CHAPTER 2-6

PROTOZOA ECOLOGY

Figure 1. The ciliate protozoan *Blepharisma americana* inhabits the lobules of the liverwort *Pleurozia purpurea*. Photo by Sebastian Hess, with permission.

General Ecology

Protozoa can probably be found on almost any bryophyte if one just looks carefully (Figure 1). Larger protozoa tend to occur in bog habitats (Chardez 1967; Bovee 1979). As drier habitats are examined, the species are smaller and smaller. *Diffflugia* (Figure 2) species are typical of aquatic mosses; *Cyclopyxis* species occur on terrestrial mosses. *Centropyxis* species distribution depends on the habitat, with *C. aculeata* (Figure 3, Figure 4) in wet locations and *C. platystoma* in dry ones. *Corythion dubium* (Figure 5), *Assulina muscorum* (Figure 6), and *Trinema lineare* (Figure 7) occur generally on forest mosses (Chardez 1957; Bovee 1979; Beyens *et al.* 1986), although *A. muscorum* also is known from the cells of living *Sphagnum recurvum* (Figure 8) (BioImages 1998). *Corythion pulchellum* (Figure 9) and *Trinema complanatum* (Figure 10) occur only on forest mosses (Chardez 1960; Bovee 1979). *Nebela collaris* (Figure 11), *Centropyxis aculeata*, and *Hyalosphenia papilio* (Figure 12) occur on *Sphagnum* and other bog mosses, but not on forest mosses (Chardez 1960; Chiba & Kato 1969; Bovee 1979).

Figure 8. *Sphagnum recurvum* var. *tenue*, a peatmoss that supports living protozoa in its hyaline cells. Photo by Jan-Peter Frahm, with permission.

Figure 9. *Corythion pulchellum*. Photo by Yuuji Tsukii, with permission.

Figure 10. *Trinema complanatum*. Photo by Yuuji Tsukii, with permission.

Figure 11. *Nebela collaris*. Photo by Yuuji Tsukii, with permission.

Figure 12. *Hyalosphenia papilio* and *H. elegans*. Photos by Edward Mitchell, with permission.

Protozoa are generally the most numerous invertebrates among the *Sphagnum* plants (Figure 8; ntham & Porter 1945). In a Canadian study, flagellates were the most numerous, but testate amoebae are often the most numerous.

Epiphytes

Despite the dryness of aerial habitats, protozoa are common among epiphytic bryophytes, drying and encysting as the bryophytes dry, then reviving, eating, and reproducing when the bryophytes are moist. This habitat may hold many species as yet undiscovered because it is a habitat less frequently studied by protozoologists. Nevertheless, a number of taxa are known from this unique habitat (Golemansky 1967; Casale 1967; Bonnet 1973a, b).

Antarctic

The role of protozoa is particularly important in the Antarctic. On Elephant Island of the South Shetland Islands in the Antarctic, moss carpets and turf form a major part of the habitat available to protozoa (Smith 1972). Mastigophoran (flagellate) moss inhabitants include 15 species. The Mastigophora are not unique to this habitat. Those that were in most of the moss samples also were in samples of grass/soil, clay, or **guano** (accumulation of feces). Furthermore, none of the species that was abundant in the other habitats was absent among bryophytes except *Tetramitus rostratus*, which was abundant only on guano. The Rhizopoda, including the testate amoebae, seemingly avoided the guano on Elephant Island, whereas 16 species occurred in the bryophyte habitats (Smith 1972). Several of those Rhizopoda present in the grass/soil habitat were not found among the moss samples. Fourteen species of Ciliata occurred among mosses.

Figure 13. *Nebela tinctoria* test with living amoeba. Photo by Edward Mitchell, with permission.

The small number of Elephant Island moss samples (4 in *Polytrichum–Chorisodontium* turf & 5 in *Brachythecium–Calliergon–Drepanocladus* carpet) precludes comparison of moss preferences (Smith 1972). The most abundant ciliate, *Urotricha agilis* (see Figure 14), was abundant in both turf and carpet. In samples of turf, mean numbers per gram of fresh weight ranged 170–4,500. In carpet they ranged 250 to 7,700. On Signey Island species numbers were higher in moss turf (40), whereas on Elephant Island they were higher in moss carpet (37) than in turf.

Nutrient Cycling

Protozoa are common predators on bacteria and fungi (Hausmann *et al.* 2003), having the role of nutrient cyclers (Mitchell *et al.* 2008). In the Pradeaux peatland in France, the testate *Nebela tincta* (Figure 13) consumed mostly micro-algae, especially diatoms, associated with mosses (Gilbert *et al.* 2003). In summer they also consumed large ciliates, rotifers, and other small testate species. Micro-organisms collect between leaves and along stems of *Sphagnum*. When the system is wet, prey organisms are mostly immobile and often dead, but when conditions are drier and the water film is thin, testate fauna are able to ingest more mobile organisms than usual because these prey are slowed down by lack of sufficient free water for rapid swimming. Although we know little about their role among bryophytes, it is likely that at least in peatlands the role of moss-dwelling protozoans in nutrient cycling is significant (Gilbert *et al.* 1998a, b; Mitchell *et al.* 2008).

Habitat Effects

When protozoa and other inhabitants live on a host, they can alter the host. Insects are well known for the many forms of galls that develop on the host plant. Gradstein *et al.* (2018) discovered a white colony of protozoa, resembling gnathifers, in the swollen shoot tips of the liverwort *Herbertus sendtneri*. This resulted in cessation of the tip growth and subsequent development of innovations below the tip.

Moss Effects on Soil Habitat

The presence of mosses also affects the micro-organisms found in the underlying soil. Miroschnichenko and coworkers (1975) found that the greatest numbers of micro-organisms were under mosses (compared to other soil substrata) in a community in Russia, and Smith and Headland (1983) found similar results for testate rhizopods on the sub-Antarctic island of South Georgia. Smith (1974a, 1986) found protozoa living among the bryophytes in the South Orkney Islands and Adelaide Island of the Antarctic. Ingole and Parulekar (1990) found that the faunal density, including protozoa, was high in moss-associated sediments. These micro-organisms may account for the ability of some macrofauna to remain within the moss mat throughout a major part of their development by serving as a food source (Smith 1974a, 1986).

Epizoites

Some of the fauna, such as *Pyxidium tardigradum* (Figure 17), an **epizoite**, are hitch-hikers. This protozoan is recorded as a **symphoriont** (organism carried by and often dispersed by its host) on two species of tardigrades (Figure 15) [*Hypsibius oberhaeuseri* (Figure 16) and *Milnesium tardigradum*] that live among mosses (Land 1964; Morgan 1976). It can be so common on them (up to 35, but more typically 1-3) as to have negative effects on the tardigrade host that must expend extra energy to carry them around (Vicente *et al.* 2008). For this reason, Vicente *et al.* (2008) suggest that it should perhaps be considered a parasite.

Figure 17. *Pyxidium tardigradum*, a tardigrade symphoriont. Redrawn from Van Der Land 1964.

Soil Crusts

Protozoan communities associated with cryptogamic soil crusts (Figure 18) have hardly been studied. In a study of only five crusts in southeastern Utah, Bamforth (2008) found 28 species of amoebae, 45 ciliates, and 19 testate amoebae. The number of amoebae ranged 680-2500, ciliates 20-460, and testate amoebae 2400-2500 per gram dry mass of crust. As crusts succeeded from *Microcoleus* (Cyanobacteria) to lichens to bryophytes, numbers of protozoa increased, perhaps reflecting longer periods of internal moisture in the crusts. Predominant taxa are somewhat different from cosmopolitan ones we have seen elsewhere, comprised mostly of *Acanthamoeba* (Figure 19), *Hartmanella* (Figure 20), *Vahlkampfiidae* (Figure 21), two species of *Colpoda* (Figure 22), several other colpodids, *Polyhymenophora* sp., and species of *Cryptodiffugia* (Figure 23) and *Diffugiella*.

Vertical Zonation

Bryophyte suitability as a protozoan habitat differs in both time and space. Bryophytes offer a vertical series of habitats (Figure 24) that differ in temperature, moisture, and light, and presumably food quality and quantity. Horizontally, the substrate or height above the water table can differ, causing species differences. Hence, the micro-organisms distribute themselves in different communities both seasonally and spatially, particularly in the *Sphagnum* peatlands (Schönborn 1963; Heal 1964; Meisterfeld 1977; Mazei and Tsyganov 2007).

Figure 24. *Sphagnum subnitens* showing tips and lower branches that create habitat zones for protozoa. Photo by Michael Lüth, with permission.

Spaces: Several studies indicate that the sizes of spaces within the bryophyte habitat influence the sizes of organisms and influence the available food (Dalenius 1962; Corbet 1973; Bovee 1979; Robson *et al.* 2001). Capillary spaces among branches and leaves hold water. Gilbert *et al.* (2003) suggested that as the *Sphagnum* becomes drier, ciliate protozoa are easier to catch for food because the thin film of water slows them down. As the moss becomes too dry, rather than migrating to lower, moister areas, many of these taxa, like several invertebrate groups, can encyst, permitting them to survive desiccation (Heal 1962; Gerson 1982). And when the moss resumes activity under the stimulation of rain (or fog), the rhizopods do likewise.

Nitrogen: Nitrogen from guano seemingly deterred all the testate amoebae on Elephant Island (Smith 1972).

Nitrogen distribution affects the vertical distribution of at least some testate amoebae in *Sphagnum* communities, but nitrogen availability does not seem important for most testate amoebae in the upper centimeters of *Sphagnum* mats in the Swiss Jura Mountains (Mitchell & Gilbert 2004). There were 22 testate taxa among these mosses, although mean diversity of a typical sample was only 6.6. The species richness increased with depth. The moss-dwelling *Assulina muscorum* (Figure 25) was most abundant in the top 0-1 cm; *Phryganella acropodia*, *Heleopera rosea* (see Figure 26), and *Nebela militaris* (Figure 27) were the most abundant taxa at 3-5 cm depth. In this case, species richness increased with depth in the mat. Only *Bullinularia indica* (Figure 28) appeared to be more abundant in plots fertilized with nitrogen.

Figure 27. *Nebela militaris*. Photo by Yuuji Tsukii, with permission.

Figure 28. Test of *Bullinularia indica*. Photo by Edward Mitchell, with permission.

Temperature: The Antarctic fauna is dominated by moss-dwelling micro-organisms, including protozoa, rotifers, nematodes, and tardigrades (Schwarz *et al.* 1993). Here, temperature may play a role as important as that of moisture. This need for adequate heat results in a vertical zonation of the fauna. For example, at the Canada Glacier, in southern Victoria Land, the majority of moss-dwelling organisms were in the top 5 mm in the post-melt samples, rather than in the pre-melt samples. However, while temperatures differed, so did the available moisture, making it difficult to determine controlling factors.

Light: As one might expect, light determines the absence of protozoa with chlorophyllous symbionts in the lower strata (Chacharonis 1956). Only those surface species contain chlorophyll, either as symbiotic algae or that of their own possession. However, some with chlorophyllous symbionts may occur as deep as 6-10 cm in *Sphagnum* mats (Richardson 1981). Of the 27 species lacking symbionts in a *Sphagnum* mat, all but two exhibited maximum abundance below 6 cm. But even within the first 5 cm, vertical zonation exists. Mitchell and Gilbert (2004) demonstrated a significant difference in number of species between the first 3 cm and the 3-5 cm depth in *Polytrichum strictum* (Figure 29) of a Swiss peatland (Figure 30).

Figure 29. *Polytrichum strictum*. Photo by Michael Lüth, with permission.

Figure 30. Vertical distribution of species richness of testate amoebae in a *Polytrichum strictum* "carpet" of a Swiss peatland. Redrawn from Mitchell & Gilbert 2004.

Community Differences: As for a number of other moss habitats, the *Sphagnum* peat mat provides vertical differences in microhabitat that are further expressed as vertical community differences (Meisterfeld 1977; Strüder-Kypke 1999; Mitchell *et al.* 2000). Strüder-Kypke found that even in the upper 30 cm of the mat, two very different protistan communities are dictated by the strong vertical zonation. Both light and nutrients differ, causing the upper region to support a denser colonization, mostly of autotrophic cryptomonads and vagile ciliates (able to move about or disperse in a given environment). On the other hand, deeper samples exhibited heterotrophic flagellates and sessile peritrich ciliates.

Presence of testate amoebae at greater depths within the moss mat does not always indicate a retreat to a location of greater moisture. Schönborn (1977) demonstrated that 15% of the shells can be transported to lower depths by 550 mm rainfall, but 400 mm generally does not seem to cause a noticeable downward loss.

Zoophagy by Liverworts?

Carnivorous plants are well known among the flowering plants, but the ability of bryophytes to attract and trap organisms has been questionable. Who would guess that these seemingly primitive organisms can attract their own prey? But one interpretation is that the leafy liverwort genera *Colura* (Figure 31, Figure 32) and *Pleurozia* (Figure 33) have **lobules** (water sacs) that do just that (Hess *et al.* 2005). And this is not an isolated example. In the Aberdare Mountains, Kenya, Chuah-Petiot and Pócs (2003) found many protozoa inhabiting the lobules of the epiphytic *Colura kilimanjarica* (Figure 31, Figure 32).

Figure 31. **Upper:** The leafy liverwort, *Colura*. **Lower:** This lobule of *Colura* houses the ciliate protozoan *Blepharisma americana*. Photos by Jan-Peter Frahm, with permission.

Figure 33. Underside of *Pleurozia purpurea* showing lobules where invertebrates often live – and die. Photo by Sebastian Hess, with permission.

Lobules are usually considered to be water storage organs. However, in these genera, they might also serve as traps. Goebel (1888, 1893, 1915) did not consider it likely that these were real traps. He argued that insectivorous plants have attractants in order to lure their prey into their traps. Although the lobule resembles the trap of the bladderwort, *Utricularia*, Goebel argued that that does not mean it is used the same way. He furthermore argued that the benefit gained by the excrement from animals (and dead animals?) would be less than that gained from the water. Since having the animals does not preclude also providing a water reservoir, it would seem that zoophagy would simply be an added benefit. Schiffner (1906) even reported chironomid larvae in the lobules, suggesting an even larger source of fecal matter. But the openings in *Pleurozia* are small, only about 300 μm , and closed by a round "lid" of hyaline cells (Hess *et al.* 2005). What causes these organisms to enter in the first place?

Figure 34. *Pleurozia purpurea*, a leafy liverwort with lobules that can house a variety of invertebrates, including the ciliate *Blepharisma americana*. Photo by Sebastian Hess, with permission.

Figure 35. **Upper:** Lobule of *Pleurozia purpurea* showing lid. Photo by Sebastian Hess, with permission. **Lower:** Lobule redrawn from Hess *et al.* (2005). This lobule of *Pleurozia purpurea* serves as home and apparently ultimately as a trap for a wide range of protozoa and invertebrates.

Barthlott *et al.* (2000), using feeding experiments with the ciliate protozoan *Blepharisma americana* (Figure 1, Figure 36-Figure 38), demonstrated that *Colura* does indeed catch protozoa with its lobules. Hess and coworkers (2005) set out to determine if *Pleurozia purpurea* (Figure 33-Figure 35) is likewise carnivorous.

Figure 36. The ciliate *Blepharisma americana* that inhabits "zoophagous" liverworts. Photo by Yuuji Tsukii, with permission.

Again using *Blepharisma americana*, a cohabitant of *Sphagnum* mats with *Pleurozia purpurea*, Hess *et al.* (2005) performed dozens of experiments in Petri dishes to

see if the dispersion of the protozoan remained random. Indeed, the protozoa gradually accumulated around the *Pleurozia*! Within only 30 minutes, 86% of the lobules contained the protozoa. After several hours, up to 16 protozoans were trapped, and further observation failed to reveal any that escaped.

The mode of attraction is only speculation. Barthlott *et al.* (2000) found that older parts of *Colura* were more effective at attracting *Blepharisma americana* (Figure 37, Figure 38) than were younger parts, suggesting that concentrations of bacteria may have been a factor. In fact, in experiments on *Colura*, Barthlott *et al.* (2000) found that *B. americana* moves over the bryophyte surface "like a vacuum cleaner," devouring the bacteria.

Figure 37. A stained *Blepharisma americana*. Photo by Yuuji Tsukii, with permission.

The shade provided by the plants could also contribute to the higher concentrations of protozoa near the branches of *Pleurozia purpurea* (Hess *et al.* 2005), but if so, the liverwort would probably be less effective as a refuge in the field where other mosses were also present.

Hess and coworkers (2005) claim that the large number of organisms in the lobules in such a short time is too great to be attributed to chance. However, they fail to provide any statistical evidence or probability to support this claim, for example, alternative liverworts or mosses. They furthermore state that the organisms die there, but they provide no data on the deaths of the organisms. They do point out that there is no direct evidence that any nutrients provided by the organisms are used by the liverworts, but there is likewise no evidence to the contrary. In any case, the liverworts could benefit from the cleaning of bacteria that block light and compete for nutrients.

Figure 38. SEM photo of *Blepharisma* demonstrating small cell on top and large, cannibalistic cell below. Under starvation conditions, larger individuals become cannibalistic. Photo by Pauline Gould, with permission.

Zoophagy is the process of eating animals (*phag* = eat, devour; Hanson 1962; Lincoln *et al.* 1998). There is a fine distinction in what constitutes just eating compared to true carnivory, wherein living organisms are killed (or not) and digested. In this case, it seems that the animals may be trapped, but there is no real proof that they are consumed by the plant. Does admitting the animals into the trap (lobule) then make the liverworts zoophagous? Hess *et al.* (2005) argue that animals die in the traps and subsequently release their cell contents, bursting in the case of *Blepharisma americana*. These dead animals are then decomposed by bacteria. Surely some of the nutrients released are absorbed by the liverworts. Is this not a process parallel to that of the pitcher plant *Sarracenia purpurea*? Many so-called carnivorous plants, like *S. purpurea*, seem to lack enzymes to digest all or some of the parts of their prey and depend on resident bacteria to accomplish the task. With this broad definition of carnivory, could we not call the liverworts **carnivorous**? I think I want more data on whether this is a chance event or true trapping before I make that claim. Such experiments would need controls of leafy liverworts with no "traps" to see if the protozoa simply accumulate wherever there is shelter. On the other hand, I wonder how many leafy liverworts with locules provide preferred housing for protozoa.

Dispersal

For any organism to succeed, it must have a means of dispersal. Protozoans can't go very far on their own. They are too small to crawl far on pseudopods or paddle their way with a flagellum or cilia, the common means of transportation for the majority of protozoan moss dwellers. But they can travel reasonable distances as passengers on the mosses, riding on fragments that establish a new home where they land.

Sudzuki (1972) conducted experiments using electric fans to determine the success of wind as a dispersal agent, using mosses as one of the sources of invertebrate fauna. He found that the smaller organisms – micro-organisms, including protozoa, were easily dispersed by light breezes as well as wind. Larger organisms such as gastrotrichs, flatworms, rotifers, nematodes, oligochaetes, tardigrades, crustaceans, and arachnomorphs, on the other hand, rarely were dispersed at wind velocities of less than 2 m per second [tornadoes are generally 27-130 m per second (Allaby 1997)]. In the field, colonization progressed from flagellates to ciliates to rhizopods, suggesting that passive dispersal was not the only factor controlling their colonization rates.

Once an organism becomes airborne, turbulent air may take them 3,000 to even 17,000 m on thermal drafts, with winds carrying them much higher and farther (Maguire 1963). Puschkarew (1913) found that protozoan cysts average about 2.5 per cubic meter, making these organisms readily available for dispersal and colonization on suitable bryophytes.

Smith (1974b) likewise considered that the mosses themselves served as dispersal agents for the protozoa. In particular, moss invasions of volcanic tephra on Deception Island in the Antarctic greatly increased the protozoan fauna. Not only do the mosses provide a great increase in suitable niches, but since they were most likely colonized

by protozoa in their former locations, fragments arriving on the island could easily carry communities of fauna as passengers.

Rain can carry many algae and protozoa (Maguire 1963). Rain-borne organisms seem to originate predominantly from splash, typically from plants and soil, and do not travel far vertically, so that mechanism is most likely only suitable for local habitat travel.

In streams, the water movement itself serves as an effective dispersal agent, and aerial dispersal from waterfalls and rapids can carry algae and other *Aufwuchs* to new locations.

Raccoons are very effective in carrying whole communities of organisms, particularly protozoa, and can accomplish distances of at least 60 meters (Maguire 1963). Both terrestrial and aquatic birds contribute to dispersal, and other mammals contribute, but their relative role is not known.

Several scientists have discussed the dispersal of micro-organisms by insects (Maguire 1963; Parsons *et al.* 1966). Such mechanisms could easily contribute to the colonization of bryophytes by their micro-inhabitants. The many aquatic insect inhabitants will be discussed in an upcoming chapter. Consider the activity of insects among bryophytes, especially in streams, and their subsequent relocation due to swimming or stream drift. The *Aufwuchs* could easily be carried from one location to another by these mobile inhabitants (Figure 39). Emerging insects may also swipe micro-organisms trapped by the surface tension and carry them to resting locations, including bryophytes, on land.

Figure 39. Dragonfly *Aeshna grandis* female ovipositing and exposing herself to possible transport of protozoa. Photo by David Kitching, with permission.

Although few studies seem to have directly addressed the dispersal of micro-organisms by insects to bryophytes, we can infer at least some possibilities from more general studies on dispersal by insects. Maguire (1963) examined the distance both horizontally and vertically to which organisms were dispersed from a pond in Texas and another in Colorado. Dragonflies (Figure 39) and wasps, in particular, carried several species of protozoa and one species of rotifer. Parsons *et al.* (1966) found amoeboid and other protozoan cysts on adult Odonata, suggesting the possibility of a relatively long dispersal range. Odonata in

a short-term experiment dispersed up to 860 m to the farthest pond in the experiment (Conrad *et al.* 1999). Michiels and Dhondt (1991) estimated that 80% of adult dragonfly *Sympetrum danae* had migrated 1.75 km or more to their study site. But more importantly, evidence suggests they can migrate 3500 km or more across the Indian Ocean (Anderson 2009). This and other long-distance migrations provide a potential yearly means of dispersal for the micro-organisms.

Cosmopolitan

'Everything is everywhere, but, the environment selects' (in Wit & Bouvier 2006; O'Malley 2008). This statement, often called the Baas Becking Principle, has been applied to microscopic organisms that are globally distributed by high dispersal, and that lack biogeographic patterns (Fontaneto *et al.* 2008). But Wit and Bouvier made it clear that the original hypothesis "did not disregard the biogeography of free-living microorganisms." Finlay *et al.* (1996) extend the concept to suggest global species diversity is inversely related to body size. Therefore, the huge number of protist individuals makes global dispersal inevitable through normal events such as ocean circulations, groundwater connections, hurricanes, damp fur, dust storms, etc. (Weinbauer & Rassoulzadegan 2003). This argument is supported by the fact that the estimated number of free-living ciliates is about 3000, whereas there are about 10,000 species of birds and 120,000 species of Lepidoptera (butterflies and moths) (Lawton 1998).

