Photo by Chris 73, through Creative Commons.

These forests not only have a higher altitude, but also have rocky soil types (Pires & Prance 1985). The rocky substrate can create extreme drought, particularly during the short dry periods. At higher elevations there is greater humidity. The air can be saturated, providing a constant mist that is available to the bryophytes. Mosses, lichens, and small ferns form carpets over the rocks, tree trunks, and branches. Where the slopes are not steep, the forest is dense. Trees become smaller with altitude, with the treeline at Serra Neblina, Brazil (Figure 14), at about 2,600 m asl. The flowering plant family Theaceae (Figure 15) becomes prominent at higher altitudes and insectivorous Sarraceniaceae (*Heliamphora*; Figure 16) occur here. Fire is more likely here, but in Guayana the humidity is high and fires are uncommon.

In the Neotropics, the upper montane rainforest (Figure 17) can be distinguished from the lower montane rainforest by the greater percentage of temperate vegetation in the upper one (Churchill *et al.* 1995). The lower montane cloud forests, typically between 1,000 and 2,000 m asl, are characterized by a high percentage of epiphytes and tropical taxa.

Figure 17. Upper montane forest, Pui-Pui, Junín, Peru. Photo by E. Lehr and R. von May, through Creative Commons.

Montane forests have a simpler structure than the lowland forest with a much more luxuriant epiphytic vegetation (Gradstein 1992). The forest floor is often covered with dense carpets of bryophytes, in contrast to the lowland forests. Low temperatures and higher light levels than in the lowland forests support a luxuriant growth of bryophytes up to 15-20 cm thick. These growths may be **tall turfs**, **feather** types, and **pendent** life forms.

The montane forest ecosystems are the most diverse of the highland habitats. In Bolivia, 88% of the liverworts and 74% of the mosses known in the country occur in the montane forest, yet this forest type occupies only 8% of the land (Churchill *et al.* 2009).

Within the highlands the 226 montane forest ecosystems are the most diverse. In Bolivia, for example, montane forests (Yungas and Tucuman-Bolivian) occupy only 8% of the land surface of the country, but contains 88% of the liverworts and 74% of the mosses recorded from the country (Churchill *et al.* 2009).

In the Ecuadorian montane (Figure 18) and lowland rainforest (Figure 19), Grubb *et al.* (1963) found an "exceedingly high" diversity of mosses (2,058 species), suggesting that the tropical Andes might be the richest in species of any tropical region of the world. The tropical Andes have approximately eight times as many species as the Amazon basin. The moss flora supports the vegetation zonation concept, with strong differences between the montane-páramo/puna ground species and the montane forest where epiphytes predominate.

In the montane rainforest of Peru, at 2,400 m asl in the Peruvian Yungas, a single tree of *Weinmannia* (Figure 20) sp. was substrate for 110 bryophyte species – 77 liverworts, 32 mosses, and 1 hornwort, a remarkably high species richness (Romanski *et al.* 2011). Using the Johansson zones (lower trunk, upper trunk, mid-crown, mid-outer crown, and outer crown), the researchers found that the upper trunk and large branches of the mid-crown had the highest species richness and abundance. Liverworts, especially *Lejeuneaceae* (Figure 9), dominated all five Johansson zones. (See Gradstein 1995 for additional discussion of the liverwort diversity in the montane forests of the tropical Andes.) The mid-crown enjoys a higher light intensity than the darkness surrounding the lower trunk, coupled with a high relative humidity. Romanski *et al.* distinguished four communities: outer crown, mid to mid-outer crown, upper trunk, and lower trunk. The outer crown had a remarkable 35 liverwort species, joined by only 2 moss species. Of these, 17 of the liverworts had a high light tolerance. This suggests that overall these liverworts have a higher tolerance to high light and exposure.

Costa and Lima (2005) supported previous studies by finding that the moss flora is not uniform in the tropical rainforests of Rio de Janeiro, southeastern Brazil. The lowland, montane, submontane, and upper montane Atlantic rainforests have very different moss floras. The highest number of exclusive species and greatest species richness occur in the montane Atlantic rainforest. The intermediate level of species richness is in the sub-montane Atlantic rainforest. The lowland Atlantic rainforest has the smallest number of species. The high diversity seen in the montane forest is most likely a consequence of the diversity of climatic, edaphic, and physiographic changes present in the macrophytic vegetation. The moss family *Sematophyllaceae* (Figure 21) comprises 19% of the taxa in the lowland forest, the **pendent** mosses of *Meteoriaceae* (Figure 22) 10% of the montane forests, and *Dicranaceae* (Figure 26) 18% of the upper montane forests. Those taxa having broad Neotropical distributions are important in all these forests. These comprise 40% of the bryophyte taxa. Grubb (1977) contributed additional information on the mineral nutrition in wet tropical mountains.