The concept of global distribution describes well the major protozoa associated with bryophytes. This concept does not preclude, however, the presence of cryptic species that differ in less recognizable traits (Richards *et al.* 2005; Fontaneto & Hortal 2008; Fontaneto *et al.* 2008; Kooistra *et al.* 2008), and in recent detailed studies distinct genetic species have been found in disparate parts of the world (Telford *et al.* 2006; Fontaneto *et al.* 2008; Kooistra *et al.* 2008).

One consideration to support "everything is everywhere" is the small number of species of protozoa relative to 750,000 species of insects and 280,000 species of other animals (Papke & Ward 2004). Morphological data support the concept that dispersal is worldwide, suggesting there would be fewer than 5000 morphological protozoan species. Could this also be the explanation for the small number of bryophytes relative to other plants? In both cases, molecular evidence is starting to suggest that there may be cryptic species with genetic differences that are not expressed morphologically (Logares 2006), revealing distributions that are much more restricted.

Bryophyte protozoan communities are remarkably similar no matter where the bryophytes occur and consist primarily of cosmopolitan species. Davidova (2008) compared the testacean communities of epiphytic bryophytes to those of soil bryophytes in Strandzha Natural Park, South-Eastern Bulgaria, and found them to be quite similar in their taxonomic richness, species diversity, and community structure. The most common taxa in both habitats were *Centropyxis aerophila* var. *sphagnicola*, *C. aerophila* (Figure 40), *Phryganella hemisphaerica*, *Euglypha rotunda* (Figure 41), *Corythion dubium* (Figure 5), *Trinema enchelys* (Figure 42), and *T. lineare* (Figure 7). Among these, only *Phryganella hemisphaerica* is

missing from the sites in Switzerland, Alaska, Sweden, Finland, Netherlands, Britain, Bulgaria, and North America as summarized in Table 1 of Chapter 2-2. The epiphytic community had 34 taxa in 13 genera, whereas the soil mosses had 31 taxa in 13 genera.

Figure 41. *Euglypha rotunda*. Photo by Yuuji Tsukii, with permission.

Figure 42. *Trinema enchelys*. Photo by Yuuji Tsukii, with permission.

The moss-dweller *Nebela* (*Apodera*) *vas* (Figure 43) has been touted to refute the Baas Becking Principle (Mitchell & Meisterfeld 2005; Smith & Wilkinson 2007). In 89 collections, representing 25 publications, mosses represented 59% of its habitat, with *Sphagnum* being the most common (Smith & Wilkinson 2007). Its distribution

is throughout the equatorial region at high altitudes, southern cool-temperate, and sub-Antarctic zones, but it is conspicuously absent in the Holarctic northern hemisphere. Its absence from hundreds of samples from seemingly suitable habitats in the northern hemisphere support the contention that its absence is not a fluke of sampling (Mitchell & Meisterfeld 2005). This distribution is definitely not cosmopolitan, despite its wide pH range (3.8-6.5) (Smith & Wilkinson 2007). Although it has a rather defined climatic range (temperate to sub-Antarctic), its absence in this climate throughout most of the more frequently studied northern hemisphere cannot support the concept of "everything is everywhere." Evidence such as this has been used to argue that micro-organisms are dispersed following the same principles as macro-organisms (BioMed Central 2007). Genetic differences that are not detectable from morphology suggest that global diversity of micro-organisms may be greater than has been suspected (BioMed Central 2007; Fontaneto *et al.* 2008). Such evidence suggests that care is needed in assigning names to microbial/protozoan collections.

Figure 43. SEM view of *Apodera* (*Nebela*) *vas* showing test. Photo by Edward Mitchell, with permission.

Jenkins *et al.* (2008) have tested the size hypothesis, using 795 data values on dispersal units from published research. They found that active dispersal vs. passive dispersal matters greatly, with active dispersers dispersing significantly farther ($p < 0.001$) while having a significantly greater mass ($p < 0.001$). They showed that size does make a difference, but not always as predicted by the Baas Beeking Principle. Among active dispersers, it is the larger dispersers that go the greater distances, perhaps related to required energy. The principle does not even hold well for the passive dispersers. The distances travelled by these dispersal units were random with respect to mass.

How well does the size:dispersal distance relationship hold for bryophytes that travel by spores? One might argue that as a group, they are more cosmopolitan than seed plants and less cosmopolitan than the protozoa. Fortunately for the protozoa, they are not very specialized for particular bryophytes.

Communities as Biological Monitors

Ciliates living among bryophytes in Czechoslovakia are sensitive to air pollution, giving us another way to assess the effects of air pollutants (Tirjakova & Matis 1987). Testate amoebae, including *Assulina* (Figure 25),

Corythion (Figure 5, Figure 9), *Euglypha* (Figure 41), and *Heleopera* (Figure 26), as well as *Euglena* (Figure 44) and Cyanobacteria, in a *Sphagnum* bog of Tierra del Fuego, South America, were sensitive to UV-B radiation (Robson *et al.* 2001). But surprisingly the testate amoebae and rotifers were significantly more abundant and had greater species diversity under current levels of UV-B radiation than those that received reduced UV-B. The fungal component likewise had significantly greater abundance and species diversity under the current dosage than under the reduced dosage.

Figure 44. *Euglena mutabilis*, a common euglenoid among bryophytes, particularly in peatlands. Photo by Yuuji Tsukii, with permission.

Because pollution affects the entire community, moss-dwelling protozoans can often be a more efficient means of assessing pollution damage than other biological components. In a study in France, Nguyen-Viet *et al.* (2007a, b) assessed the response of the protozoan community under simulated lead pollution. Using Pb^{+2} concentrations ranging from 0 to 2500 $\mu g L^{-1}$, they found that biomass decreased significantly for bacteria, microalgae, testate amoebae, and ciliates at 625 and 2500 $\mu L^{-1} Pb^{+2}$ after six weeks. The microbial biomass decreased as the densities of testate and ciliate protozoa decreased, but the relative biomass of bacteria to that of the protozoa remained constant. The correlation between the two groups increased as the lead concentration increased. Hence, the protozoa provided an effective and relatively inexpensive means of assessing the community response.

Enhanced CO_2 had the opposite effect on the community relationships (Mitchell *et al.* 2003). Biomass of the testate amoebae decreased by 13% while the heterotrophic bacteria increased by 48% when the CO_2 was increased to 560 ppm, compared to those at an ambient CO_2 concentration of 360 ppm. Mitchell *et al.* (2003) suggest that the increase in bacterial biomass may be a response to increased exudation from *Sphagnum* under the higher CO_2 regimen.

As discussed in an earlier sub-chapter, the testate amoebae can serve as indicators of drainage in *Sphagnum* mires, as noted by Warner and Chmielewski (1992) in northern Ontario, Canada. As the water level falls, some species increase while others decrease.

Collecting and Sorting

There are lots of references for collecting, preserving, and enumerating aquatic and soil taxa of protozoa, but few on methods for bryophyte fauna. However, many methods for soil will apply equally well to the bryophyte fauna. A thorough coverage of methods is in Adl *et al.* (2008), with methods for peatland microfauna in Gilbert and Mitchell (2006). A special method for holographic viewing of live testate amoebae is presented by Charrière *et al.* (2006).

Collecting

Collecting protozoa that live among mosses is simple and requires no special equipment. In thick cushions or mats of bryophytes, extraction can be achieved with a stainless steel corer. In some circumstances, a knife can be used to cut a core and the core then placed into a cylindrical plastic container (Lamentowicz & Mitchell 2005). Stream bryophytes should be collected in a way that avoids as much loss downstream as possible. This can be achieved by shielding the bryophyte from most of the flow and especially shielding it as it breaks through the surface. One's hands are often sufficient to achieve this, but a container might be used over the bryophyte, enclosing as much of its depth as possible while dislodging it from the substrate. For non-quantitative collections in almost any habitat, a hand-grab is usually sufficient. For diversity studies, it is important to get the moss down to its substrate because zonation often occurs.

Storage & Preservation

Bryophytes and adhering water/moisture can be kept in jars or polyethylene bags until they are returned to the lab. If the weather is warm, it is desirable to place the containers in a cooler with ice. Oxygen is a problem, so open containers or vials with loose lids will help. For aquatic collections, some free water might be needed, making it necessary to confine the water by such means as a wad of paper towel or cloth above the water level to avoid splashes out of the jar. Parafilm may suffice for short time periods, or two, separated layers of screen or mesh.

The most rewarding experience is to observe the protozoa live as they swim about in the water film, gyrate from a stalk, or engulf a food item. Some species will remain alive only a few hours after collection (Samworth 1995). If the organisms are to be kept for a few days, place them in a refrigerator (not freezer) or incubator that is set in the range of 5-15°C (Glime pers. obs.). The container should be covered to reduce evaporation, but not sealed. Jars with lids should have the lid on loosely to permit air exchange. If the jar is opened and a foul odor escapes, there has not been enough air exchange, and many of the organisms will be dead – and perhaps subsequently eaten by the more hardy ones.

Preservation

If the sample is to be kept for long in the field before returning to the lab, and the weather is hot, it might be necessary to preserve the organisms. This is fine for testate amoebae, but may make counting and identification of other protozoans difficult or impossible.

Preservation of bryophyte protozoan samples is like that of other protozoa, using 2% glutaraldehyde (final

solution) (Mitchell *et al.* 2003), formaldehyde (Fisher *et al.* 1998; Gilbert *et al.* 1998a, b), or glycerol (Hendon & Charman 1997b), but the water content of the bryophyte must be considered in calculating the dilution. For example, saturated *Sphagnum* typically has 95% water content (Gilbert & Mitchell 2006).

Long-term Storage of Cysts

One choice for long-term storage is to let the mosses and their fauna dry slowly in air for several days. This can be done in open paper bags, a method typically used for drying bryophytes, or in open jars. Cool drying is preferable for many species, but survivorship will vary depending on the climate of origin and should be tested against fresh samples if the samples will be used for quantitative or diversity work.

Once the samples are dry and the protozoa have encysted, they can be sealed in containers and stored at 4°C. Again, the effects of storage should be tested for any quantitative or diversity work. Tropical taxa may require a warmer storage temperature (Acosta-Mercado & Lynn 2003). This method will only work for species that readily encyst and for testate rhizopods.

Extraction

Organisms can be extracted from the bryophyte-water matrix with a teat pipette (*i.e.* volume is unimportant) and placed as a drop on a glass microscope slide. Bryophyte inhabitants can be squeezed into a sample bottle with little danger to them, but this may have disastrous results for larger fauna that may be of interest. Protozoa can be concentrated in a centrifuge or by running the water through a fine nylon mesh (Samworth 1995), but smaller organisms will be lost and adhering organisms will remain behind on the bryophyte.

Gilbert *et al.* (2003) reduced the negative effects of squeezing by pressing a sieve (1.5 mm mesh) on the moss surface and sucking the water up with a syringe. They were unable to solve the problem of adhering organisms, including some microbial groups. Others are missed because they live inside *Sphagnum* cells. This method creates minimal destruction of the *Sphagnum* mat, even through repeated sampling, except for the trampling by the people doing the sampling.

In their book on *Sphagnum* ponds, Kreutz and Foissner (2006) suggest a slide on slide method (Figure 45). Mosses can be washed in a small amount of suitable water, preferably rainwater or other water that won't kill the fauna. In most cases, lots of detrital matter will come off the mosses, along with many members of the fauna. Dense material will collect on the bottom of the container and can be drawn into a pipette/dropper (ca 2 mL). Material can be transferred onto a glass slide to cover most of the slide. A second slide is then used at an angle to push the flocculent detrital matter to the end of the slide. When the edge of the top slide reaches near the end of the bottom slide, the top slide is lowered onto the bottom one and used as a coverslip. A smaller version of this method (*i.e.* a smaller sample of water and detritus) can be done in the same way with a drop of the water and detritus in the middle. In this case, a coverslip of the desired size can be used in the same manner as the top slide described above. Note that both

methods will be biased toward mobile organisms. Tardigrades, rotifers, sessile protozoans, and other attached organisms will be poorly represented, if at all, by this method (and most others!). To see these, branches of moss need to be examined under the microscope.

Figure 45. Slide on slide method of concentrating and extracting micro-organisms. Drawing by Janice Glime based on images in Kreutz and Foissner 2006.

Testate Amoebae

The non-flooded Petri dish method (below) can be used to culture testate amoebae as well, but a longer time may be needed to wake up the cysts (Adl *et al.* 2008).

One method to extract **testate** organisms is to dry the bryophytes at 65°C, then sieve and back-sieve them with a sieve that retains all particles in the range of 10-300 µm. The standard method seems to be that of Hendon & Charman (1997b). A standard length of moss is cut and boiled for 10 minutes to loosen the amoebae. The boiled samples are filtered first at 300 µm, then back filtered through 20 µm. The organisms retained by the 20 µm filter are stored in 5 ml vials with glycerol.

Another method for extracting testate species is to put single shoots of bryophyte samples in a vial and shake them with a vortex mixer (Nguyen-Viet *et al.* 2004). This solution can be filtered through a 40 µm mesh filter and washed with deionized water to remove larger organisms. The tiny testate species will most likely all go through the filter due to the force of the water. The filtered water can then be placed in a plankton-settling chamber for 24 hours so the testae will settle to the bottom. For this method, Nguyen-Viet *et al.* (2004) used 20 samples of approximately 0.3 g fresh weight of living moss, placed in a glass vial with 7 ml of 4% formaldehyde.

A different approach to extraction is to boil the living bryophyte stems in distilled water for 20 minutes, stirring occasionally (Lamentowicz & Mitchell 2005). This

solution with moss is then sieved through a 300 µm sieve to remove large constituents. The filtrate can then be concentrated with a centrifuge at 3000 rpm for 4-6 minutes. The tests can be stored in glycerol.

Non-testate Taxa

The non-testate taxa are somewhat more difficult to work with because they are best seen while active. One alternative is to culture them, using the non-flooded Petri dish protocol described by Adl *et al.* (2008):

1. Place bryophyte sample in a 5- or 10-cm Petri dish. Several Petri plates can be set up initially and drained on different days to avoid depleting nutrients with the wash.
2. To culture, moisten sample with distilled water or wheat grass medium.
 - a. To make wheat grass medium, combine 1 g wheat grass powder and 1 L distilled or deionized water in a 2-L Erlenmeyer flask.
 - b. Boil at a gentle rolling boil for 2 minutes, then let settle and cool for 1 hour.
 - c. Filter into a new flask through several layers of cheesecloth to remove the grass residue.
 - d. Adjust the pH to appropriate level (based on sample pH) with a phosphate buffer.
 - e. Autoclave in screw top bottles for 20 minutes.
 - f. Bacteria growth can be reduced by diluting to 1/10 or 1/100 strength.
3. Alternatively, a culture can be made from a dilute solution of detritus from the moss.
4. Incubate at 15°C in the dark or at ambient field temperature. Be sure plates do not desiccate.
5. Observe every few days for signs of activity, up to about 30 days. Some testate amoebae will take several weeks or even months to leave the encysted stage and become active.
6. To observe, moisten the culture plate with a squeeze bottle of distilled or deionized water.
7. Tilt the plate until there is enough to drain the water into a new plate.
8. Observe the drained water in the new plate with a dissecting microscope and oblique transmitted illumination; capture organisms with micro-dissecting tools or a micropipette, then observe with an inverted microscope with phase contrast if possible (see observation section below). Most will require 100-400X to be seen well.
9. Note that the often abundant cercomonads form thin filopodia that explore tiny pores (<1 µm diameter). These adhere to flat surfaces and are not easily seen or dislodged. They may require staining (see below).
10. The original plate can be returned to the incubator.

Observation

Live observations can be done with a small branch, a leaf, or just a drop of adhering water on a glass slide with a compound microscope. A few larger protozoa might be observed with a dissecting microscope. A cavity slide will avoid crushing as the slide dries. Further confinement can

be achieved with this type of slide by putting a drop of water on the cover slip, then inverting it over the cavity, making a **hanging drop** slide. Alternatively, putting Vaseline at the corners of a cover slip on a standard flat slide will keep the cover slip from crushing them. More water can be added at the edge of the cover slip and will be drawn under by capillary action.

Ciliates and flagellates can be slowed down by a viscous substance such as methyl cellulose. Observing them in the interstitial water of intact bryophytes also tends to slow them down. Note that these organisms are mostly transparent and viewing may be improved by using darkfield and/or closing down the diaphragm of the microscope. An inverted microscope has the advantage of giving you a better view of those protozoa that settle on the bottom, especially testate amoebae.

Start your observations with a low magnification and move up after you have found a quiet one you want to observe, preferably surrounded by a bryophyte leaf or other confinement.

For testate amoebae, observation of dead material is not a problem, albeit not so interesting. The test is well-preserved and can be observed and identified at the convenience of the observer.

Staining

Staining can make the organisms easier to see (Figure 46), and vital stains may help to provide behavioral information. For example, neutral red can be used to follow digestion (Howey 2000). Newly formed vacuoles will stain bright red. As digestion proceeds, the vacuole will become yellowish, indicating a change in pH toward alkaline. Powdered carmine can also be used to indicate the location of the vacuole. Subsequent observation with Nomarski differential interference contrast can provide clear visibility. The observer should experiment with brightfield, darkfield, India ink in the solution, oblique illumination, phase contrast, or whatever types of optical contrast may be available. Unfortunately, all stains appear eventually to be toxic, so the viewing time is limited (Howey 2000; Table 1). **WARNING:** Read the labels carefully; many stains are also highly toxic to humans!

Figure 46. *Oxytrichia fallax* stained with Protargol. Photo by William Bourland, with permission.

Table 1. Concentrations needed to stain *Paramecium* and toxicity after one hour. Table from Howey 2000.

Stain	Min Conc to Stain	Toxicity - % dead in hour
bismarck brown	1:150,000	0
methylene blue	1:100,000	5
methylene green	1:37,500	5
neutral red	1:150,000	3
toluidine blue	1:105,000	5
basic fuchsin	1:25,000	30
safranin	1:9,000	30
aniline yellow	1:5,500	0
methyl violet	1:500,000	20
Janus green B	1:180,000	40
Nile blue	1:30,000	
Rhodamine	1:20,000	

Identification

There are some specialty keys available, and lots of pictures on the internet. However, internet pictures and keys should be used with caution and the source of information evaluated because these are unreferenced and often contain errors. A good general reference for identification is the publication by Lee *et al.* (2002), "The Illustrated Guide to the Protozoa." Its nomenclature is in places outdated, so usage should be checked in Adl *et al.* (2005). A more recent aid is a book by Kreutz and Foissner (2006). This book has wonderful color pictures, but there is no designation to tell which were on bryophytes and which were in open water.

Quantification

Adl *et al.* (2008) advised that taxa must be counted within one or two days of collection because temperature and moisture changes will shift the bacterial communities and this will, in turn, cause a change in community structure of the protozoa.

To quantify the sample size, the bryophyte can be weighed after drying. However, some amoebae will become glued to the bryophyte by the attending algae and detrital matter, thus contributing to the weight. Biovolumes can be estimated by using the geometrical shapes and an appropriate formula for that shape, then multiplying by the number obtained (Mitchell 2004).

Adl *et al.* (2008) provided a method to estimate protozoa per gram of dry soil. It could be modified for bryophyte purposes. For any quantification, the method must be consistent among those communities being used for comparison. One can use stem length, wet weight, or dry weight, but these have different biases for different bryophytes and those must be dealt with. Furthermore, different methods may favor the observations of some protozoan taxa. For example, larger organism are more easily seen, testate organisms are more likely to fall from the moss upon shaking, sessile organisms will most likely not fall at all.

Charman (1997) suggested a method for quantifying the testate amoebae and warned of its shortfalls. You may be familiar with methods of determining pollen density by including a known number of *Lycopodium* spores in the sample (for example, 200) and using the ratio of those

observed on the slide to those put in the sample. Unfortunately, in the testate samples extracted from mosses, the number of tests estimated was reduced by up to 80% and the number of taxa was reduced by 60%, probably due to differences in weight, making this a less than desirable method. Using KOH to digest the organic matter did not destroy the tests, and permitted extraction of more tests, but they were damaged and more difficult to identify. Charman concluded that a water-based preparation with sieving was the best method.

Various combinations of filtration, vortex, and centrifuge can be used to get the best results for particular circumstances. Different mesh sizes can be used with back filtration to classify the organisms into size groups (Kishaba & Mitchell 2005). The organisms collected between 15 and 350 μm are a typical size group of Testacea examined (e.g. Warner & Charman 1994; Booth & Zygmunt 2005).

Summary

Larger protozoa tend to occur in moist or bog habitats, whereas drier habitats have smaller ones. Some even occur within the hyaline cells of *Sphagnum*. Some protozoa are exclusive to *Sphagnum*; others occur only on forest mosses. Those on epiphytic bryophytes are able to dry with the mosses and encyst during periods of drought. Moisture also contributes to the vertical zonation of protozoa in peatlands. Soil crusts can have some of the highest numbers of species. Moisture is the major determining factor on species distribution and survivorship, with terrestrial species able to withstand drying more than wet habitat species can. Over 400,000 individuals can occur in one square meter of terrestrial mosses. Studies in the Antarctic suggest that temperature and moss growth form play roles in the number of species.

Drying slows the mobile organisms and permits larger protozoa to capture them. Their consumption of micro-organisms places the moss-dwelling protozoa in the role of nutrient cycling. The bryophytes further contribute to ecosystem processing by affecting the moisture and temperature, hence altering the protozoan fauna, in the underlying soil.

Some protozoa are hitch-hikers on other bryophyte inhabitants, such as those that ride around on tardigrades. Others have green algae as symbionts and are thus restricted to photic zones on the bryophytes, whereas those without these symbionts typically occur below 6 cm depth. Yet others (*Pleurozia*, *Colura*) seem to trap protozoan prey in leaf lobules. In fact, it appears that the leafy liverwort *Pleurozia purpurea* may actually attract *Blepharisma americana*.

Dispersal is likely to be as passengers on bryophyte fragments. A successional pattern from flagellates to ciliates to rhizopods suggests that other factors determine colonization rates. Some colonization comes from dormant cysts awaiting suitable conditions. Dispersal of cysts and living organisms can be facilitated by splashing raindrops. Some may even be facilitated by insects, birds, raccoons, and other mammals.

The small size of protozoans and other micro-organisms led to the assumption of cosmopolitan distribution, a concept known as the Baas Becking Principle, or "everything is everywhere." However, recent studies on distribution and genetic differences have brought this principle into question.

Bryophyte-inhabiting protozoa are sufficiently sensitive to some types of air pollution that they can be used as monitors, but not all are sensitive to the same things, so community structure is likely to change.

Collecting is relatively simple, but quantification is tricky. Testate species can be separated by physical means, but other taxa often require culturing to awaken cysts. Some may be amenable to staining to further clarify identification.

Acknowledgments

Paul Davison has been wonderful in helping me with the methods portion of this chapter, including the suggestion to include it. Edward Mitchell provided me with a large number of papers and photographs. Both of these researchers were invaluable in helping me with areas where I was often not personally familiar with the subject.

CHAPTER 3-1

SLIME MOLDS: BIOLOGY AND DIVERSITY

Figure 1. Orange slime mold on moss, Blue Lake Creek valley, Washington, USA. Photo by Matt Goff, Sitka Nature, with permission.

What are Slime Molds?

Slime mold or slime mould is an informal name given to three kinds of unrelated eukaryotic organisms. While the bryophytes were undergoing classification changes at the familial and ordinal levels, **Protista** were jumping to new kingdoms and phyla. Hence, anyone whose knowledge about these organisms is as old as mine needs a road map to understand who now belongs where. Slime molds are no longer considered fungi, but instead seem to be protozoa.

The protozoa have been joined by other groups to form the current concept of the paraphyletic kingdom **Protista**, also known as **Protozoa**, a grouping that is one of convenience. One such group to join them is the slime molds (Figure 1). Once classified as fungi, they have been booted out of that kingdom due to their lack of chitin and their feeding by engulfing food. They are now considered **Protista** due to their motile stages that look and behave like protozoa. Within the **Protozoa**, we will consider here the phylum known as **Eumycetozoa** or **Amoebozoa** (Shadwick *et al.* 2009; Kang *et al.* 2017).

The slime molds are comprised of more than 1000 species from all seven continents (Lloyd 2011). The life cycle is one reason for their current classification position. They can live freely as single cells, but in dictyostelids they

can later aggregate to form multicellular reproductive structures.

Using 18S rDNA and cladistics, Leontyev *et al.* (2019) revised the classification of the **Myxomycetes**. Noting that "Myxomycetes show a higher within-group genetic divergence than true fungi, higher animals, or vascular plants," they divide the slime molds into three classes, giving the groups taxonomic status according to the International Code of Nomenclature:

- **CLASS MYXOMYCETES** (Figure 2-Figure 9)

The **Myxomycetes**, also known as **Myxogastria**, are the **acellular** slime molds, referring to the plasmodium that is multinucleate with no cell separation. These form the largest group of slime molds and contain almost all of the slime molds that associate with bryophytes. Based on the list of genera in nomen.eumycetozoa.com (5 May 2019), I have found all but three of the genera with at least one species that has been found on bryophytes to be in this class. The **plasmodium** (Figure 22, Figure 24) moves by amoeboid movement with rapidly streaming protoplasm, reaching speeds up to 1.35 mm per second (Alexopoulos 1962, 1964). The mass can migrate when it streams to an advancing position and

withdraws its protoplasm from the rear area. When food becomes scarce, this mass will migrate to the surface of the substrate and form its rigid fruiting bodies. These produce spores that hatch into amoebae to continue the life cycle (Ling 1999).

• **CLASS DICTYOSTELIOMYCETES** (Figure 12)

Dictyostelids are cellular slime molds. I have found only two genera with any species reported on these slime molds. The **Dictyosteliomycetes** do not form huge plasmodia (Figure 22, Figure 24) and remain as individuals, feeding on microorganisms. When they run out of food, they form fruiting bodies, first releasing signal molecules that enable them to find each other and

then aggregating as swarms. They join to form a tiny multicellular coordinated slug-like creature (Figure 10). They can aggregate about 100,000 cells in *Dictyostelium discoideum* (Figure 11-Figure 12) (Kessin *et al.* 1996). This aggregate crawls to an open place in the light to form a fruiting body (Kakiuchi *et al.* 2001). While some of the amoeboid cells actually become spores, others become part of the dead stalk that lifts the spores upward. About 20% of the cells of the *Dictyostelium discoideum* die as they form the stalk (Kessin *et al.* 1996). This group is largely unrecorded from bryophytes. The only record I found was for *Dictyostelium quercibrachium* from the margin of a small bog in Ohio, USA (Cavender *et al.* 2005), and it is not clear if was actually on a moss.

Figure 12. *Dictyostelium discoideum* fruiting in an open place. Photo by Usman Bashir, through Creative Commons.

• CLASS CERATIOMYXOMYCETES

The **Ceratiomyxomycetes** is a small group of only three genera (Leontyev *et al.* 2019). Their typical substrates are dead plant material, especially decaying wood. The genus *Ceratiomyxa* has at some time been in each of these three classes. It is the only genus of this new class that I have found reported from bryophytes. These slime molds have a complex life cycle, usually with a sexual phase, and the cycle includes amoeboflagellates that do not divide but instead convert into amoebae or to form a plasmodium (Spiegel *et al.* 2018). The plasmodium most likely follows sexual reproduction and formation of a zygote, although the sexual reproduction has not been verified in all genera. Fructification produces one, two, four, or eight spores at the top of a relatively long stalk.

Figure 14. *Trichia varia* with orange sporangia. Photo by Lebrac, through Creative Commons.

Identification Difficulties

Identification of species can be difficult for a number of reasons. Not only are there different color phases during the development of the sporangia, but there are different sexual strategies within currently perceived species (Clark & Haskins 2010; Feng & Schnittler 2015). One example of this is the widespread *Trichia varia* (Figure 13-Figure 17; **Myxomycetes**), an occasional bryophyte dweller (Feng & Schnittler 2015). Within this "species" there are three distinct sexual biospecies that are reproductively isolated from each other, based on 197 specimens collected from throughout Eurasia. In this case, the genotypes are distinct, but the phenotypes are not. Furthermore, there appear to be numerous sibling species that are biologically distinct, unable to mate, but morphologically indistinguishable, and these are spread throughout the world (Clark & Haskins 2010).

Reproduction and Colonization

Slime molds sound like nasty things that grow in the corners of your refrigerator, but in fact they are beautiful and fascinating organisms that really aren't molds at all. For centuries we thought they were, but unlike true fungi, they eat bacteria and other micro-organisms. Hence, they have been reclassified into the **Protista**. Stephenson and Stephenson (2022) found that although bryophyte mats are appropriate substrata for slime molds in temperate deciduous forests, the species richness and abundance are both relatively low. Their unique call to fame is their rather strange life cycle in which they try to be fungi when fruiting and protozoa when active.

General Life Cycle

The **Myxomycetes** are the **plasmodial slime molds** and with few exceptions are the only group large enough to be noticed easily (Wikipedia: Slime Molds 2019). In these **acellular** slime molds, the **plasmodia** (Figure 18, Figure 22, Figure 24) have many nuclei with no dividing cell membranes and can form a plasmodial mass that may be several meters in size. One of the most obvious of these is the slimy yellow plasmodium of *Fuligo septica* (Figure 19- Figure 20) on rotting logs – a species that also can occur on bryophytes (Figure 18). Both the amoeboid and the plasmodial stages can engulf microorganisms as food.

Figure 18. *Fuligo muscorum* on **Polytrichaceae**. Photo by James K. Lindsey, with permission.

Figure 20. *Fuligo septica* on mosses (**Polytrichaceae**) in Orekhovo, Russia. Photo by Alexey Sergeev <asergeev@asergeev.com>.

When slime mold spores germinate, amoeba-like cells form (**myxamoebae**; Figure 21, Figure 24) (Wikipedia: Slime Molds 2019). These are typically **haploid** (have one set of chromosomes), can move about, and feed on bacteria. If these amoebae encounter the correct mating type, they can mate to form **zygotes** that develop into **plasmodia** (Figure 19, Figure 22, Figure 24). The protoplasm within the plasmodium can stream at speeds up to 1.35 mm per second, the fastest rate known for any organism (Alexopoulos 1962). When food becomes limiting, the plasmodium moves to the surface and begins to form its rigid fruiting bodies (**sporangia**; Figure 6- Figure 12, Figure 24) (Wikipedia: Slime Molds 2019). It is this stage that caused us to originally think they were fungi, but it lacks the chitin that is present in fungi. The life cycle is completed when these sporangia produce spores, usually by meiosis, for the next generation of amoebae. Some of these species go from spore to fruiting structure very quickly (Alexopoulos 1964).

Figure 21. *Didymium* myxamoebae hatched from spores. Brown structures are spores. Photo by George Barron, modified, with permission.

Figure 22. *Fuligo aurea* plasmodium. Photo through Creative Commons.

If free water is available, **myxamoebae** (Figure 21) form **swarm cells** (Figure 24) by developing flagella – one long and one very short (Myxomycota 2019). Some species mate as myxamobae (Figure 24) and others as swarm cells. Although adjoined myxamoebae are ready to mate, they generally cannot mate with the same strain, *i.e.* no sibling mating.

If conditions become too dry for the plasmodium (Figure 22), it will form a **sclerotium** (Figure 23, Figure 24), which is a dry dormant state (Wikipedia: Slime Molds 2019) and sometimes resembles the slime left by a slug. When this sclerotium once again becomes moist, it returns to the active plasmodium state. An alternative to this is that some species can form a **microcyst** (Figure 24) (Myxomycota 2019). This stage occurs when the amoeboid cells or swarm cells round up and form a thin wall, then become dormant, surviving unfavorable conditions.

Figure 23. Sclerotium. Photo courtesy of Steve Stephenson.

The multinucleate, diploid plasmodium (Figure 22) moves and feeds until conditions are right (or wrong) and it reorganizes into sporangia (Myxomycota 2019). The spores that are produced generally undergo meiosis to produce four nuclei. Three of these abort, leaving a single haploid nucleus, in a cell that becomes the haploid spore.

Figure 24. Generalized slime mold life cycle. Modified from Hoppe & Schwippert 2014.

Some species can produce **diploid** (having 2 sets of chromosomes) **amoeboflagellates** (includes flagellated cells and amoeboid cells) that develop directly into the plasmodium (Figure 22) without having any crossing with another cell (Clark & Haskins 2010). This appears to be the result of a failure of meiosis, resulting in **diploid** spores (**apomixis**). Thus a single spore of some species can complete a life cycle without any mating occurring.

Seasonal Changes

Reproduction in the **Myxomycetes** is typically seasonal. Eliasson (1980) recorded the times of **fructification** (producing sporangia) in several Swedish species over the course of four years. Those **Myxomycetes** fruiting in May-June include *Amaurochaete atra* (Figure

25), *A. tubulina* (Figure 26; not known from bryophytes), *Reticularia jurana* (Figure 27-Figure 28; a species close to the sometimes bryophyte dweller *R. lycoperdon* and that sometimes occurs close to bryophytes), and *Symphytocarpus flaccidus* (Figure 29-Figure 30; sometimes occurs on bryophytes). Those fruiting in June-August include *Ceratiomyxa fruticulosa* (Figure 31-Figure 32), *Fuligo septica* (Figure 33), *Stemonitis axifera* (Figure 34), *S. fusca* (Figure 35-Figure 36), and *Stemonitopsis hyperopta* (Figure 37; image on moss seen, but further documentation not available), all of which are known sometimes to associate with bryophytes. In September-October, those fruiting include *Colloderma oculatum* (Figure 38), *Fuligo muscorum* (Figure 39), *Trichia botrytis* (Figure 40-Figure 42), and *T. decipiens* (Figure 43-Figure 45). *Lycogala epidendrum* (Figure 46) spans May to October. Some of the species fruiting in spring may fruit again in autumn. All of these species occasionally occur associated with bryophytes.

Environmental Stimuli

Kazunari (2010) examined the succession of slime mold communities in a forest setting in southwestern Japan and found that the seasonal factors of the slime mold communities were related to the decay state of the wood. Kazunari also showed that certain species were visible at only certain times of the year. But what are the factors that trigger these responses?

Light

Many of the slime molds migrate to light before initiating development of sporangia. Loss of bark during decay could provide a light signal for amoeboid and swarm cells under the loose bark of a decaying log. Reinhardt (1968) explored the effect of light on the cellular slime mold *Acrasis rosea* (Figure 57-Figure 58), a taxon that might not be representative of the **Myxomycetes** of interest here. Both continuous light and continuous dark failed to stimulate the production of sporangia. Reinhardt was able to stimulate sporangia production by exposing the cultures to light, followed by a minimum of 7-8 hours of darkness. Hence, we see that seasonal changes in day length could synchronize the fruiting of the slime molds.

Figure 57. *Acrasis rosea* sporangia; this cellular slime mold responds to light to produce sporangia. Photo from Biology of Fungi Lab UC Berkeley, California, through Creative Commons.

Figure 58. *Acrasis rosea* amoebae, a cellular slime mold, emerging from spores. Photo by Chirley Chio at Mushroom Observer, California, through Creative Commons.

Kakiuchi *et al.* (2001) demonstrated the role of the colors of light in the initiation of reproduction in the *Myxomycetes* slime mold *Physarum polycephalum* (Figure 59). Light initiates the breakup of the plasmodium (Figure 22) into equal-sized spherical pieces within about five hours. Blue and far-red light both initiate this behavior, whereas red light (but not blue) inhibits the far-red induction. These fragments develop the sporangia and spores. When it is time to develop sporangia, plasmodia can creep out from under bark or the bases of bryophytes and seek higher ground and more light.

Figure 59. *Physarum polycephalum* on leafy liverworts. Photo by Bernard Spragg, through Creative Commons.

pH and Volatile Substances

Researchers have found that bark pH is important in determining slime mold distribution on bark, but that it might be masked by geographic location (Everhart *et al.* 2008; Keller & Everhard 2010). It is reasonable to ask, then, if substrate pH is important in the reproductive cycle.

Early work by Reinhardt (1968) demonstrated that pH was important for fruiting in *Acrasis rosea* (Figure 57-Figure 58); a cellular slime mold in an entirely different clade), with growth occurring at pH 3.5-7.6, but fruiting only at 5.0-6.6. Such differences in pH could occur as a result of changes in the decay state of a log or litter. Of course this is only one species, and not even in the *Myxomycetes*, but it illustrates the mechanisms that might be used by other slime molds as well.

Gray (1939) found that temperature and pH are closely interrelated, at least in the *Myxomycetes* slime mold *Physarum polycephalum* (Figure 59). When pH remains constant, the time required for fruiting varies directly with the temperature, requiring longer times at higher temperatures. Furthermore, the higher the temperature, the fewer cultures produce fruiting bodies. When pH also varies, higher temperatures require greater acidity to produce fruiting bodies. At a constant temperature, the greatest fruiting occurs at pH 3.0. The maximum temperature at which this species will produce sporangia is 32.5°-35.0°C. **Sclerotia** will not form at low temperatures (8°-12°C) or high temperatures (32.5°-35.0°C). Light still seems to be necessary for fruiting at all temperatures.

While the change in pH could be a seasonal phenomenon, research by Newell *et al.* (1969) suggests a different relationship. In the slime mold *Dictyostelium discoideum* (Figure 11-Figure 12; **Dictyosteliomycetes**), a dweller of shallow soil, also known from bryophytes and litter, the amoebae form multicellular aggregates from which they are able to form fruiting bodies with stalks and spores. This change of state may occur at the same microsite, or it can change its structure into a form that can migrate to a more favorable location. This migration can be stimulated by the accumulation of metabolites from the slime mold or a low ionic strength in its substrate. This migration is inhibited by the presence of a buffer or overhead illumination. In an unbuffered system, the stimulus for fruiting is "appreciably volatile." In the presence of a buffer, the slime molds transformed from a migrating **slug** (Figure 10) and sat still, producing fruiting bodies on that spot. The strong base NaOH was completely ineffective in preventing the formation of the moving slug. Furthermore, the transformation into a moving slug was inversely related to the density of the slime mold cells, indicating that it was something produced by the slime mold that signalled the migration. Others (Bonner *et al.* 1950; Francis 1964) have observed that this species moves toward heat, following a very low temperature change gradient (as little as 0.05° C per cm). This behavior could decrease the volatile substance produced by the slime mold – an indicator that it is not too dense a population. But a heat gradient also would lead the moving slug form toward the light, which would then stop the migration and cause it to form the fruiting bodies.

Using the unicellular slime mold *Dictyostelium mucoroides* (Figure 10; **Dictyosteliomycetes**), Filosa (1979) similarly demonstrated the presence of a volatile substance by using charcoal as an absorbent. In the dark, this species produced **macrocyts** (encysted, resting plasmodium), but in the light it produced fruiting bodies. But if the dark cultures were grown over activated charcoal, they likewise would form fruiting bodies. When grown in light with KOH (a CO₂ absorbent), they produced macrocyts, but if activated charcoal was added, they again only produced fruiting bodies.

All of these responses to heat, light, pH, and an exudate from the slime molds themselves could optimize their reproductive potential. These stimuli cause the slime molds to move to a location where spores are more easily dispersed and will have less competition for space during fruiting and food for the next generation.

Water

In the cellular slime molds, surface water is a key factor as well (Bonner *et al.* 1982). When the plasmodial slug tip reaches above the water film, it usually causes the slime mold to shift gears and produce the fruiting structures. Among the cellular slime molds, light seems to be less important, promoting fructification only in those phototactic slugs that orient away from the surface.

Reproduction in Myxomycetes

Some slime molds are particularly associated with bryophytes (Ing 1994), and almost all of these are in the **Myxomycetes**, the acellular or plasmodial slime molds. *Myxo* means slime. They gain their energy by engulfing and digesting bacteria, yeasts, fungal spores, and decaying material in their amoeboid stage (Wikipedia: Slime Molds 2019), food sources that are often available on bryophytes. Spores are formed in a capsule-like structure. When the spores germinate, they release the amoeboid cells, referred to as the **myxamoebae** (Figure 21). If there is sufficient water for swimming, the myxamoeba may develop flagella and become a **swarm cell**. This process can be reversed, the flagellum retracted, and the amoeboid stage returned. Unlike the **Dictyosteliomycetes**, the **Myxomycetes** are sexual. When two different mating strains find each other, they join to form a **zygote**. Even in forming the **plasmodium** (Figure 22), the **Myxomycetes** differ from the **Dictyosteliomycetes**. In **Myxomycetes**, the zygote does not form an amoeba, but instead divides only its nucleus. These nuclei continue to divide to form the **plasmodium** – a large, multinucleate body composed of a single cell.

In their **plasmodium** (Figure 22) stage, the **Myxomycetes** can flow like an amoeba, feeding as they traverse their substrate (Wikipedia: Slime Molds 2019). The plasmodium prefers darkness, and when it ventures into the light it is likely to go into its **sclerotium** (Figure 23, Figure 24) stage – a dormant stage that can remain so for years; this stage is also imitated by drying conditions. That shiny dry covering that looks like a slug's slime trail on the surface of a moss might be a sclerotium. The sclerotium is particularly likely to form if the plasmodium dries out. If, on the other hand, it runs short on food first, it goes into its fruiting stage. Such factors as light and temperature can induce the plasmodium to transform into fruiting structures (Figure 61 that produce **meiospores**, hence returning the organism to its *1n* state (having only one set of chromosomes). The subsequent spores may germinate into flagellated cells or amoeboid cells that multiply vegetatively and engulf food to gain energy.

Temperature plays an important role in maintaining the active state of the amoeboid stage, and any habitable site must have sufficient moisture, making bryophytes necessary for survival of any that venture onto rocks (Ing 1994). The behavior of the slime mold under adverse conditions is reminiscent of the bryophytes and many of the fauna found there. When the going gets rough, they sleep like Rip Van Winkle! For the slime molds, it is the **sclerotium** (Figure 23, Figure 24); for many fauna it is a cyst; and for the bryophytes it is a simple dormancy without any change of state.

The **Physarales** (Figure 2-Figure 9; Figure 60-Figure 68), and especially *Diderma* (Figure 62-Figure 68), frequently fruit extensively where bryophytes and lichens cover the bark (Brooks *et al.* 1977). We know substrate is important for finding food in the mobile stages, but is it important for fruiting? Do the bryophytes offer the advantage of a higher perch for dispersal of these tiny beings?

Dispersal

Using 18S rDNA variants from 125 specimens from 91 localities of the myxomycete *Badhamia melanospora* (sometimes a moss dweller; Figure 69-Figure 70), Aguilar (2014) set out to determine if the Baas-Becking hypothesis of "everything is everywhere" can be applied to **Myxomycetes**. They found two distinct groups within this

species: one group comprises all populations from Argentina and Chile; the other is formed by populations from North America together with human-introduced populations from other parts of the world. For this species, they concluded that everything is not everywhere. Instead, the taxon consists of a complex that has at least two cryptic species that probably diverged as **allopatric** (having non-overlapping distributions) in North and South America. But as will be seen in this chapter, many of the slime molds do have widespread distributions on several continents.

Figure 70. *Badhamia melanospora* spore SEM. Can it travel around the world? The Eumycetozoon Project, DiscoverLife.org, with permission.

It appears that some slime molds occur in the same places for multiple years, but their propensity for living on logs and even living trees means that at some time they

must disperse to survive. Schnittler and Tesmer (2008) asked if the habitat colonization model for spore-dispersed organisms works for slime molds. They found spore numbers per sporangium ranging from 1 to 106. Average spore size ranges 10.3 μm to 14.8 μm in the studied taxa. Culture data suggest that the number of spores required to create the observed frequencies (as a percent of successfully colonized habitat islands) is generally three orders of magnitude higher. Species with sexual reproductive systems typically produce more spores than do asexual ones.

The presence of individual species is limited not by dispersal, which seems to be efficient, but by suitable substrate (Ing 1994). We have seen that the species are seasonal, but as we might expect, the time of year for the conspicuous fruiting varies with climatic zone. The dispersal is primarily tied to the onset of rain after a long warm period. This is typically autumn in the temperate regions, whereas in parts of the tropics it begins with the monsoon season. Dispersal does not determine species presence, except perhaps among the corticolous species. Rather, it is suitable substrates that determine presence.

One factor in dispersal of the spores is their surface structure. Three types exist in the **Myxomycetes**: spiny, reticulate, and smooth surfaces (Hoppe & Schwippert 2014). Using spores from 17 species, including *Metatrichia floriformis* (Figure 71) (reticulate; see Figure 72), *Fuligo septica* (Figure 33) (spiny; see Figure 73), and *Licea parasitica* (smooth; see Figure 74) as well as *Ceratiomyxa fruticulosa* (Figure 31-Figure 32; **Ceratiomyxomycetes**) (smooth) (all known from bryophytes as well as other substrata), they determined the wettability of the spores. Spiny spores would half sink into the water but nevertheless they floated. Reticulate spores are superhydrophobic and float on the surface tension of the water. Spores with no ornamentation sink to the bottom rather quickly.

Figure 74. *Licea deplanata*, not a known bryophyte dweller, smooth spore. SEM photo courtesy of Yuri Novozhilov.

Dispersal by wind seems to predominate (Keller & Smith 1978). Underlying bryophytes can become covered in spores (Figure 75). Dispersal may be aided by the **capillitium** (Figure 76) that in some species twists in response to changing moisture conditions. The capillitium also is likely to act like a salt shaker, doling out a few spores at a time instead of releasing all of them in a single

burst of wind, a function similar to that of the peristome in mosses.

Figure 75. *Tubulifera ferruginosa*. Photo by David Mitchell, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Figure 76. *Trichia varia* spores and capillitium. Photo by Alain Michaud, The Eumycetozoon Project, DiscoverLife.org, with online permission.

In some species, insects and mites seem to be important dispersal agents (Keller & Smith 1978; Eliasson 1977). Beetles are abundant on *Amaurochaete* (Figure 25) species and spores that cling to the body and legs would get a free ride for dispersal (Eliasson 1977).

Eliasson (1980) indicated that invertebrates are important in the dispersal of several species of slime molds. This is sometimes accomplished through predation by snails and insects that carry the spores on their bodies or in their digestive tracts (Ing 1967; Angela Newton, Bryonet, 20 November 2006).