Gradstein and Vána (1994) noted the similarity of the bryophyte community of tropical montane forests of Mexico to that of the boreal community. For example, in the central highlands of the Chiapas, the *Nowellia curvifolia* (Figure 23) community is common on rotten logs and is rich in boreal liverworts. Among these, *Cephalozia catenulata* (Figure 24), *Nowellia curvifolia*, *Campylopodia stenocarpa* (Figure 25), and *Dicranum frigidum* (Figure 26) were the most abundant. The humid flanks of logs typically had *Syzygiella autumnalis* (Figure 27), *Leptoscyphus amphibolius* (see Figure 28), and *Lophozia longiflora* (Figure 29), with *Anastrophyllum hellerianum* (Figure 30-Figure 31) also being frequent. In addition to these locations on logs, *Nowellia curvifolia* is very abundant on logs that have already lost their bark (decorticated logs).

Among the early south American bryophyte studies was that of Linares (1986). This researcher studied the taxonomic and ecological aspects of the high Andean strip of the El Tabalzo, Cundinamarca, Colombia.

As already noted for epiphytes in earlier subchapters, Veneklaas (1990) reported that the bryophytic epiphytes in the montane rainforests can play a major role in the nutrient dynamics of the rainforest. Veneklaas found that in two epiphyte-rich Andean rainforests of the Central Cordillera of Colombia, the elevation of 2,550 m exhibited a higher nutrient input to the forest through bulk precipitation, at least in part because this elevation has higher total precipitation. At the same time, losses of nutrients from the canopy were also higher, both in total amounts and per unit of precipitation. Bryophytes are able to capture and hold nutrients, often releasing pulses in the first rainfall after a drying period.

Concerned with the role of bryophytes in maintaining water balance and contributing to nutrient cycling in tropical montane forests, Benítez *et al.* (2015) assessed bryophytes and lichens on tree bases of 240 trees in both primary and secondary forests in southern Ecuador (Figure 19). As expected, diversity was higher in primary forests than in monospecific secondary forests. The reduction of canopy diminished bryophyte species. Shade epiphytes were intolerant of the increased light penetration and were replaced by sun epiphytes in the secondary forests.

Bisang *et al.* (2003) explored the diaspore banks in three Malaysian mountain rainforests (Figure 32). They

incubated soil samples from 0-5 cm depth for 15 hours of light daily and mean daily temperature of 19°C with radiation of $3-5 \mu\text{E m}^{-2} \text{s}^{-1}$. These were kept moist with sterilized water as needed. After 5 months the cultures were gently disturbed with forceps. After 4 and 5 months they were placed under a bright light intensity of $100 \mu\text{E m}^{-2} \text{s}^{-1}$. Liverwort emergence exceeded that of mosses, especially from soils from lower altitudes. Consistent with living bryophytes, the species diversity was twice as high in samples from higher elevations compared to those from lower ones.

Figure 32. Montane rainforest in tropics on Gunung Batu Brinchang, Malaysia. Photo by Peter Coxhead, through Creative Commons.

In Costa Rica, Dauphin L. and Grayum (2005) collected from dry lowland forests and moist montane forests in Guanacaste Province, Costa Rica (Figure 33). In the moist montane forests, **corticolous** (growing on bark) bryophytes predominate. This is in contrast to the soil, log, and rock substrates that are most important in the lowland dry forests. The submontane zone had significantly less species richness. The researchers considered higher temperatures, limiting water availability, and human disturbance as factors limiting the diversity of the submontane zone. Rare species occurred on the tree boles, with 99% of the locally rare species occurring on the tree boles.

Figure 33. Guanacaste, Costa Rica, montane forests. Photo by Jason Folt, with permission.