The isopod *Philoscia muscorum* (Figure 77) appears to spread the cellular slime mold *Didymium bahiense* (Figure 78) (Ing 1004). Huss (1989) verified the potential of dispersal by earthworms (Figure 79) and pillbugs (**Isopoda**; Figure 77). Some of these invertebrate species are bryophyte dwellers, although typically not the ones used in the experiments. These invertebrates were fed both spores and myxamoebae of slime molds. Although percentages of both survived, the spores survived better

than the myxamoebae. When invertebrate feces were cultivated, the species the invertebrates had eaten developed in the cultures.

Figure 79. The earthworm *Octolasion cyaneum*; some species in this genus ingest slime molds and disperse them. Photo by Chih-Han Chang, through Creative Commons.

A similar relationship was found between the cellular slime mold *Dictyostelium discoideum* (Figure 11-Figure 12; *Dictyosteliomycetes*), an occasional bryophyte dweller, and the nematode *Caenorhabditis elegans* (Figure

80) (Kessin *et al.* 1996). This nematode is an inhabitant of the moss *Sphagnum* (Figure 81) (Glatzer & Ahlf 2001) and feeds on slime molds, including consumption of the spores. It kills the amoeboid stage, but the spores survive the digestive tract, making this another organism capable of moving the spores from one place to a new location for germination.

Habitat Needs

Publications on slime molds are in no short supply. Gray and Alexopoulos (1968) published a treatise on the biology. Martin and Alexopoulos (1969) wrote a general treatise on the group. Ing (1994) summarized the phytosociology, arranged according to major vegetation types. Rollins and Stephenson (2011) summarized the global distribution and ecology.

As of 2011, Sarah Lloyd reported that only 1000 species of slime molds had been described. Their greatest abundance is in temperate forests, where they occur on living and dead trees and rotting wood, but also in some unusual habitats, including on dung and on living animals (Stephenson & Rojas 2017).

Moisture

Ing (1994) related the slime molds to their habitat factors, surmising that temperature is an important limiting factor in tropical, subtropical, Mediterranean, and alpine species. There is a consistent distinction between the corticolous, lignicolous, and epiphyllous species, and the lignicolous species have a preference for either conifers or deciduous trees. Ing even referred to bryophyte associations, noting that a few slime molds are particularly

associated with them. This may be due to water relations, with Ing noting that water and water-retaining substrates are of prime importance. The presence of fruiting structures (sporangia) is dependent on the arrival of rain after a prolonged warm period, making their presence most common in autumn in temperate regions. In the tropics, capsules form when the monsoon season begins. Fruiting seems to be independent of substrate.

Eliasson (1980) noted that species that have large plasmodia (Figure 22) typically are rare under arid conditions. This would suggest that the slime molds on bryophytes are the larger species in most habitats because of the moisture-holding capacity of the bryophytes.

On the other hand, Schnittler *et al.* (2013), based on observations in Xinjiang Province, China, concluded that corticolous **Myxomycetes** are some of the most drought-tolerant organisms in that habitat. They are opportunistic, permitted by their ability to survive in a dormant state for decades and to complete their life cycles in a few days of appropriate conditions.

Latitude

Stephenson *et al.* (1993) found recognizable patterns in the latitudinal variation of slime molds. The species assemblages in the tropical-subtropical regions is distinctly different from that found in temperate regions. Furthermore, the species differ in their substrate usage at different latitudes. Some species that are rare outside the Arctic and subArctic can be relatively common in these northern regions (Stephenson *et al.* 2000).

Food and Light

Naturally, available food is of importance in the location of active slime molds. Slime molds frequently make "decisions" for location based on the quality of food available. The common **Myxomycetes** slime mold ***Physarum polycephalum*** (Figure 59, Figure 82; sometimes a bryophyte dweller), in its amoeboid phase and if both locations are shaded, will choose the higher food quality 100% of the time (Latty & Beekman 2010). When a much higher quality food is in the light, it is selected, but when the difference in quality is small, the slime mold will select the shade over the light location, even if its food is of lesser quality.

Figure 82. *Physarum polycephalum* plasmodium on rotting wood. Photo by Frankenstoen, through Creative Commons

Role of Bryophytes as Slime Mold Habitat

Stephenson and Studlar (1985) found representatives of all six orders (at that time) of slime molds, exclusive of the **Labyrinthulomycota** and the **Plasmodiophorids** in their study of bryophyte-dwellers in the United States and Canada. The **Physarales** (Figure 2-Figure 9; Figure 60-Figure 68) (38% of all collections) were the most abundant, but members of the **Stemonitales** (Figure 34-Figure 37) (23%), **Trichiales** (Figure 13, Figure 40-Figure 45) (18%), and **Liceales** (Figure 83-Figure 84) (17%) were also commonly bryophyte associates. The order **Echinosteliales** (Figure 99-Figure 100) and the class **Ceratomyxomycetes** (Figure 31-Figure 32) comprised only 4% and 1%, respectively. All four of the major types of slime mold fruiting bodies (sporangia, aethalia, plasmodiocarps, and pseudoaethalia) were represented in their 170 collections.

Figure 83. *Licea floriformis* fruiting bodies on moss leaves. Photo by David Mitchell, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Figure 84. *Licea retiformis* plasmodium. Photo by David Mitchell, The Eumycetozoon Project, DiscoverLife.org, with online permission.

But are these slime molds preferential colonists of bryophytes? Stephenson and Studlar (1985) set out to try to answer this question. By examining 170 collections throughout North America, they found that three species were particularly common: ***Fuligo septica*** (Figure 33), ***Stemonitis axifera*** (Figure 34), and ***S. fusca*** (Figure 35).

Furthermore, they found that some bryophytes were more likely than others to be suitable substrata: *Nowellia curvifolia* (Figure 85), *Brotherella recurvans* (Figure 86), *Thuidium delicatulum* (Figure 87), and *Hypnum imponens* (Figure 88). The slime mold order **Physarales** (Figure 2-Figure 9; Figure 60-Figure 68) was the most commonly represented. Taxa producing sporangia were the most abundant, representing 79% of the collections, but this is also the most common type of slime mold fruiting body (Gray & Alexopoulos 1968).

Figure 88. *Hypnum imponens*, one of the more common moss substrata for the slime molds *Fuligo septica*, *Stemonitis axifera*, and *S. fusca*. Photo by Jason Hollinger, through Creative Commons.

Most of the slime molds examined by Stephenson and Studlar (1985) occurred only one or two times among the 170 bryophyte collections that had slime molds, suggesting that there is little specificity involved. They suggest that three cases warrant further examination: *Stemonitis axifera* (Figure 34) with *Thuidium delicatulum* (Figure 87), *Barbeyella minutissima* (Figure 89) with *Nowellia curvifolia* (Figure 85) and *Lepidozia reptans* (Figure 90), and *Lepidoderma tigrinum* (Figure 91) with *Nowellia curvifolia*. Certainly *S. axifera* (Figure 34) is not specific for bryophytes; 78% of those examined were from decorticated areas of logs. Likewise, the second and third most common species were more commonly collected from other substrata. *Barbeyella minutissima* was only associated with liverworts, but it is so small that it was not seen in the field. Therefore, it was found only on liverwort samples that were examined in the lab. In the Stephenson and Studlar study, **smooth mats** support more slime molds than other life forms. And slime molds that live on rotten wood seem to be the most common bryophyte associates.

Figure 91. *Lepidoderma tigrinum* immature on moss with slug. Photo by Marianne Meyer, through Creative Commons.

But other studies suggest there really are some bryophyte-specific slime molds. *Fuligo muscorum* (Figure 39), named for a mossy habitat, is common on *Polytrichum* (Figure 92), *Dicranum* (Figure 93), and *Hypnum* (Figure 88) species (Ing 1994). *Elaeomyxa cerifera* (Figure 94), although very rare, is known only from terrestrial bryophytes, including the liverwort *Pellia epiphylla* (Figure 95) (Hadden 1921).

Figure 95. *Pellia epiphylla* is a suitable substrate for *Elaeomyxa cerifera*, a species only known from bryophytes. Photo by Bernd Haynold, through Creative Commons.

If bryophytes are indeed a preferred substrate for some species, the next question is why. Stephenson and Studlar (1985) suggest that bryophytes serve as spore traps, increasing the chances of the trapped species becoming residents here. The bryophytes then provide a moist habitat, again favoring growth of slime molds. These same conditions provide a habitat for numerous protozoa and bacteria, providing food for the slime molds, and even the detritus produced by tardigrades, annelids, and arthropods can serve as food sources (Gerson 1969, 1982; Richardson 1981).

In a single study, Bovee (1979) reported 68 species of protozoa (particularly shelled amoebae and ciliates) among mosses, mostly the mosses *Brachythecium salebrosum* (Figure 96), *Plagiomnium cuspidatum* (Figure 97), and *Pylaisiella selwynii* (Figure 98) on a rotten log in Minnesota. Many of these protozoa provide suitable food for the slime molds in their mobile phase.

Figure 96. *Brachythecium salebrosum*, home of many protozoa. Photo by Michael Lüth, with permission.

Figure 97. *Plagiomnium cuspidatum*, home of many protozoa. Photo by Janice Glime.

Bryophytes may provide a preferred location for forming sporangia. Slime molds migrate to the highest position available before making sporangia (Stephenson &

Studlar 1985), and bryophytes on a log could very well be that place.

Figure 98. *Pylaisiella selwynii*, home of many protozoa. Photo by Jan-Peter Frahm, with permission.

In any case, the slime molds, like the tardigrades, rotifers, and protozoa, seem to be well-adapted to the **poikilohydric** (having no mechanism to prevent desiccation) existence of living among bryophytes (Gerson 1982). When the bryophyte and the slime mold dry out, the myxamoebae and swarm cells of the slime mold can form **microcysts**; plasmodia (Figure 22) are able to form **sclerotia** (Figure 23, Figure 24). These structures are all resistant and survive well under desiccating conditions. They can quickly resume activity when water becomes available. The tolerance of slime molds to alternate wetting and drying that typically accompanies the bryophytes provides us with another reason to suspect that they can live within, as well as sporulate upon, bryophyte clumps.

But not all slime molds benefit from the moist environment of the bryophytes. The genus *Echinostelium* (Figure 99-Figure 100) is comprised of tiny slime molds that live on bark (Keller & Brooks 1976). But in areas that support the growth of algae, mosses, and leafy liverworts, larger aphano- and phaneroplasmodial slime molds are favored. Keller and Brooks surmised that the tiny protoplasmodial *Echinostelium* species were unable to compete.

Figure 99. *Echinostelium minutum*, a tiny species that is probably unable to compete. Photo by Satyendra Rajguru, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Slime Mold Effects on Bryophytes

A takeover by slime molds on mosses is apparently a rare occurrence (Coker 1966). Nevertheless, at least one example exists. Coker reported that the slime mold *Cribraria rufa* (Figure 101) had apparently destroyed a patch of the moss *Orthodontium lineare* (Figure 102- Figure 103) on a rotten conifer stump.

Figure 101. *Cribraria rufa* fruiting, a species that apparently can destroy the moss *Orthodontium lineare*. Photo by Alain Michaud, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Figure 103. *Orthodontium lineare* with capsules, a moss that can be destroyed by the slime mold *Cribraria rufa*. Photo by Malcolm Storey, DiscoverLife.org, with online permission.

Almost 100 compounds have been identified from the slime molds (Dembitsky *et al.* 2005). These include lipids, fatty acid amides (pigments) and derivatives, alkaloids, amino acids and peptides, naphthoquinone pigments, aromatic compounds, carbohydrate compounds, terpenoid compounds, and arcyriflavin derivatives (alkaloids). Some of these give the slime molds their unique colors. But some have antimicrobial activity against bacteria like *Bacillus cereus* (Figure 104) (Pereira *et al.* 1996). These compounds might permit them to compete with other slime molds, but do they have any effect on the bryophytes?

Figure 104. *Bacillus cereus* SEM, a species that is inhibited by some of the secondary compounds produced by slime molds. Photo by Mogana Das Murtey and Patchamuthu Ramasamy, through Creative Commons.

Slime molds do not usually appear to be any threat to the bryophytes. However, in some cases, it appears that the slime molds are aggressive enough to overgrow and destroy the bryophytes (Coker 1966). *Fuligo intermedia* (Figure 105) seems to be harmful (Pant & Tewari 1982), most likely due to its density of fruiting bodies that can cover patches several centimeters in diameter. Such growths would deprive the moss of light and may interfere with gas exchange.

Figure 105. *Fuligo intermedia* fruiting bodies on bryophytes. Photo by David Mitchell, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Bryophytes Growing on Slime Molds

In some species, the fruiting bodies of slime molds can persist. That can lead to a reverse relationship with bryophytes. It gives the bryophytes sufficient time to grow over the slime molds, as observed by Sarah Lloyd (2011). She found a growth of leafy liverworts on the stalk of a slime mold on decaying wood, undoubtedly a very rare occurrence.

Epizooites

One of the most unusual habitats for slime molds is on living lizards, *Corytophanes cristatus* (Figure 106), in Mexico and Costa Rica (Lloyd 2011). This lizard is a sit-and-wait predator and therefore moves around little. It uses its head to dig its nest and often has residual soil in the scoop on the top of its head. This microenvironment is home to the tiny liverwort *Lejeunea obtusangula* (see Figure 107) (Gradstein & Equihua 1995). But this lizard is also sometimes home to the slime mold *Physarum pusillum* (Figure 108). The co-occurrence of the liverwort and the slime mold, if at all, is most likely one of chance resulting from the scooping behavior of the lizard.

Potential for Symbiosis?

In sharp contrast to the casual and accidental associations of most slime molds with their substrates and neighbors, some relationships might be more directly beneficial. In pure cultures of the slime mold *Fuligo cinerea* (Figure 109; sometimes a bryophyte dweller) (and the green alga *Chlorella xanthella* – Figure 110), sodium radiophosphate accumulated in them both from the medium. When these were separately mixed with the opposite species, both species were able to accumulate the radiophosphorus from the other species cultured with it. While this suggests the potential for a symbiosis, it fails to demonstrate any dependency or benefit. Nevertheless, a **protocooperation** could exist with nutrients, moisture, or other conditions that enhance the environment created by a bryophyte and a slime mold living together. Adding algae or *Cyanobacteria* to the mix might make it even better.

Interactions with Invertebrates

Both bryophytes and slime molds often host a variety of invertebrates. Among the inhabitants of slime molds, nematodes can be numerous, as they are among some bryophytes. In *Dictyostelium discoideum* (Figure 12; **Dictyosteliomycetes**), the aggregate of slime mold cells protects the formation from nematode predation, whereas nematodes readily feed on the individual cells (Kessin *et al.* 1996). Nematodes are also known from the **Myxomycetes** slime molds *Trichia varia* (Figure 13-Figure 17) and *Stemonitopsis typhina* (Figure 111; both can occur on bryophytes) on rotten wood (Ing 1967).

Figure 111. *Stemonitopsis typhina* sporangia, a species where nematodes can thrive. Photo from George Barron, with online permission.

Snails (Figure 112) and slugs (Figure 113) also can feed on slime molds, and these slime molds may be moss inhabitants. Snails and other invertebrates feed on the fruiting bodies of *Lycogala epidendrum* (Figure 46) (Eliasson 1980; Pant & Tewari 1982).

Some tardigrades (water bears) feed selectively on slime molds (Kylin 1991). Since tardigrades are common on bryophytes, it is likely that this three-way association occurs, with bryophytes providing the substrate for the slime molds and the slime molds providing food for the tardigrades. *Milnesium tardigradum* (Figure 114), used in the experiments, is a moss inhabitant (see Chapter 5 in this volume). Kylin demonstrated that it not only will consume some slime molds and spurn others, those consumed can be moss inhabitants. These include the **Myxomycetes** *Diderma* cf. *testaceum* (Figure 115; an inhabitant of species of mosses, leaves, and twigs), *Trichia botrytis* (Figure 40-Figure 42), and *Clastoderma debaryanum* (Figure 116-Figure 117). The response of *D. cf. testaceum* is interesting. The tardigrade typically attacks the vein where protoplasm is streaming. The slime mold responds by streaming away from the bite. The tardigrade seldom takes a second bite, causing little damage to the slime mold. But when the slime mold begins forming sporangia, the tardigrade once again attacks, burrowing into the developing sporangium. This causes the sporangial development to cease. Occasionally the sporangium will collapse onto the tardigrade, trapping it. *Trichia botrytis* elicits similar responses when the plasmodium (Figure 22)

is attacked, usually feeding for about 12 hours, but has a sporangium that is too small for the tardigrade to burrow into it. *Clastoderma debaryanum* is a much smaller slime mold and the tardigrade usually consumes the entire plasmodium.

Isopods are common inhabitants on bryophytes and will readily consume them (Hames & Hopkin 1989). They likewise can occur on slime molds (Ing 1967). They eat both plasmodia (Figure 22) and fruiting bodies of the *Myxomycetes* slime molds. The isopods *Trichoniscus pusillus* (Figure 118) and *Oniscus asellus* (Figure 119) feed on the slime molds *Trichia varia* (Figure 13-Figure 17) and *Arcyria denudata* (Figure 120). The isopod *Androniscus dentiger* (Figure 121) eats both plasmodia and sporangia of *Didymium iridis* (Figure 122), at the same time dispersing this species across the substrate. Spores have been found in the isopod digestive tracts undigested. All of these three slime molds are known from bryophytes.

Millipedes are likely known from both bryophytes and slime molds. The millipede *Cylindroiulus punctatus* (Figure 123) consumes the sporangia of the slime mold *Trichia varia* (Figure 13-Figure 17) on wet, rotten wood (Ing 1967).

Figure 123. *Cylindroiulus punctatus*, a millipede that feeds on the slime mold *Trichia varia*. Photo by Saxifraga-Ab H Baas, through Creative Commons.

Collembola (springtails; Figure 124) are avid consumers of small slime molds on bark (Ing 1967). Some of these springtails eat *Stemonitopsis typhina* (Figure 111; sometimes a bryophyte dweller) and *Cribraria piriformis* (Figure 125-Figure 126) on rotten wood. Both *Stemonitopsis typhina* and *Cribraria piriformis* can occur on or with bryophytes, making it likely that a 3-way association sometimes occurs among the bryophytes, slime molds, and springtails.

Figure 126. *Cribraria piriformis* sporangia with spores gone, perhaps being eaten by springtails. Photo by Myxotropic, through Creative Commons.

Insects are common on both bryophytes and slime molds. Some **Coleoptera** (beetles) may be occasional or accidental feeders on *Myxomycetes* (Ing 1967). Among these, the beetle *Anisotoma humeralis* (Figure 127) seems to be confined to large slime molds such as *Fuligo septica* (Figure 33), *Reticularia lycoperdon* (Figure 128-Figure 129), *Stemonitis fusca* (Figure 35-Figure 36), *Symphytocarpus flaccidus* (Figure 29-Figure 30), and *Tubifera ferruginosa* (Figure 55); all of these slime molds can sometimes be found associated with bryophytes. The spores are held in the capillitium and are relatively accessible (Figure 130).

Some beetles even seem to be obligate feeders on slime molds (Dudka & Romanenko 2006). Lawrence and Newton (1980) reported on about 35 beetle species, mostly from North American, that feed on slime mold spores. Dudka and Romanenko (2006) found that slime mold spores occurred in 19 of the 25 beetle (*Latridiidae*) guts they examined from Crimea. These included *Latridius*

hirtus (Figure 131), *Enicmus rugosus* (Figure 132), and *E. fungicola* (Figure 133) as obligate slime mold feeders. On the other hand *Corticarina truncatella* (Figure 134) is a facultative slime mold feeder. The most common 13 species of slime molds, including *Fuligo septica* (Figure 33), *Mucilago crustacea* (Figure 135), *Stemonitis axifera* (Figure 34), *S. fusca* (Figure 35), and *S. splendens* (Figure 136), were inhabited by five species of *Latridiidae*; all of these slime molds can occur on bryophytes.

Figure 136. *Stemonitis splendens*, one of the slime molds eaten by the beetle family Latridiidae. Photo by Dan Molter, through Creative Commons.

Some **Coleoptera** (beetles) in the **Leiodidae** can be considered slime mold beetles (Wheeler & Miller 2005). *Stetholiodes* sp. (Figure 137) is a slime mold beetle that was originally described from moss in northern Indiana (Blatchley 1910). Several species of *Agathidium* (Figure 138) are known moss inhabitants, including *A. brevisternum*, *A. rhinocerellum*, and *A. cavisternum*

(Figure 139) (Wheeler & Miller 2005). The only known host for *Agathidium rhinocerellum* is the *Myxomycetes* slime mold *Fuligo septica* (Figure 33, Figure 140), a widespread generalist species that includes bryophytes among its substrates. It is likely that other moss dwellers in this family also feed on slime molds.

Figure 140. *Fuligo septica* on moss, a slime mold that is host for the beetle *Agathidium rhinocerellum*. Photo by David Mitchell, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Some **Diptera** larvae live on the slime mold plasmodia (Figure 22) and feed on them, with some remaining there as pupae. *Bradysia* (Figure 141) species feed on plasmodia of *Fuligo septica* (Figure 33) and sporangia of *Lycogala epidendrum* (Figure 46) and *Arcyria incarnata* (Figure 142-Figure 143), all occasional bryophyte dwellers. In fact, some flies can be reared on slime molds as their only food.

Summary

Slime molds are really not molds, but protozoa, with an amoeboid feeding stage and a spore-producing, non-feeding stage. They also lack chitin, a compound found in true molds. The bryophyte dwelling members are included in the **Eumycetozoa** or **Amoebozoa** and classified into the classes **Myxomycetes**, **Dictyosteliomycetes**, and **Ceratiomyxomycetes**.

The life cycle has a dormant spore that will germinate when adequate water is available and develop into **swarm cells** or **amoeboid cells**. This stage feeds like an amoeba. In **Myxomycetes**, either of these cell types can form a zygote that divides to form a **plasmodium**. This stage likewise feeds on bacteria, algae, and protozoa. It can dry out to form a **sclerotium** that can remain dormant for years, or move to higher ground in the light to form sporangia and spores. Either stage can occur on bryophytes, but the plasmodium stage is likely to be unnoticed. The life cycle is usually keyed to seasons, with autumn being the more favorable fruiting season for most species. Dispersal is most likely primarily by wind, but animals are also dispersal vectors, either by carrying spores on the outside or by digesting them or plasmodia and dispersing them in the feces.

The slime molds respond to light, pH, volatile substances, temperature, and water availability to trigger fruiting. We know most slime molds seek higher positions with more light before forming sporangia. Do bryophytes provide a more suitable location for that event? Do slime molds benefit in their dispersal by the activities of moss fauna?

The slime molds known to associate with mosses are predominantly in the **Myxomycetes**. The mosses may provide prolonged moisture and a place to get above the prevailing substrate for better dispersal, or they may be dispersed by some of the invertebrates living among the bryophytes. Little is known about the effect the slime molds have on the bryophytes. Some slime molds live on animals, and these may be the same animals that have bryophytes growing on them. The potential for symbiosis exists, but little evidence supports any symbiotic relationship.

Acknowledgments

Thank you to Sarah Lloyd for challenging my organization of this subchapter and to Steve Stephenson for providing me with recent literature that helped me untangle the classification of these slime molds. The Eumycetozoan website has been invaluable for checking current nomenclature and finding suitable images. Thank you to Yuri Novozhilov for providing me with images to illustrate the three spore surface types.

CHAPTER 3-2

SLIME MOLDS: BRYOPHYTE ASSOCIATIONS

Figure 1. Slime mold, probably *Fuligo septica*, on mosses in New Zealand. Photo by Bernard Spragg, through public domain.

Bryophyte Associations

Slime-mold-bryophyte associations can occur for a number of reasons. These can be accidental associations in which spores find favorable conditions to germinate, *i.e.*, sufficient moisture. Others are facultative, living on logs, but creeping onto mosses as the plasmodium moves about to feed and be able to survive there. Still others may climb up the bryophytes, as indicated in the previous subchapter, to emerge from bark crevices and reach the light for fruiting. Others germinate within the bryophyte mat where moisture conditions are maintained and bryophytes hide the slime mold plasmodium from our searching eyes. It is not until the slime mold is ready to produce sporangia that it climbs out where it is visible on the bryophyte. And finally, there are those slime molds that live only on bryophytes – the **bryophiles**. This latter group is a small one, but of the most interest to a bryologist. This chapter is

a gathering of all sources I could find to demonstrate slime molds that ever occur on or with bryophytes.

Bryophiles

Dudka and Romanenko (2006) described a variety of cases in which slime molds interact or co-exist with other organisms. They found 13 species of slime molds on 9 species of mosses and 3 species of liverworts on decaying wood or bark in the Crimean Nature Reserve. These included their relationships with bryophytes and they noted that the slime mold **sporophores** (sporangial stalks) at the surface of mosses and liverworts are rather widespread in nature (Stephenson & Stempen 1994; Härkönen *et al.* 2002; Stojanowska & Panek 2004). But it appears that the best known bryophiles include only *Barbeyella minutissima* (Figure 2-Figure 3), *Colloderma oculatum* (Figure 4), and *Lepidoderma tigrinum* (Figure 5) (Schnittler & Novozhilov 1996; Dudka & Romanenko 2006).

Figure 5. Fruiting bodies of *Lepidoderma tigrinum* on bryophytes. Photo by Alain Michaud, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Barbeyella minutissima (Figure 2-Figure 3) is a rare slime mold with a disjunct distribution in the northern Alps of Germany and several states in the Appalachian Mountains of the eastern USA (Schnittler *et al.* 2000). The distribution of this species is centered in montane spruce-fir forests, where it commonly associates with *Colloderma oculatum* (Figure 4), *Lamproderma columbinum* (Figure 6), and *Lepidoderma tigrinum* (Figure 5). *Barbeyella minutissima* is associated with several leafy liverwort species. In particular, the leafy liverwort *Nowellia curvifolia* (Figure 7-Figure 8) serves as an indicator for the presence of *Barbeyella minutissima*.

Figure 6. *Lamproderma columbinum* on mosses. Photo from The Eumycetozoon Project, DiscoverLife.org, with online permission.

Figure 8. *Nowellia curvifolia*, a leafy liverwort substrate for the slime mold *Barbeyella minutissima*. Photo from Bioimages, through Creative Commons.

One very rare slime mold (*Elaeomyxa cerifera* – Figure 9) is known primarily from the soil-dwelling thallose liverwort *Pellia epiphylla* (Figure 10) (Hadden 1921; Ing 1994), a soil-dwelling liverwort that is common on stream banks, but also occurs on decorticated logs, often in association with bryophytes. Similarly, *E. reticulospora* (Figure 11) is known only from its type locality on bryophytes in the tropics (Moreno *et al.* 2008).

Figure 9. *Elaeomyxa cerifera* with sporangia on bryophytes. Photo by Sarah Lloyd, with permission.

Figure 10. *Pellia epiphylla* with capsules. Photo by Li Zhang, with permission.

Figure 11. *Elaeomyxa cf. reticulospora*, a tropical slime mold known only from bryophytes in its type locality. Photo by Sarah Lloyd, with permission.

Little study of tropical slime molds has occurred, with most of it in the last 20 years. One of these more thorough studies is that of Rojas *et al.* (2010) in Costa Rica. They determined that elevation was a key factor in determining distribution. Lowland substrate preferences include litter, inflorescences, and bryophytes (Schnittler & Stephenson 2000, 2002; Schnittler 2001). Species of these substrates tend to be specialized and have narrow niches. *Lamproderma columbinum* (Figure 6) and *L. scintillans* (Figure 12) seem to prefer bryophytes. *Stemonitis fusca* (Figure 13-Figure 14) and *Lycogala epidendrum* (Figure 15), both known from bryophytes, prefer higher elevation forests.

Commonly Associated Slime Molds

Despite the apparently limited number of true bryophilous species, other coincidental associations may offer some moisture advantages. *Arcyria cinerea* (Figure 16-Figure 17; see also Robbrecht 1974), *Echinostelium arboreum* (Figure 18), *E. minutum* (Figure 19), *Macbrideola cornea* (Figure 20), *Perichaena vermicularis* (Figure 21), and *Physarum cinereum* (Figure 22-Figure 23) in the montane Crimea are most commonly associated with the mosses *Hypnum cupressiforme* (Figure 24) and *Leucodon sciuroides* (Figure 25), and leafy liverwort *Porella platyphylla* (Figure 26).

Figure 16. *Arcyria cinerea*. fruiting bodies. Photo by George Barron, The Eumycetozoon Project, DiscoverLife.org, with online permission.

The following **Myxomycete**-bryophyte associations are also known, but more rarely (Dudka & Romanenko 2006):

Didymium trachysporum (Figure 27) on *Ctenidium molluscum* (Figure 28)

Licea minima (Figure 29-Figure 30) on *Hypnum cupressiforme* (Figure 24)

Perichaena chrysosperma (Figure 31) on *Frullania dilatata* (Figure 32)

Stemonitis fusca (Figure 14) on *Leucodon sciuroides* (Figure 25)

Symphytocarpus amaurochaetoides (Figure 33-Figure 34) on *Pterigynandrum filiforme* (Figure 35-Figure 36)

Symphytocarpus impexus (Figure 37) on *Porella platyphylla* (Figure 26)

Trichia varia (Figure 38-Figure 39) on *Anomodon viticulosus* (Figure 40-Figure 41)

In addition to these, *Physarum cinereum* (Figure 22-Figure 23) occurs on fallen leaves and decaying wood, but it occurs more frequently on bryophytes.

While some slime molds prefer bryophyte substrates, lichens are rarely preferred (Ing 1999; Leontyev 2010). Among these bryophyte inhabitants in the Ukraine are *Metatrichia vesparia* (Figure 42; probably should be *Trichia*) and *Tubifera ferruginosa* (Figure 43-Figure 44), two slime molds typically found on decaying wood that is covered with mosses (Leontyev 2010).

Figure 42. *Metatrichia vesparia* fruiting on mosses. Photo by Alexey Zakharinskij, through Creative Commons.

Figure 44. *Tubifera ferruginosa* with mature sporangia on mosses and wood. Photo by David Mitchell, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Novozhilov *et al.* (2006) reported slime mold diversity and ecology from arid regions in Russia. They noted that *Physarum bivalve* (Figure 45), *Physarum leucophaeum* (Figure 46), and *Didymium melanospermum* (Figure 47-Figure 48) occurred on living mosses. It is likely that the mosses lengthened the period of available moisture in these dry habitats.

Figure 45. *Physarum bivalve* on wood, a slime mold known to inhabit mosses. Photo by Clive Shirley, The Hidden Forest, with permission.

Figure 46. *Physarum leucophaeum*, a slime mold known to grow on mosses. Photo by Jerry Cooper, through Creative Commons.

Figure 48. *Didymium melanospermum* fruiting bodies. Photo by Ray Simons, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Although I have found few Asian records, Ukkola *et al.* (2001) reported *Physarum album* (Figure 49) on moss-covered rotting logs and *P. pusillum* (Figure 50-Figure 51) on moss-covered bark of a living tree in China. In Nainital, India, *Fuligo intermedia* (Figure 52) occurs on mosses (Pant & Tewari 1982).

Figure 52. *Fuligo intermedia* on *Polytrichum*. Photo by David Mitchell, The Eumycetozoon Project, DiscoverLife.org, with online permission.

It is clear that slime molds are often associated with bryophytes (Sean Edwards, pers. comm. 7 December 2013). But these associations may simply be two organisms with similar environmental requirements, particularly for moisture. Among these, Edwards was able

to list several of these moss-slime mold associations from England:

Fuligo septica (Figure 53, Figure 62) pulsing plasmodium with *Hypnum andoi* (Figure 54)

Physarum leucophaeum (Figure 46) encrusted sporangia, dehiscing on *Leptodictyum riparium* (Figure 55)

Diderma deplanatum (Figure 56-Figure 58) on *Mnium hornum* (Figure 59).

Figure 53. *Fuligo septica* on *Hypnum andoi*. Photo by Sean Edwards, with permission.

Figure 54. *Hypnum andoi*, a moss known to form a substrate for *Fuligo septica*. Photo by Michael Lüth, with permission.

Figure 59. *Mnium hornum*, a moss known to provide a substrate for *Diderma deplanatum*. Photo by Tim Waters, through Creative Commons.

Elsewhere in Europe, Eliasson and Adamonyte (2009) reported *Licea operculata* on mosses in Sweden.

Figure 60. *Licea operculata* sporophytes, a species also known from mosses. Photo by Clive Shirley, The Hidden Forest, with permission.

Stephenson and Studlar (1985) found that a number of species of slime molds are associated with bryophytes in temperate North America (Table 1). Although their study was targetted and extensive, revealing a number of bryophytes that have slime mold associates, the data were insufficient to determine any preferences.

Table 1. Slime molds occurring among the 17 most frequent species of bryophytes with sporulating slime molds (120 collections) from 20 localities in Tennessee, Kentucky, West Virginia, Virginia, Pennsylvania, Colorado, and Montana, USA, and one from British Columbia, Canada. Number of collections indicates the number of times the slime mold species was collected among the 120 collections. Based on table in Stephenson & Studlar 1985.

Others, collected in Maine, USA, that may have a moss preference are *Trichia subfusca* (Figure 85), cultured from mosses in a moist chamber, and *Paradiachea rispaudii* (Figure 86), a rather rare species that Stephenson collected only twice in 30 years, both times with mosses on the forest floor (Zoll & Stephenson 2013).

Lado *et al.* (2003) examined slime molds in two Neotropical forest reserves in Mexico. *Physarum alvaradianum* occurred on mosses along with the slime mold *Diderma rugosum* (Figure 87). Other slime molds are sometimes associated with dead or living bryophytes, including *Diderma chondrioderma* (Figure 88), *Didymium bahiense* (Figure 89), *Licea* sp. (Figure 29-Figure 30, Figure 90-Figure 91), *Physarum album* (Figure 92), *P. crateriforme* (Figure 93), *P. didermoides* (Figure 94), and *Stemonitis flavogenita* (Figure 95-Figure 96).

Even in the Antarctic, bryophytes, in this case the leafy liverwort *Lepidozia* (Figure 97), support the growth of the slime mold *Lamproderma* (Figure 6) (Stephenson *et al.* 1992).

Figure 97. *Lepidozia glaucophylla*; the genus *Lepidozia* is a substrate for slime molds in the genus *Lamproderma* in the Antarctic. Photo by Janice Glime.

Collection Records in Floras

Most of the records of slime molds associated with bryophytes are in floristic treatments where species are listed, described, and known habitat affinities provided. Hence, I was able to add a number of bryophyte associates to this chapter by searching this body of literature, albeit not extensively. Unfortunately, these usually fail to state where the bryophyte is growing, much less the species. Thus we cannot separate those that expand from a log onto the moss from those that become established on the moss by preference or even restriction. When the more specific substrate is known, the relationship is in the Slime Mold subchapter on Ecology and Habitat.

A further difficulty is that the plasmodial stage may reside in a different place from the fruiting stage. The plasmodial stage can usually only be identified by culturing it until it produces sporangia. Even then, beginners will be confounded by the many color phases seen in some species (Figure 98-Figure 104).

Among the early North American records, Sturgis (1893) in Massachusetts, USA, reported that *Paradiachea caespitosa* (syn=*Comatricha caespitosa*; Figure 105-Figure 111) occurred on moss and the lichen *Cladonia* (Figure 112). Ricker (1902) reported *Craterium obovatum* (Figure 113) on moss and sticks, *Physarum leucophaeum* (Figure 46) on moss, *Lepidoderma tigrinum* (Figure 5) in moss on tree, *Diachea thomasi* (Figure 114) on moss, and *Cribraria argillacea* (Figure 115) among mosses in Maine, USA. Gilbert (1927) reported *Physarum virescens* (Figure 116) on moss in eastern Massachusetts, USA. Greene (1929) reported *Diderma deplanatum* (Figure 56-Figure 58), *Diderma radiatum* (Figure 117), *Didymium melanospermum* (listed in publication as *D. melanosporum*; Figure 118), *Physarum bivalve* (syn=*Physarum sinuosum*; Figure 45), and *P. contextum* (Figure 119) on moss in western Washington, USA. Gray (1938) added *Physarum gyrosum* (Figure 120) as a species fruiting on living moss in Indiana, USA.

Lister (1917) cultured the slime mold *Colloderma* sp. (Figure 4) from mosses in the UK, maintaining it until the slime mold produced spores. More recent references include a greater number of records of moss dwellers, and often more details of the habitat. Doidge (1950) reported *Lamproderma scintillans* (Figure 12) growing on mosses and roots of epiphytic orchids in a greenhouse.

Based on collections from Lake Itasca State Park, Minnesota, USA, Palm *et al.* (1979) listed bryophytes as the substrate for a number of slime molds, but they did not give the substrate of the bryophytes. These bryophyte-dwelling slime molds included *Arcyria oerstedtii* (Figure 121), *Craterium leucocephalum* (Figure 122), *C. minutum* (Figure 123-Figure 124), *Diderma crustaceum* (Figure 125), *Didymium melanospermum* (Figure 48), *D. nigripes* (Figure 126), *D. squamulosum* (Figure 127), *Fuligo septica* (Figure 53, Figure 62), *Hemitrichia serpulula* (Figure 128-Figure 129), *Leocarpus fragilis* (Figure 81), *Metatrichia vesparia* (Figure 42), *Mucilago crustacea* (Figure 130), *Physarum bivalve* (Figure 45), *P. cinereum* (Figure 22-Figure 23), *P. notabile* (Figure 131), *P. album* (Figure 49), *Stemonitis fusca* (Figure 14), and *Tubifera ferruginosa* (Figure 65).

New records continue to appear. Baba and Er (2018) added *Craterium dictyosporum* (Figure 132) to the records from Turkey by finding this species on mosses. In 2013, Mishra and Phate added the new species *Badhamiopsis stipitata* to the slime molds of Maharashtra, India, noting its fruiting occurrence on living mosses, but that species does not seem to appear in any checklists or nomenclatural lists.

Figure 132. *Craterium dictyosporum* sporangia on moss. Photo by John Davis, with permission.

Perhaps the most interesting recent study for bryologists (since that of Stephenson and Studlar in 1985) is that of Yatsiuk *et al.* (2018) in the Ukraine. They not only noted the species of slime molds, but also identified the moss species substrate in many cases. They found *Didymium melanospermum* (Figure 48) on the living moss *Atrichum undulatum* (Polytrichaceae; Figure 133). *Didymium ovoideum* (Figure 134) and *Stemonitis axifera* (Figure 135) were restricted to species of *Sphagnum* (Figure 136) and/or Polytrichaceae.

Figure 136. *Sphagnum palustre*; the genus *Sphagnum* is a known substrate for slime molds. Photo by Bob Klips, with permission.

Ranade *et al.* (2012) also reported *Stemonitis axifera* (Figure 135; as *S. smithii*) from bryophytes in India. *Didymium* species are typically organisms of litter and parts of living plants (Liu *et al.* 2015), but several species have already been reported in this subchapter as living on bryophytes. Furthermore, *D. melanospermum* seems to prefer acid substrates (Stephenson & Studlar 1985; Ing 1994), explaining its presence in a *Sphagnum* habitat. Yatsiuk *et al.* (2018) found *Stemonitis axifera* (Figure 61) not only on living mosses, but also on litter and wood debris, as was the case for *Arcyria cinerea* (Figure 16).

Photographic Indicators

One way to determine which slime molds are able to live on bryophytes is to search for images that show them with bryophytes. This doesn't work for most animal relationships because photographers are likely to pose their animals on bryophytes to provide a pleasing background, but it seems unlikely that this happens with slime molds, particularly when it appears to be taken in the field.

The following images (Figure 137-Figure 173) provide such pictures to increase our knowledge of slime molds one might find on bryophytes. Some of these are adjacent, but not intermingled, suggesting that they do well in similar habitats and on the same substrate, frequently indicating similar moisture and pH requirements.

Generalists – Bryophytes Are Okay

Many of the slime molds that occur with or on bryophytes are **generalists**. This is not to be confused with those species that prefer bryophytes and that are typically **specialists**. Lado and de Basanto (2008) highlighted the abundance and widespread distribution of generalist *Arcyria cinerea* (Figure 16) in their review of Neotropical slime molds, indicating its presence in 28 of 30 countries. Tropical generalists include *Arcyria denudata* (Figure 174; known from bryophytes – Stojanowska & Panek 2004), *Cribraria cancellata* (Figure 175; known to associate with bryophytes on logs – Schnittler & Novozhilov 1998), *Didymium nigripes* (Figure 126; known from bryophytes – Palm *et al.* 1979), *D. squamulosum* (Figure 127; known

from bryophytes – Palm *et al.* 1979), *Fuligo septica* (Figure 53, Figure 62; known from bryophytes – Stephenson & Studlar 1985), *Hemitrichia calyculata* (Figure 77-Figure 79; known from bryophytes – Stephenson & Studlar 1985), *H. serpula* (Figure 128-Figure 129; known from mosses – Ranade *et al.* 2012), *Lycogala epidendrum* (Figure 15; known from bryophytes – Stephenson & Studlar 1985), *Perichaena chrysosperma* (Figure 31; known from liverworts – Dudka & Romanenko 2006), *Physarum album* (Figure 92; known from bryophytes – Lado *et al.* 2003), *Ph. viride* (Figure 66; known from bryophytes – Stephenson & Studlar 1985), *Stemonitis fusca* (Figure 14; known from bryophytes – Palm *et al.* 1979; Dudka & Romanenko 2006), and *Trichia favoginea* (Figure 63; known from bryophytes – Stephenson & Studlar 1985).

Figure 175. *Cribraria cancellata* fruiting body showing threadlike capillitium. Photo by Dmitry Leontyev, The Eumycetozoan Project, DiscoverLife.org, with online permission.

Härkönen and Ukkola (2000) considered the occasional moss dwellers *Arcyria cinerea* (Figure 16), *A. pomiformis* (Figure 176) and *Echinostelium minutum* (Figure 19) to be indifferent to substrate.

Figure 176. *Arcyria pomiformis* with mosses. Photo by Ray Simons, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Interactions Can Be Helpful or Hinderling

Despite the number of associations between bryophytes and slime molds, the relationship is often negative. Schnittler and Stephenson (2000) found that the higher the epiphytic coverage was, the lower the number of slime mold records obtained in culture (Figure 177). In Costa Rica, both slime mold species diversity and abundance decreased with increasing elevation, as well as with higher moisture levels, relationships that suggest they should not correlate well with bryophytes, which typically increase with altitude. Furthermore, on litter, the slime mold species with robust plasmodia increased with increasing elevation, further supporting the hypothesis of a negative relationship with bryophytes. On the other hand, Schnittler and Stephenson suggest that excess moisture of tropical forests does not favor the slime mold development. This conclusion is supported by the observation that the two seasonal dry forest types accounted for 90% of the total slime mold diversity. Nevertheless, the typical wood inhabitant *Ceratomyxa fruticulosa* (Figure 72) was recorded twice from mossy bark in the wet forest. Schnittler and Stephenson suggested that a possible explanation for the decreasing slime molds with altitude (Figure 177) is that a closed epiphyte (bryophytes and lichens) cover interferes with slime mold growth.

Figure 177. Myxomycete species richness vs epiphyte (including bryophyte) cover. Modified from Schnittler & Stephenson 2000.

Novozhilov *et al.* (2000) considered that the bryophilous slime molds, or at least the plasmodial slime molds (*Myxogastria*), albeit associated with mosses, were probably there due to slime algae (Figure 178), wood, or rocks that occurred where moisture was maintained by humid ravines. The ravine taxa include less than 5% of the slime molds and are mostly macroscopic taxa of temperate and boreal zones. Their fructification and spore release typically occurs in late autumn. The ravine species are all but impossible to grow in culture, making it likewise all but impossible to identify those not fruiting at the time of collection.

Figure 178. *Cribraria personii* fruiting bodies; the substrate appears to have algae with the slime molds growing on them. Photo by David Mitchell, The Eumycetozoon Project, DiscoverLife.org, with online permission.

On the other hand, Landolt *et al.* (1992) suggested that the antibiotic properties of bryophytes might inhibit the growth of slime molds on or among many kinds of bryophytes. This could be particularly important for those slime molds that might use the bryophytes as feeding grounds for bacteria and other micro-organisms (Banerjee & Sen 1979). Landolt and coworkers observed that slime molds exhibited greater numbers in forests with a groundcover of deciduous litter than in those with a bryophyte ground cover. But is that due to inhibition or to differences in habitat requirements?

Schnittler and Stephenson (2000) commented further on the decreasing abundance and diversity of slime molds with elevation, whereas bryophytes increase in both. They suggested that competition for nutrients could cause bryophytes, especially in the tropics, to outcompete the slime molds for nutrients.

But as also noted by Schnittler and Stephenson (2000), slime mold species diversity is positively correlated with substrate pH on both litter and bark. Since conifer litter and conifer forests tend to be acidic, could that explain the absence of slime molds on bryophytes there, as observed by Landolt *et al.* (1992)? On the other hand, studies in the conifer *Cryptomeria japonica* forests in Japan indicate a negative correlation between slime mold abundance and pH, particularly for some species (Takahashi 2018; Takahashi & Harakan 2018).

Summary

Few bryophytes seem to be restricted to bryophytes (**bryophiles**). These include *Barbeyella minutissima* on leafy liverworts (especially *Nowellia curvifolia*), *Colloderma oculatum*, and *Lepidoderma tigrinum*, the latter two often in association with *B. minutissima*. This raises so many questions about the relationship between bryophytes and slime molds. Why is *Barbeyella minutissima* so restricted in its substrate? Does it derive some benefit from the liverworts? Could it really be elsewhere but in a form we have recognized as a different species?

And why do some slime molds seem to grow to the edges of moss mats and stop? Does the moss produce an inhibitory substance? Or is it the darkness at the base of the moss mat that stops the plasmodium in its tracks?

Other slime molds with a preference for bryophytes include *Lamproderma columbinum* and *L. scintillans*. But most of the associations seem to be coincidental – the bryophytes are in the preferred habitat and nothing stops the expansion of the slime molds simply grow onto the bryophytes. And how many associations are we missing in the amoeboid, swarm cell, and plasmodial stages because they are hard to find and require culturing for identification? And even if they grow in culture and produce identifiable sporangia, would they do this in nature on or among the bryophytes?