Song *et al.* (2015) compared bole bryophytes in three protected forests, one in sub-montane, one in montane, and one in subalpine regions in Yunnan, China (Figure 34). Five plots were established at each of 12 altitudes, using 200 m intervals, totalling 594 subplots. The total number of species identified was 226. Life forms differed among the forest types, with **smooth mat** dominating the sub-montane, **fan** in the montane, and **turf** in the subalpine.

Figure 34. Lowland forest, Guangnan, Yunnan, China. Photo by Anders Johnson, through Creative Commons.

The Itatiaia National Park in Brazil (Figure 35) has well-defined climatic bands of montane, upper montane, and high-altitude fields. Costa *et al.* (2015) used literature, herbarium material, and data banks in addition to examining 10 representative elevations. These sources revealed 519 taxa. As in many other studies, the mid-altitudinal range (2,100-2,200 m asl) had the highest species richness. The number of threatened species increased with elevation. Furthermore, the upper montane forest had the most endemic species (47).

Figure 35. Mountains in Itatiaia National Park, Brazil. Photo by Pedroivan, through Creative Commons.

In Indonesia (Figure 36), submontane forests are known to have a very rich bryophyte flora (Gradstein & Culmsee 2010). On only eight canopy trees, 150 species were present. The researchers found that the lower

montane and upper montane forests of Sulawesi have very different bryophytes that characterize them. The low elevations have mostly mosses in **Calymperaceae** (Figure 37), **Fissidentaceae** (Figure 38), **Hypopterygiaceae** (Figure 93), **Leucobryaceae** (Figure 39), **Meteoriaceae** (Figure 40), **Neckeraceae** (Figure 41), **Pterobryaceae** (Figure 42), and **Thuidiaceae** (Figure 43), and liverworts in **Lejeuneaceae** (Figure 8-Figure 9), **Lophocoleaceae** (Figure 100), **Porellaceae** (Figure 60), **Radulaceae** (Figure 56). By contrast, the high elevations are characterized by the leafy liverworts **Herbertaceae** (Figure 44), **Lepidoziaceae** (Figure 97-Figure 99), **Mastigophoraceae** (Figure 45), **Scapaniaceae** (Figure 46), **Schistochilaceae** (Figure 47), and **Trichocoleaceae** (Figure 102). As is typical, the liverwort family **Lejeuneaceae** has the most species in the submontane and lower montane forests, whereas the leafy liverwort family **Lepidoziaceae** has the most in the upper montane forest. Moss dominance decreases while liverwort dominance increases with elevation. Some of these species prefer rough bark, but none shows a preference for smooth bark. Trunk diameter is important for some species, but communities don't seem to be affected by it.

Based on investigations in Southeast Asia, Africa, and South America, as the mountain vegetation zones shift from submontane to lower montane, the bryophyte life forms also shift (Kürschner *et al.* 1999). The **mats** are replaced by **fan** and **weft** formers that are able to take advantage of the cooler air with higher humidity. **Perennial stayers** and **perennial shuttle species** have a greater reliance on asexual propagules and clonal growth. The plants furthermore have a structure that permits them to take advantage of water vapor from fog, to conduct water internally, and to store water.

Lower Montane

In the lowland forest and the lower montane rainforest of Colombia (Figure 48), Wolf (1993a) identified four main bryophyte community groupings, primarily related to position within the host tree:

1. Communities of the lowland forest at 1,000 m (valley floor)
2. Communities of the lower montane rainforest, 1,250 m to ca. 2,130 (2,550) m
3. Communities of the upper montane rainforest, ranging from ~2,460 m to the treeline at 3,700 m.
4. Communities of *Polylepis* (Figure 49-Figure 50) dwarf forest at 4,130 m.

Figure 50. Subalpine dwarf mossy *Polylepis pauta* forest in Ecuador. Photo by K. Romolero, courtesy of S. Robbert Gradstein.

The *Polylepis pauta* (Figure 49-Figure 50) forests have dominated in many humid environments of the high Andes of Ecuador, Peru, and Bolivia (3,500-4,500 m asl) (Gradstein & León-Yáñez 2018). However, now these forests are greatly diminished due to replacement with grasslands for grazing. They have become one of the most threatened ecosystems in South America. Gradstein and León-Yáñez have documented the liverwort flora in the remnant forests in the páramo of Papallacta, Ecuador, finding 51 liverwort species. The forest floor and tree bases were nearly completely covered with bryophytes, in particular *Lepidozia auriculata* (see Figure 99) and the robust *Plagiochila* species *P. dependula*, *P. ensiformis*, *P. fuscolutea* (Figure 51), and *P. ovata*. The branches had abundant growths of *Frullania paradoxa* (see Figure 55), *Leptoscyphus hexagonus* (see Figure 28), *Plagiochila bifaria* (Figure 52), and *P. punctata* (Figure 53).