Stemonitis axifera may be a candidate that prefers bryophytes, being restricted to *Sphagnum* and **Polytrichaceae** in a peatland study.

Checklists and photographs can be used to find some of those species that sometimes occur on bryophytes. From these, one can surmise that most of the bryophyte dwellers are **generalists** that can live on a bryophyte, whereas those that prefer or only live on bryophytes are **specialists**.

Evidence from elevational studies suggests that bryophytes might actually inhibit or outcompete the slime molds at higher altitudes by overgrowing them, shading them, or competing for nutrients. Antibiotics produced by the bryophytes could inhibit the microorganisms needed by the slime molds as food or even inhibit the slime molds themselves. In some cases, pH is a deterrent for many slime mold species. Presence of algae and Cyanobacteria, as well as protozoa and bacteria, may enhance the suitability of bryophytes as a substrate for slime molds.

Acknowledgments

Thank you to Sarah Lloyd for early inspiration in writing this chapter and for her generous help with images and knowledge. The Eumycetozoon Project has been invaluable in providing images.

CHAPTER 3-3

SLIME MOLDS: ECOLOGY AND HABITATS – BARK AND LOGS

Figure 1. *Fuligo cf. septica* growing on bryophytes on a log. Photo by Janice Glime.

Habitats

It is well known that many slime molds have a substrate preference (Eliasson 1980), including dead wood, bark, twigs, dead leaves, and dung (Stephenson *et al.* 2000). But are there truly species that prefer bryophytes? It would appear that some may prefer leaves with bryophyte associations, as described in the ecology subchapter. But there are a number of species that are likely to be found in bryophyte associations, particularly in the high latitudes of the Northern Hemisphere (Kaiser 1913; Gray & Alexopoulos 1968; Farr 1979; Ing 1994; Stephenson *et al.* 2000). Martin and Alexopoulos (1969) reported 49 different species on some sort of mossy substrate.

Rollins and Stephenson (2011) identified five substrate types for slime molds: soil, leaf litter, twigs, bryophytes, and snow. For some reason, they did not list logs as a habitat/substrate, although the paper did discuss slime molds on logs.

Döbbeler & Nannenga-Bremekamp (1979) suggest that some slime molds may indeed be unique to bryophytes, or at least use them as primary substrate. Similarly, Ing (1994), in studying the phytosociology of slime molds, reported that a few species are "particularly associated" with bryophytes. Likewise, several other authors have reported that some (few) bryophytes appear almost invariably in association with bryophytes (Gray & Alexopoulos 1968; Ing 1983, 1994).

However, the majority of slime mold associates most frequently encountered by Stephenson and Studlar (1985) in the USA and Canada include *Brotherella recurvans* (Figure 2), *Thuidium delicatulum* (Figure 3), *Hypnum imponens* (Figure 4), and *Hypnum curvifolium* (Figure 5) – species that show a broad ecological amplitude, and characteristically grow not only on rotten wood but also on soil, living trees, and rocks.

Figure 5. *Hypnum curvifolium*, a frequent slime mold substrate in North America. Photo by Bob Klips, through Creative Commons.

Stephenson and Studlar (1985) found that most of the bryophyte species that support the development of slime mold colonies are low-growing. Their life forms include **smooth mats** (58%) > **short turfs** (19%) > **rough mats** (13%) > **wefts** (9%) > **tall turfs** (2%) > **turfs with creeping primary stem** (1%) > **small cushion** (1%). The

only species that exceeded 2 cm in height were *Polytrichum commune* (Figure 6) and *Sphagnum recurvum* (Figure 7) (both **tall turfs**) and *Pleurozium schreberi* (Figure 8) (**weft**). Longton (1980) determined that **short turfs** retain more capillary water than do the other life forms, perhaps explaining that these were the second most abundant life form.

Bark Associations

Ing (1994) concluded that slime molds are more likely to be found on bryophytes in woodlands having high humidity. This is probably more important on standing tree bark associations than on fallen logs. Bryophytes on the bark can help to retain moisture and to trap airborne spores, thus making it likely that at least some slime molds should be favored by or restricted to mossy areas. This affinity might also differ with the moisture availability in the habitat.

In addition to water-holding capacity of bark, the general shape of the tree, surface texture of the tree bark, (fibrous, furrowed, ridged, scaly, smooth) along with epiphytic cover of algae, mosses, liverworts, and lichens may also influence the presence of corticolous slime molds (Brooks *et al.* 1977).

Diderma corrugatum (Figure 9) is a slime mold that seems to be restricted to moss-covered bark, occurring in the southeastern United States (Brooks *et al.* 1977). It typically occurs in the top part of the canopy on branches and on the upper trunk, in both places where bryophytes form extensive cover. It has a watery white phaneroplasmodium often associated with mosses and liverworts (Brooks *et al.* 1977). Although it can live on several kinds of trees, elms (*Ulmus*; Figure 10) seem to be the more common substrate. Everhart and Keller (2008) suggested that bryophytes may contribute to the necessary moisture for this species.

Figure 10. *Ulmus americana* bark, a preferred substrate for *Diderma corrugatum*. Photo by Downtowngal, through Creative Commons.

The closely related *Diderma rugosum* (Figure 11) differs in microhabitat from *D. corrugatum* (Figure 9), but still is often associated with mosses (Brooks *et al.* 1977). It occupies leaf litter and the basal part of tree trunks. Unlike *D. corrugatum*, it seems to prefer mossy bark of the sycamore (*Platanus occidentalis*; Figure 12) along streams. Ing (1982) reported *Diderma chondrioderma* (Figure 13) as a rare species from mossy bark of living trees in the UK. Ranade *et al.* (2012) contributed to our knowledge of bryophyte-*Diderma* associations in India. In their checklist, they reported *Diderma badhamioides* on mosses growing on the bark of a tree; *Diderma chondrioderma* occurs on live mosses as well tree bark in India.

Figure 13. *Diderma chondrioderma*, a rare species in the UK, living on the mossy bark of trees. Photo by James K. Lindsey, with permission.

Diderma cinereum likewise lives on bark, including sometimes living on the epiphytic mosses (Figure 14-Figure 15). So far I have found only a photographic record of this.

Figure 14. *Diderma cinereum* sporangia on bryophytes. Photo by James K. Lindsey, with permission.

Figure 15. *Diderma cinereum* sporangia on bryophytes. Photo by James K. Lindsey, with permission.

Doidge (1950) noted *Badhamia affinis* (Figure 16-Figure 17) on both mosses and bark of dead and living trees in Africa. *Badhamia versicolor* (Figure 18) usually occurs on bark of living trees, and similarly it often uses mosses and lichens as a substrate (Ing 1982; Poulain *et al.* 2011).

Ing (1982) reported that *Badhamia versicolor* is a rare species on mossy bark of living trees in the UK. Keller and Brooks (1975) described *Badhamia rugulosa* from bark and moss-covered tree substrata and grape vines (*Vitis*). They noted that this slime mold tends to occur in flowways and in areas of the bark that retain moisture, with both mosses and liverworts, as well as algae, satisfying that need for moisture retention. In Taiwan, *Badhamia formosana* occurs on bark of living trees where it often appears also on the epiphytic mosses (Liu *et al.* 2002).

Figure 20. *Physarum tessellatum* sporangia, a species of bark and living mosses. Photo from Myxotropic, through Creative Commons.

Ranade *et al.* (2012) contributed to our knowledge of bryophyte-slime mold associations on bark in India. In their checklist, they reported *Physarum mortonii* (Figure 19) and *P. tessellatum* (Figure 20) on bark and living mosses, whereas *Physarum album* (Figure 21) occurs not only on moss growing on bark of trees, but also on dead twigs; this species is also known from moss-covered rotting logs in China (Ukkala *et al.* 2001). Ukkala *et al.* (2001) found that in Hunan, China, the slime mold *Physarum pusillum* (Figure 22) is sometimes associated with mosses on the bark of broad-leaved trees.

Figure 21. *Physarum album* sporangia on decaying wood, a species that also lives on mosses of bark and dead twigs. Photo by George Shepherd, through Creative Commons.

Figure 19. *Physarum mortonii* sporangia, a species of bark and living mosses. Photo from The Eumycetozoon Project, DiscoverLife.org, with online permission.

Stemonitis axifera (Figure 23-Figure 24) and *Trichia botrytis* (Figure 25) both occur on bark of trees and mosses growing on them in India (Ranade *et al.* 2012).

Figure 22. *Physarum pusillum* sporangia, a species that sometimes is associated with epiphytic mosses. Photo by Clive Shirley, The Hidden Forest, with permission.

Figure 25. *Trichia botrytis* on mosses, a species that occurs both on bark and bark mosses. Photo by Dragiša Savić, with permission.

Gilert and Neuendorf (1991) reported *Elaeomyxa reticulospora* (Figure 26; as *Lamproderma reticulosporum*) from its type locality in western Java in Indonesia, where it

was found on the moss-covered trunk of a huge evergreen tree.

Figure 26. *Elaeomyxa reticulospora*, a species known from moss-covered bark. Photo by Sarah Lloyd, with permission.

Large colonies of *Colloderma oculatum* (Figure 27) occur on the moss-covered bark of living trees in coastal Central Europe (Schnittler & Novozhilov 1996). *Clastoderma pachypus* occurs on bark covered with mosses in Lithuania (Adamonyté 2007).

Figure 27. *Colloderma oculatum* on bryophytes, a typical habitat for it on bark of living trees. Photo by The Eumycetozoon Project, DiscoverLife.org, with online permission.

Schnittler *et al.* (2002) reported *Didymium floccosum* (Figure 28) from the densely moss-covered bark of a living tree. The single large colony grew among mosses and small amounts of leafy debris.

Figure 28. *Didymium floccosum* sporangia, a species that can occur on dense moss cover on bark. Photo by Ray Simons, The Eumycetozoon Project, DiscoverLife.org, with online permission.

The slime mold *Paradiacheopsis solitaria* (Figure 29; syn.=*Comatricha solitaria*) occurs on bark, often with mosses and lichens, in the UK (Ing 1982). Eliasson and Gilert (2007) found *Paradiacheopsis solitaria* on mosses and lichens on bark of living *Malus* (apple) in Sweden. *Perichaena chrysosperma* (Figure 30) occurs in Sweden as solitary, globose or subglobose sporangia on bark or mosses on bark of living trees.

Figure 30. *Perichaena chrysosperma*, a species of bark and mosses on living trees. Photo by Ray Simons, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Some corticolous species of slime molds may invade the bryophytes from their bark substrate (Brooks *et al.* 1977). On the other hand, some taxa may start on mosses and then invade the bark. If a plasmodium lives under the bark, it may sometimes be difficult to avoid mosses when it crawls out to produce sporangia (Figure 31).

In their study of corticolous taxa in Costa Rica, in four different forest types, Schnittler and Stephenson (2000) found that those species found on bark at higher elevations also occurred on lush bryophyte mats that covered the bark: *Arcyria cinerea* (Figure 32-Figure 33), *Physarum cf. roseum* (Figure 34-Figure 35), *Ceratiomyxa fruticulosa* (Figure 36), *Cribraria oregana* (Figure 37), and *Didymium iridis* (Figure 38). Nevertheless, they found that when no bare bark was present, the growth of slime molds was diminished. But, in culture, bark with no epiphytes failed to provide successful slime mold cultures. Perhaps the bryophytes act as a trap, but the sporelings quickly migrate to a more open surface in this habitat.

Among these Costa Rican bryophyte inhabitants, only *Arcyria cinerea* (Figure 32-Figure 33) was also present in Virginia (Schnittler & Stephenson 2000). The most common species in each of these two areas were absent in the other. *Arcyria cinerea* is a widespread species tolerant of an array of substrates, including mossy bark of living trees, especially oak (Ing 1982). Furthermore, as elevation increased, the number of species of slime molds decreased (Schnittler & Stephenson 2000), contrasting with the elevational relationship of bryophytes in the Colombian Andes (Gradstein *et al.* 1989; Wolf 1993).

Everhart and Keller (2008) examined the life history strategies of slime molds that live on bark, including six tree species and two vine species in Kentucky and Tennessee, USA. They cultured 580 samples and found 46 slime mold species in 20 different genera. The majority of

these had stalked sporangia. They concluded that the corticolous slime molds in the tree canopy are **r-selected** (optimized for high reproduction). Their resistant, dormant, resting stages permit them to survive the irregular wet periods interspersed with prolonged dry periods in their habitat. The most abundant species, especially the **Echinosteliales** (Figure 39-Figure 40), have a plasmodial stage that exhibits the smallest surface to volume ratio (**protoplasmodium**) and produces spores quickly over 2-4 days by producing a single, tiny, stalked sporangium (Figure 40). Their spore release is efficient, with an rapidly disappearing **periderm** (outer covering of the sporangium).

Figure 39. *Echinostelium minutum*, showing the tiny, stalked sporangia. Photo by Satyendra Rajguru, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Figure 40. *Echinostelium minutum* sporangium showing absence of periderm when spores are dispersing. Photo by Dmitry Leontyev, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Slime mold specialists are using rope-climbing techniques like those used by bryologists in the tropics.

Snell and Keller (2003) collected slime molds from bark at 3-m increments to the tops of five different tree species in the Great Smoky Mountains National Park, USA. They identified 84 species from their 418 cultures, representing 25 trees. They found similar slime mold community composition among the five tree species, but occurrence and abundance differed and were related to differences in bark pH. No height differences were apparent, nor did bark moisture seem to make any difference.

Melissa Skrabal found a new myxomycete species (plasmodial slime mold) *Diachea arboricola* (Figure 36) in the tree canopy using rope-climbing techniques (Keller & Skrabal 2002). Although these slime molds occur primarily on bark, one collection developed on bark-dwelling bryophytes (Keller et al. 2004). Observations of this species may help to explain the occasional occurrence of some slime molds on bryophytes. The plasmodium (jelly-like slime stage) of *Diachea arboricola* moves great distances across the bark surface, but is apparently confined to the tree canopy. In order to traverse the canopy, the plasmodium often encounters bryophytes living there. This behavior was also observed in a Petri dish, where a large plasmodium covered the moss in a moist chamber. Thus, when cultures of slime molds include bryophytes, mosses and liverworts, they serve as a substratum to renew the myxomycete life cycle and develop sporangia. A possible explanation for the bryophyte occurrence of *Diachea arboricola* sporangia, and that of other occasional slime mold species on bryophytes, is that the bryophyte dries while the slime mold is on it, and on a sunny day, may trigger fruiting body formation.

Figure 41. *Diachea arboricola* sporangium, a bark species that migrates on the tree as a plasmodium. Photo by Kenny Snell, courtesy of Harold W. Keller, from Keller & Skrabal 2002; Keller & Barfield 2017; Keller 2019.

Liverwort vs Moss Associations

In humid forests, the epiphytic liverworts often serve as substrates for slime molds (Ing 1994). Coincidentally, they also serve as substrates for myxobacteria, providing a food source for the slime molds and permitting their development. Schuster (1957) reported fruiting bodies of *Lamproderma columbinum* (Figure 42), *Collaria arcyronema* (Figure 43), *Physarum flavidum* (Figure 44), and *Cribraria violacea* (Figure 45) on both stems and leaves of leafy liverworts. Ing (1994) considered the epiphytic liverworts to be frequent developmental substrates for slime molds. *Hemitrichia minor* is typically associated with *Metzgeria furcata* (Figure 46) and *Radula complanata* (Figure 47). Isabelle Mazaud photographed *Diacheopsis synspora* (Figure 48-Figure 49) from *Metzgeria furcata* on the bark of *Quercus robur* (Figure 50). *Licea bryophila* (Figure 51) seems to be confined to bark-dwelling liverworts, and *L. gloeoderma* is found only on the epiphytic leafy liverwort *Frullania* (Figure 52) species in Bavaria (Döbbeler & Nannenga-Bremekamp 1979).

Figure 52. *Frullania* sp.; *Licea gloeoderma* is found exclusively on this genus of leafy liverworts. Photo by Felipe Osorio-Zúñiga, with permission.

The slime mold *Diacheopsis mitchellii* grows on epiphytic bryophytes in Flanders, Belgium (de Haan 2017). De Haan included an image of it growing on *Lophocolea heterophylla*.

Diderma chondrioderma (Figure 13) is commonly associated with the moss *Hypnum andoi* (Figure 53; syn.=*Hypnum mammillatum*) and the slime mold *Macbrideola cornea* (Figure 54) occurs with several acrocarpous moss species (Ing 1994). *Macbrideola cornea* forms a single plasmodium that can migrate to the tips of moss leaves and form stalked sporangia (Harold Keller, pers. comm. 22 April 2019). Unlike most of the known moss dwellers, the common *Licea parasitica* (Figure 55) is not confined to mosses in fructification, but its **microcysts** (resistant dormant stage) can become conspicuous on the moss leaves.

It is likely that slime mold preferences for mosses vs liverworts relate to moisture or other bark preferences of these two groups of bryophytes. There has been no experimental work to attempt to find the determining factors.

Limiting Factors

Studlar (1982) examined host specificity of epiphytic bryophytes, reporting on 54 moss and 18 liverwort species on 120 trees comprised of 6 species. She found that among those bryophytes with a frequency of 20% or more on tree trunks up to 1.8 m, only three species were restricted to just one host, with another 21 exhibiting a strong single-host preference. She found that the bryophyte species richness and frequency decreased with decreasing bark pH, with water absorption capacity of the bark having a lesser effect. It would be interesting to see if slime molds associated with bryophytes have the same gradients on these trees.

Everhart *et al.* (2009) evaluated the bark characteristics and canopy epiphytes (mosses, lichens, and algae) associated with corticolous slime molds in three temperate forests in the southeastern USA. They used rope-climbing techniques to sample trees and grapevines up to 15 m above the ground. They used five 2 x 2 cm quadrats, resulting in 187 sample sites, for determining percent

cover. They found no association between epiphytic percent cover and slime molds. Rather, like Studlar (1982), they found that bark pH was the major factor apparently influencing the presence of the corticolous slime mold species. They considered the patchy distribution to be the result of the small plasmodium typical of most of the corticolous species. They concluded that rather than improving the growing conditions for the slime molds, bryophytes had a negative correlation with them, albeit not a significant one.

Härkönen (1977) actually measured pH at the locations of slime molds living on bryophytes. Overall, the bark-dwelling slime molds occurred on a wide range of pH from 2 to 9. Specifically, *Perichaena chrysosperma* (Figure 30) occurred on *Populus tremula* (Figure 56) with a pH of 5.5; *Stemonitis pallida* (Figure 57) occurred on *Juniperus communis* (Figure 58) with a pH of 4.5.

Figure 58. *Juniperus communis*, a species with a bark pH of 4.5. Photo by Chris Cant, through Creative Commons.

Härkönen *et al.* (2004) found that slime mold species richness on bark of forests in Hunan, China, was highest when the bark was relatively acidic and had a high water-retention capacity. The bryophytes, on the other hand, had a higher diversity on less acidic, relatively smooth bark. It is assumed that smooth bark holds less water.

Härkönen (1977) inferred that the mosses trapped the spores of the slime molds. To test this hypothesis, he cultured bark from living trees at three localities in Finland. In these moist chambers, 19 species of slime molds appeared on the pieces of bark. He found that *Comatricha nigra* (Figure 59) preferred an acid substrate, whereas others like *Arcyria cinerea* (Figure 32-Figure 33) preferred a less acid one. Fructification in the cultures varied from a few days to more than 40 days. Source of origin affected the species diversity, with the urban locality samples producing only six species. Interestingly, the virgin forest samples exhibited more species, but fewer fructifications. *Salix caprea* and *Alnus incana* have very few epiphytic mosses, presumably greatly reducing the capture of slime mold spores.

Figure 59. *Comatricha nigra* young sporangia, a species that prefers an acid substrate. Photo by Bjorlil, through Creative Commons.

Interestingly, Ing (1994) found that temperature was the only significant factor limiting tropical, subtropical, Mediterranean, and alpine species. Nevertheless, water is of prime importance, with water-retaining substrates being essential. They considered only "a few species" to be particularly associated with terrestrial bryophytes. The slime molds tended to prefer either coniferous or angiospermous wood.

Unlike bryophyte diversity, slime mold diversity and abundance decrease with elevation and associated higher moisture levels in the tropical Costa Rica (Gradstein *et al.* 1989; Wolf 1993; Schnittler & Stephenson 2000). Furthermore, it is in two seasonally dry forests where 90% of the slime mold diversity occurs. The negative correlation between slime molds and bryophytes suggests that the bryophytes may actually out-compete the slime molds in the more moist, bryophyte-dominant ecosystems at higher elevations. Nevertheless, higher species diversity seems to be correlated with higher substrate pH. On the other hand, litter-inhabiting slime molds with robust phaneroplasmodia increase with increasing elevation. It also appears that the continuously moist forests at higher elevations are not favorable for slime mold growth and development. These factors all contribute to the fact that biodiversity of slime molds does not reach its highest levels in tropical forests.

Schnittler and Stephenson (2000) found *Ceratiomyxa fruticulosa* (Figure 36) twice on mossy bark in the wet Costa Rican forest. All the species found on bark at higher elevations occurred not only on bark, but also on lush epiphytic moss and liverwort mats on the bark. These were *Arcyria cinerea* (Figure 32-Figure 33), *Physarum cf. roseum* (Figure 34-Figure 35), *Ceratiomyxa fruticulosa*, *Cribraria oregana* (Figure 37), and *Didymium iridis* (Figure 38). The culture studies made it "obvious" that a closed cover of epiphytes hampers growth of slime molds. Nevertheless, many cultures prepared with bark having low cover of epiphytes likewise produced no slime molds. In any case, the number of slime mold records, based on cultures, clearly decreased with increasing elevation. Schnittler and Stephenson suggested that the abundant bryophytes use the bark nutrients, hence making them unavailable for bacterial growth, thus making less bacterial

food available for the slime molds. But they pointed out that slime molds were often absent at low elevations where bryophytes were likewise rare.

In addition to bark-dwellers, some slime molds find substrates of liverworts growing on leaves to provide a suitable substrate (Schnittler *et al.* 2006). In the tropical forest, these habitats typically have a poor species richness of slime molds (Schnittler *et al.* 2006), but an assemblage dominated by members of the **Physarales** (Figure 19-Figure 22) is common (Schnittler 2001).

Log and Stump Associations

The most common habitat for slime molds seems to be that of logs (see, for example, Stephenson & Studlar 1985). These include a variety of stages of decay, and the logs often have a dense cover of bryophytes. Stumps offer similar habitats, but may differ in having exposed wood before decay sets in.

Doidge (1950), in her African report, included more detail on substrate than many of the early studies. She reported *Cribraria cancellata* (Figure 60) on dead wood and moss. *Trichia affinis* (Figure 61) occurred on decayed wood and moss. While it is likely that some of these slime molds grew from a primary substrate onto the mosses, that cannot be discerned from the report.

Figure 61. *Trichia affinis* sporangia. Photo by Malcolm Storey, DiscoverLife.org, with online permission.

A number of species are common on rotten wood, where they are able to provide food for a number of invertebrate organisms (Ing 1967). These slime molds include *Arcyria denudata* (Figure 62-Figure 63), *Stemonitopsis typhina* (Figure 64), *Cribraria piriformis* (Figure 65), *Didymium iridis* (Figure 38), *Fuligo septica* (Figure 1, Figure 66), *Lycogala epidendrum* (Figure 67), *Reticularia lycoperdon* (Figure 68), *Stemonitis fusca* (Figure 69), *Symphytocarpus flaccidus* (Figure 70-Figure 71), *Trichia varia* (Figure 72), *Tubifera ferruginosa* (Figure 73-Figure 74). All of these slime mold species occur on the same substrata preferred by a number of bryophyte species and are known to occasionally occur on the bryophytes.

Figure 76. *Metatrichia floriformis* sporangia, a species that occurred together with *Trichia varia* on a moss-covered aspen log. Photo by Clive Shirley, The Hidden Forest, with permission.

Rojas and Stephenson (2007) examined **Myxomycetes** at high elevations in Costa Rica. They determined that *Didymium squamulosum* (Figure 75), *Lycogala epidendrum* (Figure 67), and *Metatrichia floriformis* (Figure 76) seem to group together at high pH levels and lower substrate heights. The sometimes-moss-dwellers *Cribraria mirabilis* (Figure 77) and *Trichia botrytis* (Figure 25) prefer more acidic substrates and higher substrates. They concluded that while bryophytes are important on the ground there, but not on logs, the bryophytes are not the reason for the presence of these slime molds at greater heights. As seen elsewhere, *Lamproderma columbinum* (Figure 42) is strongly associated with bryophytes. *Cribraria piriformis* (Figure 65), *Ceratiomyxa fruticulosa* (Figure 36) (on stumps overgrown with mosses – see also Stojanowska & Panek 2004), *Cribraria mirabilis*, and *Cribraria vulgaris* (Figure 78) exhibited most of their fruitings on logs, twigs, and bryophytes. Rojas and Stephenson concluded that most of these slime molds were generalists that are able to survive changing microenvironmental conditions.

Figure 80. *Barbeyella minutissima* sporangia on leafy liverwort. Photo by Randy Darrah, The Eumycetozone Project, DiscoverLife.org, with online permission.

The slime mold *Hemitrichia minor* is relatively common on logs covered with the leafy liverwort *Lophocolea heterophylla* (Figure 79). As shown in many studies cited herein, *Barbeyella minutissima* (Figure 80) occurs on such small liverworts as *Lepidozia reptans* (Figure 81) and *Nowellia curvifolia* (Figure 82) on montane forest logs in such distant locations as Japan, Europe, and North America (Kowalski & Hinchee 1972; Stephenson & Studlar 1985), with a similar relationship shown by the rare *Licea hepatica* (Kowalski 1972). *Lepidoderma tigrinum* (Figure 83) forms a strong association with both lichens and liverworts, the latter including *Anastrophyllum michauxii* (Figure 84), on damp coniferous logs. The frequent association of *Perichaena corticalis* (Figure 85) and *P. depressa* (Figure 86) with species of *Hypnum* (Figure 4) on ash (*Fraxinus*; Figure 87) fallen trunks that haven't "quite reached the ground" is notable (Ing 1982, 1994). I have already noted that *Cribraria rufa* (Figure 88) actually seems to damage the moss *Orthodontium lineare* (Figure 89) where both grow on conifer logs (Coker 1966).

Clissmann *et al.* (2015) considered the diversity of slime molds on decaying beech (*Fagus sylvatica*; Figure 90) logs. They found that the conspicuous slime molds with large fruiting bodies displayed a strong preference for well-decayed, moist wood. These included *Fuligo septica* (Figure 1, Figure 66), *Lycogala epidendrum* (Figure 67), and *Reticularia lycoperdon* (Figure 68), all of which are known from mosses. DNA identifications revealed that the majority of representatives were in the genera *Arcyria* (Figure 32; Figure 62-Figure 63), *Trichia* (Figure 72, Figure 92), and *Lycogala* (Figure 67). The most common species on these logs were *Arcyria cinerea* (Figure 32-Figure 33), *Hemitrichia clavata* (Figure 91), *Trichia scabra* (Figure 92), and *T. varia* (Figure 72). It is notable that all the species named here by Clissmann and coworkers are also known from bryophytes on logs.

There are even new species to be found in this common Myxomycetes habitat. Sarah Lloyd collected a new species, *Alwisia lloydiae* (Figure 93-Figure 94) (Leontyev *et al.* 2014). This species grows on logs, stumps, and mossy logs in New South Wales and Tasmania in Australia.

Figure 93. *Alwisia lloydiae* sporangia on mosses. Photo by Sarah Lloyd, with permission.

Figure 94. *Alwisia lloydiae* dehiscing capsules with mosses. Photo by Sarah Lloyd, with permission.

It is with this background of the strong relationship between slime molds and logs, and with the most common taxa occurring with bryophytes, that we must evaluate the relationship, if any, of slime molds with the bryophytes that grow on the logs. Are they simply benefitted by the same growing conditions? Or is the relationship **commensalism**, wherein one benefits and one is neither benefitted nor harmed? The slime molds could benefit from the moisture-holding capacity of the bryophytes, or the food organisms they house. It is harder to imagine any benefit to the bryophyte. Or do the slime molds provide food for invertebrates that in turn disperse the bryophyte spores?

Comparison of Checklists

Many researchers have reported slime molds growing on or over bryophytes on logs. Greene (1929) reported *Tubifera ferruginosa* (Figure 73) on mossy logs. Hagelstein (1941), using specimens added to the *Tubifera applanata* (Figure 95-Figure 96) similarly grows on decaying logs (Yatsiu, *et al.* 2018) and can grow on the bryophytes there (Figure 95). Herbarium of the New York Botanical Garden, reported a number of species from logs, noting those of conifer logs with a thick cover of mosses, lichens, and liverworts. These bryophyte associates included *Colloderma oculatum* (Figure 27), *Lepidoderma tigrinum* (Figure 83), *Diderma roanense*, and *Lamproderma columbinum* (Figure 42). Others only indicated mossy logs, including *Diderma roanense* and *Lepidoderma tigrinum*. Thus the short-comings of collections in herbaria deprive us of detailed information from which to draw inferences regarding specificity of the substrate, moisture and light levels, and pH. Hagelstein further pointed out that even in the sporangial stage, mosses can conceal the slime molds, so at best the ecology of slime molds associated with bryophytes is poorly represented.

Figure 95. *Tubifera cf. applanata* with bryophytes on decaying wood. Photo by Sarah Lloyd, with permission.

Figure 96. *Tubifera applanata* dispersing spores onto bryophytes. Photo by Sarah Lloyd, with permission.

Critchfield and Demaree (1991) reported *Badhamia nitens* (Figure 97-Figure 98) from dead wood and bark, but sometimes on mosses (and lichens) in California. Singer *et al.* (2005) reported *Diderma montanum* (Figure 99; syn.=*Chondrioderma montana*) and *Diderma asteroides* (Figure 100) on mosses on decayed wood. Robbrecht (1974) noted that *Arcyria* (Figure 101) occurs on diverse substrates, but mostly on dead wood (including alder, poplar, beech, oak, spruce, willow) at various stages of decay, but also on mosses, presumably on decaying wood. Ing (1982) reported *Physarum psittacinum* (Figure 102-Figure 103) on mossy rotten logs and *Trichia affinis* (Figure 104) on moss and rotten wood. Nissan (1997) found *Physarum decipiens* (Figure 105) on dead branches in association with mosses. Johannesen (1984) found *Didymium ochroideum* on mosses on dead wood of the Norway spruce (*Picea abies*; Figure 106). Stephenson

(1985) found *Licea pusilla* on the moss *Hypnum imponens* (common on logs; Figure 4) and on decaying coniferous wood.

As we entered the 21st Century, new records continued. Adamonyte (2000) found *Cribraria argillacea* (Figure 107) and *Trichia favoginea* (Figure 108-Figure 109) on very rotten, moss-covered logs, *Hemitrichia clavata* (Figure 91) and *H. serpula* (Figure 110) together on a moss-covered deciduous log, *Metatrichia floriformis* (Figure 76) with *Trichia varia* (Figure 72) on a moss-covered aspen log, *Stemonitis axifera* (Figure 23) on a moss-covered log in Estonia. Ukkala *et al.* (2001) reported several *Physarum album* (Figure 21) on decayed wood covered with mosses in China. Similarly, Castillo *et al.* (2009) reported *Physarum leucophaeum* (Figure 111) "in" moss on wood of the oak *Quercus pyrenaica* (Figure 112) in Cabañeros National Park, Spain. Working on Pantelleria, a volcanic island located 110 km southwest of the island of Sicily, Italy, Compagno *et al.* (2016) found *Trichia persimilis* (Figure 113-Figure 114) on rotten stumps and mosses.

The interesting thing in these lists of slime molds reported by various researchers in diverse parts of the world is that in my limited perusal of various checklists, searching for bryophyte associations, a species has rarely been listed on bryophytes in more than one list. While this perusal is far from extensive, it nevertheless suggests to me that the slime molds on the bryophytes are not unique to that substrate. A more thorough study of the published records, backed up by field studies, will be necessary to support that hypothesis.

A more extensive study of slime molds and their substrates is that of Schnittler and Novozhilov (1996) in the boreal forests of northern Karelia in Russia. Some of these weren't picky about the type of wood, but others seemed to be more specific. Many occurred insufficiently to generalize. For example, *Badhamia foliicola* (Figure 115) occurred only once, in that case on a strongly decayed deciduous, moss-covered, decorticated log lying on the forest floor of a spruce-birch-aspen forest. *Physarum globuliferum* (Figure 116) produced only two records, both from moderately decayed coniferous wood that was partially covered with mosses. *Physarum leucophaeum* (Figure 117) was likewise not very common, but was always on dead wood, mostly aspen (*Populus*; Figure 56), but less commonly on spruce, and was often associated with mosses; lab cultures came from mossy living or dead bark of aspen.

Figure 117. *Physarum leucophaeum*, a species that in Russia was not common, occurred on dead aspen wood, but occasionally occurred on bryophytes. Photo by Jerry Cooper, through Creative Commons.

On the other hand, the common *Physarum album* (Figure 21) and *Stemonitis fusca* (Figure 69) occurred on all kinds of well-decayed wood, but despite records of these species on bryophytes elsewhere, none were mentioned in this Karelian study (Schnittler & Novozhilov 1996). *Physarum viride* (Figure 118) likewise occurred on decayed wood, mostly of conifers, but occasionally on deciduous trees; there was no mention of bryophytes, although it has been associated with them in other studies. *Comatricha laxa* (Figure 119) was very frequent, and displayed a strong preference for coniferous wood, usually on small branches that had lost their bark and were lying on wet mosses. Might these have spent their plasmodial stage among the mosses, crawling up onto the branches to produce their sporangia?

Figure 119. *Comatricha laxa* sporangia on decaying log, a slime mold that also occurs on logs lying on wet moss. Photo by Clive Shirley, The Hidden Forest, with permission.

Schnittler and Novozhilov (1998) conducted another extensive study on slime molds on those fruiting in the late autumn in the Northern Ammergau Alps on the Bavarian-Tyrolean border. Some of these indicated successional stages, as discussed below. Others related to bryophytes include *Lamproderma columbinum* (Figure 42) on thick moss beds of fallen logs (see also Ing 1982) and rocks. The *Licea pygmaea* (Figure 120) group, mostly rare, prefer strongly decayed (37% of records), moss-overgrown (31%), or algae-covered wood (22%). But some [*Hemitrichia clavata* (Figure 91), *H. serpula* (Figure 110), *Collaria arcyronema* (Figure 43; syn.=*Lamproderma arcyronema*), *Lamproderma* cf. *sauteri* (Figure 121), *Lepidoderma tigrinum* (Figure 83), *Trichia varia* (Figure 72)] occurred on wood without bryophytes, despite all of these being known elsewhere from bryophytes as well. For example, Ing (1982) reported *Lepidoderma tigrinum* from mossy wood.

Figure 120. *Licea pygmaea* peridium with sporangia, a species with a moderate frequency with mosses. Photo from The Eumycetozoon Project, DiscoverLife.org, with online permission.

A number of biologists have considered *Barbeyella minutissima* (Figure 80) to be restricted to bryophytes. Kowalski and Hinchey (1972) found it in relatively good abundance on the slopes of Mount Baker and Mount Rainier, Washington, USA. There it formed associations with the leafy liverworts *Anastrophyllum michauxii* (Figure 84), *Blepharostoma trichophyllum* (Figure 122), *Cephalozia bicuspidata* (Figure 123), *Plagiochila asplenoides* (Figure 124), and *Scapania bolanderi* (Figure 125). The small size of this slime mold makes it easy to overlook, especially with its very restrictive habitat. Kowalski and Hinchey hypothesized that it is usually overlooked, and that it is likely to occur in any montane area. They suggested searching for it among the leafy liverworts, using a hand lens or dissecting microscope.

Figure 124. *Plagiochila asplenoides*, a common leafy liverwort substrate for *Barbeyella minutissima*. Photo by Hermann Schachner, through Creative Commons.

Barbeyella minutissima (Figure 80) seems to be distributed primarily in montane spruce-fir forests (Schnittler *et al.* 2000). It typically is associated with three other slime molds, *Colloderma oculatum* (Figure 27), *Lamproderma columbinum* (Figure 42), and *Lepidoderma tigrinum* (Figure 83). The leafy liverwort *Nowellia curvifolia* (Figure 82) is such a common substrate for it that the liverwort can serve as an indicator species for its presence.

Working in India, Ranade *et al.* (2012) added a different group of species. On living mosses and bark of stumps they found *Badhamia capsulifera* (Figure 126), whereas *B. utricularis* (Figure 127-Figure 129) seemed to prefer dead wood and mosses; *Trichia affinis* (Figure 104) likewise occurred on wood of a stump and live mosses growing on it. Similarly, *Hemitrichia serpula* (Figure 110) occurred on both mosses and dead wood, but the researchers specifically stated that *Arcyria stipitata* (as *Hemitrichia stipitata*; Figure 130) and *Stemonitis axifera* (Figure 24) occurred on dead wood and living mosses. *Trichia botrytis* (Figure 25) occurs on the bark of trees and mosses growing on it, on dead coniferous wood, and on living mosses. *Diderma cor-rubrum* and *Lamproderma columbinum* (Figure 42) occurred on a moss-covered stump. *Physarum stellatum* (Figure 131), instead, occurred on dead wood, mosses, and an oak stump. As might be expected, *Barbeyella minutissima* (Figure 80) was associated with mosses and liverworts on decaying logs. *Stemonaria nannengae*, *Stemonitis farrensis*, and *Trichia favoginea* (Figure 132) were seemingly more particular about the wood, occurring on decaying gymnosperm wood covered with mosses, whereas *Diderma alexopouli* and *D. indicum* occurred on a moss-covered conifer stump, with the latter also occurring on mosses. *Physarum flavidum* (Figure 44, Figure 133) was found in coniferous forests, where it occurred on decorticated logs and mosses. *Fuligo aurea* (Figure 134) was even more specific (or maybe the collectors were able to be more specific), growing on moss covering the decaying wood of the fir, *Abies pindrow* (Figure 135-Figure 136). *Cribraria rubiginosa* (Figure 137) occurred on mosses on a log.

Joshaghani *et al.* (2013) added to our knowledge of both slime mold geography and their substrate uses by studying the slime mold flora of Iran. He named *Arcyria cinerea* (Figure 32-Figure 33), *A. incarnata* (Figure 138), *Fuligo septica* (Figure 1, Figure 66), *Hemitrichia clavata* (Figure 91), *H. serpula* (Figure 110), *Lycogala epidendrum* (Figure 67), *Lycogala exiguum* (Figure 139-Figure 140), *Metatrichia vesparia* (Figure 141), *Physarum didermoides* (Figure 142), *Stemonitis axifera* (Figure 24), *S. fusca* (Figure 69), *S. splendens* (Figure 143), *Stemonitopsis typhina* (Figure 144), *Trichia decipiens* (Figure 145-Figure 146), *T. favoginea* (Figure 132), and *T. scabra* (Figure 92) as occurring on rotten wood and mosses.

Stephenson *et al.* (1993) carried out the unusual comparison between slime molds of the two locations in the middle Appalachian Mountains in eastern USA with those of two regions in India. Using 3788 collections, covering 1954-1990, they compared slime molds from tropical-subtropical southern India and three temperate

sites. As one might expect, the tropical-subtropical site had the least similarity to the other three sites. The **Physarales** (Figure 19-Figure 22) formed a greater proportion of the southern India collections (63%), whereas the **Liceales** (Figure 51, Figure 55, Figure 120) were much better represented in the three more northern sites. Furthermore, the typical substrata differed, with more than 63% of the southern collections coming from leaf litter and other non-woody debris. On the other hand, more than 80% of the temperate collections were from woody substrates. These differences in slime mold species groups and substrate preferences may help to explain differences seen in their associations with bryophytes. With 80% of the northern species occurring on woody substrates, and the common presence of bryophytes on such substrates, we should expect them to be associated frequently. It is the nature of that association that remains to be defined.

Where Bryophyte and Slime Mold Meet

Stephenson and Studlar (1985) attempted to determine if the association of slime molds with bryophytes, particularly on logs and stumps, was a preference or just a coincidence. They included only those plasmodial slime molds for which bryophytes served as the primary substrate for fruiting. They concluded that most of the 52 slime mold species occurring on 55 bryophyte species that they were able to sample in North America were coincidental. Only *Barbeyella minutissima* (Figure 80) and *Lepidoderma tigrinum* (Figure 83) exhibited a preference for leafy liverworts on rotten conifer logs. In fact, *B. minutissima* occurred only on the leafy liverworts *Nowellia curvifolia* (Figure 82), *Lepidozia reptans* (Figure 81), and *Cephalozia lunulifolia* (Figure 147) on decorticated logs of *Picea rubens* (red spruce; Figure 148). This is a tiny slime mold and was not even seen until collections were examined in the lab with a microscope. *Lepidoderma tigrinum* was usually associated with leafy liverworts, especially *Nowellia curvifolia* and *Lepidozia reptans*, but also occasionally with the mosses *Dicranum montanum* (Figure 149) and *Dicranodontium denudatum* (Figure 150). This species also was fruiting on parts of the logs that were devoid of bryophytes. Kowalski (1971) likewise reported *L. tigrinum* on badly decayed coniferous wood growing over and among the mosses and liverworts.

Dudka and Romanenko (2006) considered the relationships between the slime molds and bryophytes to be spatial when they occur together on woody substrata, not

trophic. Rather, they may be regulated by their specific microclimatic conditions within the bryophyte colonies. Nevertheless, they considered most of the slime mold associations with bryophytes to be accidental. They seem to develop more extensively and occur more frequently on fallen decaying logs overgrown with bryophytes because of the high humidity that both thrive in (Stojanowska & Panek 2004).

What Do These Associations Offer?

Life Cycle Relationships

It appears that bryophytes might play a role in the life cycle of slime molds. Stephenson and Studlar (1985) found a number of slime molds fruiting on bryophytes in temperate North American forests. They considered that 52 of the slime mold species occurring with the 55 bryophytes species were "coincidental." However, the slime molds *Barbeyella minutissima* (Figure 80) and *Lepidoderma tigrinum* (Figure 83) appear to be truly bryophilous, particularly on leafy liverworts on rotten conifer logs. *Barbeyella minutissima*, *Colloderma oculatum* (Figure 27), and *Lepidoderma tigrinum* are not only truly bryophilous, but *Barbeyella minutissima* is especially associated with *Nowellia curvifolia* (Figure 82) and members of *Cephalozia* (Figure 147) (Dudka & Romanenko 2006), species that can completely cover a decaying coniferous log (Schnittler & Novozhilov 1998; Schnittler *et al.* 2000; Novozhilov 2005). Stephenson and Studlar (1985) suggested that in most cases the bryophytes provide exposed surfaces that are convenient for slime mold spore production. On the other hand, the plasmodial stages might reside there without being noticed. *Barbeyella minutissima* and *Lepidoderma tigrinum* are often associated with the bryophytes aligned with algal layers on decorticated wood (Stephenson & Studlar 1985; Schnittler 2001; Smith & Stephenson 2007; Rollins & Stephenson 2011).

Stephenson and Studlar (1985) were unable to determine if the bryophytes provided a sustainable food source by harboring microorganisms useful for the feeding stages (swarm cells, myxamoebae, plasmodia) of the life cycle. They did consider the bryophytes to be obvious exposed surfaces "convenient for sporulation." Their conclusion was that plasmodia do not avoid bryophytes, but that their sampling was inadequate to determine exclusivity or preference for bryophytes.

Algae and Cyanobacteria

Algae and **Cyanobacteria** (Figure 152-Figure 153), in addition to bryophytes, are common on decorticated logs. In their investigation of decaying red spruce (*Picea rubens*; Figure 148) logs with both leafy liverworts and slime molds, Smith and Stephenson (2007) found nine **Cyanobacteria** species, two **Chlorophyta** (Figure 154, Figure 156, Figure 157) species, and one **Bacillariophyta** (diatom; Figure 151) species. Of these, two **Cyanobacteria** [*Chroococcus tenax* (Figure 152) and *Aphanothece saxicola* (Figure 153)] and one green alga (*Chlorococcum humicola*; Figure 154) dominated. In addition to potential nitrogen addition through N-fixation, these **Cyanobacteria** and algae could provide a food source for the slime molds.

Figure 151. Mixed diatoms (**Bacillariophyta**). Photo by Janice Glime.

Figure 154. *Chlorococcum* sp.; *C. humicola* accompanies both leafy liverworts and slime molds on decaying logs. Photo by Yuuji Tsukii, with permission.

The slime mold *Clastoderma debaryanum* (Figure 155) occurs on Norway spruce (*Picea abies*; Figure 106) logs in Lithuania (Adamonyté 2007). These logs are covered with algae and some mosses. In other cases, slime molds occur on dead wood covered with a scanty growth of liverworts and algae, or with only algae. This slime mold species is unusual in its ability to grow on substrates with a wide pH range of 3.8 to 7.5 (Rosing *et al.* 2007).

Figure 155. *Clastoderma debaryanum* on mosses. Photo from Myxotropic, with online permission.

Interestingly, *Barbeyella minutissima* (Figure 80) grows on leaf tips that protrude above the water film (Schnittler & Novozhilov 1998). Association with algae was "obvious" in 70% of the collections and in 60% of the collections of *Colloderma oculatum* (Figure 27). The late season fruiting insures cool nights that provide extended dewfall, keeping the logs moist enough for algal/Cyanobacterial growth for weeks. On the other hand, *Barbeyella minutissima* and *Licea pygmaea* (Figure 120), accompanied by scattered sporocarps of *Colloderma* and *Lepidoderma* (Figure 83), occur primarily on the lower sides of logs directed towards the rivulet but preserved from rainfall itself.

Slime molds are known to feed on algae (Zabka & Lazo 1962). In fact, Lazo demonstrated that the slime

mold *Physarum didermoides* (Figure 142) can incorporate cells of the green alga *Chlorella* (Figure 156), a common symbiont in lichens and even *Hydra*, into its plasmodium, causing the plasmodium to be green. In addition to these examples, the plasmodium of occasional moss dweller *Didymium iridis* (Figure 38) is known to contain the green alga *Trebouxia* (Figure 157) (Keller & Braun 1999), a common lichen symbiont. But who benefits in this relationship with slime molds, and how?