The secondary, semi-deciduous lowland forest is dominated by *Machaerium capote* (Figure 54) (Wolf

1993a). The epiphytes are characterized by the leafy liverworts *Frullania ericoides* (Figure 55) and *Radula tectiloba* (Figure 56), as well as various *Lejeuneaceae* (Figure 9). *Frullania ericoides* is a pantropical xerophytic species. The canopy is characterized by a lichen community of *Heterodermia albicans* (Figure 57)-*Trypethelium eluteriae* (Figure 58). The trunk, by contrast, is dominated by the pendent moss *Meteorium nigrescens* (Figure 22) and the leafy liverwort *Radula caldana* (see Figure 56). Exclusive taxa in this association are *Papillaria nigrescens*, *Radula caldana*, *Mastigolejeunea auriculata* (Figure 59), *Porella brasiliensis* (see Figure 60), and *Sematophyllum subpinnatum* (see Figure 21). This community occurs from the tree base up to the inner crown. Epiphytes are absent on the twiglets of the outer canopy.

Because of the high humidity, every surface is potentially a bryophyte substrate. But these are also suitable substrata for other types of plants. Ingram and Nadkarni (1993) reported that the bryophytes formed only 5% of the epiphytic organic matter in a Neotropical lower montane forest where the dominant host was *Ocotea tonduzii* (see Figure 61). Flowering plants formed only 10% of the species biomass, with dead organic matter being the dominant portion at 60%.

Figure 61. *Ocotea cf. leucoxylon*, a species that is dominant in a Neotropical lower montane forest where bryophytes comprise only 5% of the epiphytic organic matter. Photo by Jens G. Rohwer, through Creative Commons.

The lower montane rainforest communities differ from those of the lowland forest (Wolf 1993a). Exclusive species include the leafy liverwort *Lejeunea flava* (Figure 62-Figure 63), the pendent moss *Squamidium nigricans* (see Figure 116), and the foliose lichen *Parmotrema subsumptum* (Figure 64). Three of the six identified communities of epiphytes [*Bryopteris filicina* (Figure 65) tree bole community, *Cheilolejeunea trifaria* (Figure 66) - *Schlotheimia acutifolia* var. *angustifolia* (see Figure 67) community, *Plagiochila fragilis* (see Figure 51-Figure 53) community from tree crowns] share the liverwort species *Cheilolejeunea rigidula* (see Figure 66), *Frullania caulisequa* (Figure 68), *Lejeunea laetevirens* (Figure 69), and the moss *Sematophyllum subpinnatum* (see Figure 21). Furthermore, *Cheilolejeunea rigidula* and *Lejeunea laetevirens* are exclusive to these three communities. In other communities, exclusive species include *Diplasiolejeunea pauckertii* (see Figure 70) in the *Diplasiolejeunea pauckertii* - *Brachiolejeunea laxifolia* community and *Squamidium nigricans* in the *Frullania arecae* (Figure 71) - *Frullanoides densifolia* (Figure 72) - *Squamidium nigricans* community. In the *Bryopteris filicina* (Figure 65) community, present in the range of 1,210 and 1,980 m asl on the lower parts of tree trunks and less commonly on steep inner branches in the lower canopy, *B. filicina* is exclusive, accompanied by the

liverworts *Cheilolejeunea rigidula* and *Lejeunea laetevirens*. The liverworts are closely appressed and grow intermixed with feather-shaped dendroid genera such as *Bryopteris*, *Neckeropsis* (Figure 41), and *Porotrichum* (Figure 114) that stand out for several centimeters as horizontal shelves. The *Cheilolejeunea trifaria* - *Schlotheimia acutifolia* var. *angustifolia* community occurs in the inner crowns of trees in the range of 1,210 to 1,980 m asl. This Columbian community shares *C. trifaria* and *Lopholejeunea subfusca* (Figure 73) with a lower trunk community of open secondary forests at 1,300 m asl in Malaysia (Kürschner 1990). The *Diplasiolejeunea pauckertii* - *Brachiolejeunea laxifolia* community occurs in the outer canopy at elevations primarily from 2,460 to 2,550 m asl.

In the lower montane rainforest of Panama, water content of bryophytes experiences pronounced daily flux (Zotz *et al.* 1997). These low and high levels are more important in limiting CO₂ exchange than the low photon flux density (light level) during rainstorms. More than half of the fixed carbon was lost to respiration during the night. Lösch *et al.* (1994) contributed an additional study on the photosynthetic gas exchange of bryophytes from the tropical lowlands and mountain forests of Central Africa.

In a lower montane rainforest of New Guinea, Edwards and Grubb (1977) estimated the epiphytic biomass to be 2 t ha⁻¹. Unfortunately, the bryophyte component of this was not measured separately, but the role of the epiphytes and accumulated "soil" in the crowns contribute ca. 1 t ha⁻¹ of soil. Minerals are released slowly from this epiphytic mass accumulation, providing a reservoir of nutrients for the soils.

Upper Montane

As the lower montane transitions into the upper montane, the proportion of **cushion**, **short**, and **tall turf** life forms of **perennial stayers** and **perennial shuttle species** begin to predominate (Kürschner & Parolly 2005). And as the habitat becomes more open, the bryophytes often have a dense rhizoid tomentum and a central conducting strand, aiding in rapid water conduction.

In the ericaceous forest of the upper montane of the Rwenzori Mountains of Uganda (Figure 74), Pentecost (1998) studied the epiphytes on mature trees of *Phillipia* (Ericaceae). *Usnea* spp. (Figure 75) and other macrolichens dominate the upper canopy. In the lower canopy, large cushion-forming liverworts such as *Chandonanthus* (Figure 76), *Herbertus* (Figure 44, Figure 77), and *Plagiochila* (Figure 10, Figure 51-Figure 53) dominate. Pentecost concluded that light intensity and age of host tree controlled the distribution of the bryophytes and lichens. Using fallen trees, Pentecost identified 14 bryophyte species, along with 2 algae, 22 lichens, and 2 ferns. The biomass of these organisms was nearly 1 ton ha⁻¹ and comprised 10% of the above-ground standing crop. Bryophytes held 8% of the above ground nutrients, with concentrations of 10 kg ha⁻¹ of N, 1 of P, and 3 of K. This

forest was cool, with the temperature below the canopy ranging 4-9.5°C during the 10-day study period. The temperature increased slightly with canopy height. Evaporation below the canopy decreased significantly with increasing altitude from 2,300 to 3,600 m asl.

Bizot *et al.* (1978) conducted one of the early studies on East African bryophytes, sampling in Ethiopia, Kenya, and the United Republic of Tanzania. They identified 96 liverwort and 211 moss species. They concluded that the Ethiopian Highlands are a part of the Afromontane vegetation group. Here they found disjunct populations of *Garckea comosa* (see Figure 78) and *Aongstroemia julacea* (Figure 79).

Figure 78. *Garckea flexuosa*; *G. comosa* occurs as a disjunct in the Afromontane region. Photo by Manju C. Nair, through Creative Commons.

Figure 79. *Aongstroemia julacea*, a disjunct in the Afromontane region. Photo by Jan-Peter Frahm, with permission.

Kürschner (2003) expanded his studies of epiphytic bryophytes to Arabia. He described the associations *Leptodonto* (Figure 80) - *Leucodonetetum schweinfurthii* (see Figure 81) and *Orthotricho* (Figure 82)-*Fabronietum socotranae* (see Figure 83) from the Yemen escarpment mountains. These associations are typical in the monsoon-impacted *Juniperus procera* (Figure 84) and *Acacia origena* (Figure 85) woodland. The species of bryophytes are typically drought-tolerant Afromontane mosses, with *Orthotrichum diaphanum* (Figure 82) and *Syntrichia laevipila* (Figure 86) typifying the synusia. The drought-tolerant *Orthotricho-Fabronietum socotranae* (see Figure 83) is dominated by **cushions**, **short turf**, and **mat-forming**

perennial stayers that regularly produce capsules. The sunny sites, by contrast, have **tail** or **fan** pleurocarpous **perennial shuttle species** with large spores and either moderately low reproduction or more "generative" reproduction, in addition to liverworts. This grouping forms the subhumid *Leptodonto* (Figure 80) – *Leucodonetetum schweinfurthii* (see Figure 81).