Decay Stages

As noted by Leontyev (2010), most slime molds tend to be limited to a particular type of substrate. Some become more specific, occupying only a particular stage of wood decay. For example, *Arcyria incarnata* (Figure 138) and *Comatricha nigra* (Figure 158-Figure 159) prefer the second stage, one of firm, decorticated wood. *Trichia favoginea* (Figure 132) and *T. scabra* (Figure 92) prefer the third stage in which the wood has an average degree of decomposition, but is still not colonized by mosses. In the fourth stage, the wood is fully decomposed and covered by mosses, a stage preferred by the slime molds *Metatrichia*

vesparia (Figure 141) and *Tubifera ferruginosa* (Figure 160).

Figure 158. *Comatricha nigra* young sporangia. Photo by Bjorlil, through Creative Commons.

Figure 159. *Comatricha nigra* sporangia on firm, decorticated wood. Photo by Helen Ginger, through Creative Commons.

Figure 160. *Tubifera ferruginea* on bryophytes, a slime mold that prefers fully decomposed wood covered with mosses. Photo by Amadej Trnkoczy, through Creative Commons.

As wood decays, its structure and moisture content change. Initially, the logs have the species that were present on the living trunk. However, as the log changes,

the bark falls off, and the species of mosses, liverworts, lichens, and algae go through a successional process that results in very different assemblages from those on the living tree (Ing 1994).

Schnittler and Novozhilov (1998) describe the decay stages of the wood from decorticated logs, thicker than 15 cm, that are slightly to moderately decayed. These come from very moist (water-saturated air) and shady places and are covered by a thin, slimy layer of algae and liverworts. The moist wood stage is mostly decorticated, with a moderate to strong decay, and are covered with a thicker cover (>1 cm thick) of mosses, frequently *Paraleucobryum* sp. (Figure 161) and sometimes species of the leafy liverwort *Mylia* (Figure 162). This association is typically enriched with detritus. Differing from *Barbeyella minutissima* (Figure 80) and *Colloderma oculatum* (Figure 27) that occur almost entirely on the decorticated spruce and fir logs that have coverings of slimy algae and *Cyanobacteria*, *Cribraria cancellata* (Figure 163) and *Diderma montanum* (Figure 164) tend to occur in the cooler valley bottoms, where they produce sporangia on moderately decayed wood of spruce and beech, often on logs with mossy, loose bark.

Figure 164. *Diderma montanum* sporangia, a species that occurs on moderately decayed wood of spruce and beech, often on logs with mossy, loose bark. Photo by Alain Michaud, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Stephenson and Studlar (1985) concluded that *Barbeyella minutissima* (Figure 80) and *Lepidoderma tigrinum* (Figure 83) are bryophilous, being almost invariably associated with bryophytes, and in particular with leafy liverworts. Schnittler *et al.* (2000) examined collections from 27 localities in the Northern Hemisphere. They concluded that these two species are restricted to decorticated coniferous wood covered by 40-100% leafy liverworts, based on 41 collections. They furthermore noted the importance of a "thin, slimy layer" of algae.

Stojanowska and Panek (2004) reported a number of bryophyte-slime mold-log associations from a nature reserve in southwest Poland. *Cribraria vulgaris* (Figure 78) and *Lycogala epidendrum* (Figure 67) occur there on moss-covered stumps and logs. *Fuligo septica* (Figure 1, Figure 66), *Lycogala exiguum* (Figure 139-Figure 140), *Metatrichia vesparia* (Figure 141), *Stemonitis fusca* (Figure 69), *S. pallida* (Figure 57), *Trichia botrytis* (Figure 25), *T. persimilis* (Figure 113-Figure 114), *T. varia* (Figure 72), and *Tubifera ferruginosa* (Figure 73) occur on bryophyte-covered stumps. *Diderma radiatum* (Figure 165-Figure 166) occurs on stumps overgrown with the moss *Brachythecium rutabulum* (Figure 167). *Arcyria cinerea* (Figure 32-Figure 33), *A. denudata* (Figure 62-Figure 63), *Physarum compressum* (Figure 168-Figure 169), *Physarum gyrosum* (Figure 170-Figure 171), *Stemonitis axifera* (Figure 24), and *Trichia scabra* (Figure 92) occur on bryophyte-covered logs. *Lepidoderma tigrinum* (Figure 83) occurs on decaying logs densely

overgrown with *Dicranum montanum* (Figure 149) (see also Neubert *et al.* 1993), whereas *Badhamia panicea* (Figure 172-Figure 173) occurs on bark of a recent log with *Brachythecium rutabulum*. *Reticularia lobata* (syn.=*Enteridium lobatum*; Figure 174) occurs on bryophyte-covered conifer wood. They also mentioned that *Lamproderma columbinum* (Figure 42) occurs on *Tetraphis pellucida* (Figure 175), a moss species most typical of decaying stumps, but that also occurs on rocks. The co-occurrence of particular slime molds with specific mosses may reflect a preference of both for the same microclimate.

Spore Traps

We know from studies on dwarf males that some bryophyte spores successfully germinate on leaves of the same species. This raises the questions of what other kinds of propagules are successful there, and how widespread are these relationships with other kinds of organisms.

Stephenson and Rojas (2020) raised this question regarding slime molds associated with bryophytes. Most spores are dispersed by wind; some are dispersed by animals. The wind dispersal appears to be very efficient within distances of at least 50 meters (Schnittler *et al.* 2006; Schnittler & Tesmer 2008). The spores seem able to travel until they meet a physical surface where they can rest (Stephenson & Rojas 2020). Since mosses can provide such surfaces, Stephenson and Rojas used nylon bags containing sterilized mosses from the tropics in Costa Rica (predominantly *Pilotrichella flexilis* – Figure 176) and the temperate deciduous forest of northwest Arkansas, USA (predominantly *Thuidium delicatulum* – Figure 3). The mosses in the bags were collected after more than four months and cultured. Of the 40 moist chamber cultures from the tropics, 95% showed growth of *Myxomycetes* and 90% of these produced fruiting bodies. However, the temperate cultures produced *Myxomycetes* growth in only 70% of the cultures, with only 18% producing fruiting

bodies. The Costa Rica cultures similarly had 91 specimens appearing; the Arkansas cultures had only three species, representing three different genera. *Diderma effusum* (Figure 177) was the only species present in cultures from both locations. From Arkansas, only *Diderma effusum* (3 records) and *Cribraria microcarpa* (2 records; Figure 178) were present in at least two cultures. Interestingly, the most abundant species in Costa Rican cultures were *Diderma effusum* (16 records) and *Cribraria violacea* (16 records; Figure 45, Figure 179), as well as *Perichaena dictyonema* (16 records; Figure 180) and *Gulielmina vermicularis* (15 records; Figure 181-Figure 182). Furthermore, 44% of the 91 Costa Rican specimens were members of the genus *Perichaena/Gulielmina*. However, many of these species occurred only once. Those cultures from Costa Rica had a mean of 2.3 specimens per culture; those from Arkansas had only 0.2 per culture.

Differences in environmental factors may be responsible for the differences in species abundance between the two sites (Stephenson & Rojas 2020). The Arkansas site had a lower mean pH and was drier during the study period. Sporangia of *Myxomycetes* are more common in moist periods. There are insufficient data from the two regions to make a comparison of number of species present in the area. This study demonstrates the potential role of mosses as spore traps that increase the diversity of slime molds and remind us of the moss potential to serve a similar role for other kinds of organisms with small propagules.

Summary

Bark and logs are the two most common substrata for slime molds. And both of these substrates frequently have bryophytes on them. The motile slime molds therefore encounter bryophytes as they move about and may traverse them or stay and form sporangia. On logs in particular, leafy liverworts are common, and these seem to be suitable substrates for a

number of slime molds. In some cases, the underlying algae might contribute to this association, providing fixed nitrogen or food.

Slime molds that move upward and into the light to produce sporangia may gain some advantage on the slightly elevated bryophytes. This positioning can provide greater access to dispersal agents, including wind and invertebrates. Nevertheless, the bryophytes used are of low stature, with **smooth mats** being the most frequent.

Diderma corrugatum seems to be restricted to moss-covered bark, whereas *D. chondrioderma* seems only to prefer it. Some of the slime molds seem to be confined to liverworts, including *Barbeyella minutissima* on logs, *Licea bryophila* on bark, and *Licea gloederma* on bark. *Licea parasitica* seems to prefer mosses in its **microcyst** stage. *Colloderma oculatum*, *Lamproderma columbinum*, and *Lepidoderma tigrinum* are common only associated with *Barbeyella minutissima* on bryophyte-covered logs, especially with the liverwort *Nowellia curvifolia*. On the other hand, most of the bryophyte dwellers seem to be accidentals – generalists that tolerate the substrate with no preference for it. Others occur on mossy logs or bark, but not directly on the bryophytes.

In some cases, the slime mold seems to start on bark and invade the bryophyte. In other cases, it germinates on the bryophyte and moves onto the bark or wood. In the latter case, the bryophyte might benefit from the greater moisture in the bryophyte mat, in addition to the ability of the bryophyte to trap the spores.

Both of bark and logs have periods of drying out, especially tree boles. The slime molds and mosses are both tolerant of these events, but mosses are able to slow the drying process due to their capillary spaces. In addition to moisture, pH seems to be important in separating substrata among slime mold species. Decay stages are likewise important, with different stages providing different moisture levels, but also typically having more bryophytes as they decay more. Slime molds on logs with bryophytes are often also associated with algae and Cyanobacteria, especially *Chroococcus tenax*, *Aphanothece saxicola*, and *Chlorococcum humicola*.

Bryophytes are important as spore traps for slime molds, but many questions remain regarding the importance of this relationship.

Acknowledgments

Marianne Meyer and Isabelle Charissou were very helpful in providing me with pictures of slime molds on mosses and Marianne helped me with identification of some images contributed by others. Harold W. Keller provided additional information and images to support the story on *Diachea arboricola*. Steve Stephenson provided me with the paper on spore traps and helped me sort out the nomenclature.

CHAPTER 3-4

SLIME MOLDS: ECOLOGY AND HABITATS – LESSER HABITATS

Figure 1. *Lophocolea heterophylla* with slime molds. Photo by Sture Hermansson, with online permission.

Epiphyllous Leafy Liverwort Associations

In the tropics, **epiphyllous** (growing on leaves) liverworts (Figure 2) are common, typically associated with lichens, fungi, algae, and bacteria. Mosses are rare in this association. But some associations also include slime molds.

Schnittler (2001) found eleven species of slime molds associated with epiphyllous liverworts (Figure 2) in Ecuador, Costa Rica, and Puerto Rico. He found 11 species, with 97% of the 131 cultures producing growths of slime molds. One of his finds, *Arcyria afroalpina* (Figure 3-Figure 4), was a new find for the Neotropics (Schnittler *et al.* 2002). When samples of 15 leaf pieces were cultured in moist chambers, the most frequent slime mold species (59-66%) were *Arcyria cinerea* (Figure 5), *Didymium iridis* (Figure 6), and *D. squamulosum* (Figure 7). These most likely occur with the epiphylls as myxamoebae. Lowland rainforests that have a high annual rainfall provide the greatest numbers of slime molds. However, the

habitat appears to be less than ideal, as evidenced by the atypically small sporocarps.

Figure 5. *Arcyria cinerea*, one of the most frequent epiphyllous species of slime molds cultured from leaves with epiphyllous liverworts. Photo by Kim Fleming, through Creative Commons.

On the other hand, all six sites clearly share an assemblage of common species (Fig. 2) (Schnittler 2001). The average frequency of the three most common species on epiphyllous liverwort covers was surprisingly high, with 0.59 for *Arcyria cinerea* (Figure 5) and 0.66 for both *Didymium iridis* (Figure 6) and *D. squamulosum* (Figure

7). At least the three most common species of slime molds (*Arcyria cinerea*, *Didymium iridis*, and *D. squamulosum*) are very probably regular inhabitants of liverwort-covered leaves. Several lines of evidence seem to support this. First, all three species were found with very scattered and often solitary sporocarps considerably smaller than typical for fructifications of these species in other microhabitats. In addition, tiny **phaneroplasmodia** (conspicuous plasmodia, as in the **Physarales**; Figure 8), 1-3 mm in extent were frequently observed in the first two weeks of culture. Plasmodia migrating from the litter layer to fruit on living plants are much larger.

Figure 6. *Didymium iridis* sporangia, one of the most frequent epiphyllous species of slime molds cultured from leaves with epiphyllous liverworts. Photo through Creative Commons.

Figure 7. *Didymium squamulosum*. Photo by John Shadwick, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Figure 8. Phaneroplasmodium. Photo by Sarah Lloyd, with permission.

There is a potential for direct leaf-to-leaf dispersal of myxamoebae as well as their dormant stages (**microcysts**) by rainwater or leaf-dwelling insects (Schnittler 2001). Occasional cultures produce growths of *Diderma effusum* (Figure 9), *D. hemisphaericum* (Figure 10), *Lamproderma scintillans* (Figure 11), and *Physarum compressum* (Figure 12); all other recorded slime molds are rare. None of the slime molds found in this study seems to be specialized for living leaves as a microhabitat. The leaf microflora most likely supplies ample food for successful colonization. However, some differ sufficiently from non-epiphyllous populations that they might be separate races.

Figure 12. *Physarum compressum*, a slime mold that occasionally occurs with epiphyllous liverworts. Photo by David Mitchell, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Camino *et al.* (2008) reported on the slime molds in the mountains of central Cuba. There they found two species associated with epiphyllous liverworts: *Arcyria afroalpina* (Figure 4-Figure 3) and *Comatricha laxa* (Figure 13).

Figure 13. *Comatricha laxa* sporangia on decaying log, a species known to also associate with epiphyllous leafy liverworts. Photo by Clive Shirley, The Hidden Forest, with permission.

Non-Epiphyllous Liverwort Associations

Stephenson and Studlar (1985) reported *Arcyria cinerea* (Figure 5), *Physarum viride* (Figure 14), *Stemonitis axifera* (Figure 15-Figure 16), *Trichia decipiens* (Figure 17), and *T. favoginea* (Figure 18) associated with non-epiphyllous leafy liverworts, but they were not restricted to this substrate. As already noted, *Barbeyella minutissima* (Figure 19) and *Lepidoderma tigrinum* (Figure 20) exhibited a preference for leafy liverworts on rotten conifer logs. In fact, the rare *B. minutissima* is mostly known from the leafy liverworts *Nowellia curvifolia* (Figure 19, Figure 21), *Lepidozia reptans* (Figure 22), and *Cephalozia lunulifolia* (Figure 23-Figure 24).

Figure 24. *Cephalozia lunulifolia*, a suitable substrate for a number of species of slime molds. Photo by Hermann Schachner, through Creative Commons.

Nowellia curvifolia (Figure 19, Figure 21) is the most common slime mold associate (Stephenson & Studlar 1985); it is a liverwort found almost exclusively on rotten logs (Schuster 1957). Hence, the preference in the rotting log habitat for leafy liverworts may simply be that leafy

liverworts are common on rotting logs. The mosses *Tetraphis pellucida* (Figure 25) and *Dicranum montanum* (Figure 26-Figure 27) are also common associates of slime molds, and likewise are characteristic of rotting wood (Stephenson & Studlar 1985). It is likely that the slime molds are opportunists or simply have broad enough habitat requirements to permit their survival on the potentially competing bryophytes.

Leaf Litter

Some moss dwellers are also litter slime molds. Compagno *et al.* (2016) reported *Didymium melanospermum* (Figure 28) on mosses or litter. Moreno *et al.* (2018) found *Didymium nigripes* (Figure 29) on moss debris in Spain. Doidge (1950) reported *Diderma subdictyospermum* on moss and dead leaves. Similarly, Ranade *et al.* (2012) reported *Diderma alpinospumarioides* on dead leaves and twigs, but sometimes on living moss in India. Renade and coworkers found that *Physarum melleum* (Figure 30) occurs on dead leaves as well as among living mosses. Sarah Lodge photographed *Collaria aff. rubens* (Figure 31) on mosses; this is a species that typically is associated on deciduous leaf litter (Takahashi 2015).

Soil Associations

Soil associations between bryophytes and slime molds seem to be much less common than associations in other habitats. In temperate forests, mosses of **Polytrichaceae** (Figure 32, Figure 36), **Dicranaceae** (Figure 33-Figure 34), and **Hypnaceae** (Figure 35) are common, with the slime molds *Fuligo muscorum* (Figure 36), *Physarum citrinum*, *P. confertum* (Figure 37), and *P. virescens* (Figure 38-Figure 39) occasionally occurring on them (Ing 1994). One very rare slime mold (*Elaeomyxa cerifera* – Figure 40-Figure 41) is known from the soil-dwelling thallose liverwort *Pellia epiphylla* (Figure 42) (Hadden 1921; Ing 1994) and from decaying wood, usually in association with bryophytes (Steven Stephenson, pers. comm. 1 June 2019).

Pant and Tewari (1982) described the growth of *Fuligo intermedia* (Figure 43) on mosses in Nainital in the Himalayan region of India. These slime molds occurred on the mosses *Atrichum obtusulum*, *Pogonatum aloides* (Figure 44), *Barbula* sp. (Figure 45), and *Leucodon secundus*. Only the green tips of the mosses appeared above the yellowish-white of the *Fuligo intermedia* (Figure 43). They suspected that the growth of the mosses was retarded. A related species, *Fuligo cinerea* (Figure 46-Figure 47) occurs on dead leaves, yeast, and rotten cloth pieces, as well as on mosses and lichens.

It is not unusual to find that species cannot be put into their proper substrate heading when using the descriptions. This is not necessarily the fault of the author. Information is often based on herbarium labels and material present with the specimen, but not seen in the field by the author(s). *Physarum citrinum* occurs on terrestrial mosses in woodlands, but were the mosses on soil (Ing 1982)? Later, Ing (1994) reported this species from soil. Ing (1982) was able to be more specific in reporting *Physarum virescens* (Figure 38-Figure 39) as mostly on terrestrial mosses in woodlands and characteristic of sessile oakwoods, a species that elsewhere is also almost always associated with bryophytes (Steven Stephenson, pers. comm, 1 June 2019). In Spain, *Physarum bivalve* (Figure 49) occurs on mosses (Castillo *et al.* 2009), but in what habitat?

Figure 48. *Typhula lutescens* with sporangia on mosses. Photo by Tomasz Pachlewski, with permission.

Figure 49. *Physarum bivalve*, a species known from mosses in Spain. Photo by Rod Nelson, DiscoverLife.org, with online permission.

Schnittler and Novozhilov (1996) described several slime mold-bryophyte associations that appear to be on soil in their study of the northern Karelia of Russia. One they noted as a very scanty collection of *Physarum cf. carneum* on mosses. They were more specific in noting *Physarum virescens* (Figure 38-Figure 39) as preferring big moss tussocks on the ground, especially *Dicranum* (Figure 103). *Stemonitis fusca* (Figure 50) was represented by a single collection on moss tussocks in a spruce-birch-aspen woodland. *Didymium melanospermum* (Figure 28) typically occurs on thick moss tussocks on soil, but it also occurs at the base of rocks, or even more rarely on litter.

Similarly, *Leocarpus fragilis* (Figure 51-Figure 52) can grow on the ground, on mosses, and on litter, but it can only be located in autumn.

Figure 50. *Stemonitis fusca* with sclerotia and sporangia on mosses. Photo by Deryni, through Creative Commons.

Figure 51. *Leocarpus fragilis* on moss. Photo by Matt Goff, Sitka Nature, with permission.

Figure 52. *Leocarpus fragilis* on a soil moss in the Polytrichaceae. Photo by Boris Loboda, with permission.

Ranade *et al.* (2012) reported several species that are likely to be associated with soil or litter. *Cribraria intricata* (Figure 53; syn.=*C. dictydioides*) occurs not only on rotten wood, but also on roots and dead mosses. *Cribraria languescens* (Figure 54-Figure 55) occurs on rotten stems and mosses, presumably on the ground. They reported that *Physarum didermoides* (Figure 56; syn.=*Diderma spumarioides*) occurs on living moss, presumably on soil mosses. *Collaria arcyronema* (Figure 57; syn.=*Lamproderma arcyronema*) occurs not only on wood, but also on dead leaves and mosses. *Lamproderma echinulatum* (Figure 58) and *Metatrichia floriformis* (Figure 59; syn.=*Trichia floriformis*) likewise occur on mosses, presumably on the forest floor. *Physarum brunneolum* (Figure 60) occurs not only on mosses, but also on lichens and decaying wood; again, the substrate of the mosses and lichens is not provided. The most unusual substrate is that of *Stemonitis flavogenita* (Figure 61) on a dead archegoniophore of the thallose liverwort *Marchantia* sp. (Figure 62), presumably with the latter growing on soil.

Joshaghani *et al.* (2013) reported *Badhamia ovispora* as occurring on forest mosses in Iran. This suggests that they grew on soil mosses as the other records were more specific in referring to wood or rotten wood.

Stojanowska and Panek (2004) were specific about a number of species of slime molds that occurred on mosses on logs or stumps, but they reported some simply from mosses. Presumably, these were forest floor mosses, including *Diachea leucopodia* (Figure 63), *Diderma testaceum* (Figure 64), and *Physarum virescens* (Figure 38-Figure 39) (plasmodial stage). They described *Diderma deplanatum* (Figure 65) as surrounding mosses. *Lamproderma columbinum* (Figure 66) occurred on the moss *Tetraphis pellucida* (a species of rocks and decaying wood; Figure 25), but also on the moss *Dicranum scoparium* (Figure 33-Figure 34) – a moss that could occur on soil, rocks, logs, or tree bases.

Rock Associations

Among the earliest moss-slime mold associations reported is that of Kaiser (1913). Brown capsules of the slime mold *Leocarpus fragilis* (Figure 51) occurred on the moss *Dicranum fulvum* (Figure 67) in the southern Catskill Mountains of New York. The substrate was not reported, but this moss commonly occurs on sandstone rocks (Seltzer & Wistendahl 1971). The slime mold is not bryophilous, being common on dead leaves (Kaiser 1913).

Figure 67. *Dicranum fulvum*, sometimes a substrate for the slime mold *Leocarpus fragilis*. Photo by Bob Klips, with permission.

Schnittler and Novozhilov (1996) reported on a number of slime molds using bryophytes as a substrate in the northern Karelia of Russia. One of the most common species, *Physarum album* (Figure 68) appears to be a generalist and includes moss tussocks on rocks among its substrata. *Physarum viride* (Figure 14) likewise accepts a number of substrata, including moss and liverwort layers of

rocks, where "it prefers medium-wet places between the pure slimy algae layers and the big moss tussocks."

Figure 68. *Physarum album* sporangia on decaying wood, a generalist that also occurs on mosses. Photo by George Shepherd, through Creative Commons.

On granite rocks Schnittler and Novozhilov (1996) found two subassociations of slime molds. One prefers the thicker tussocks (> 0.5 cm), especially the mosses *Sanionia uncinata* (Figure 69), *Dicranum fuscescens* (Figure 70), and *Cynodontium strumiferum* (Figure 71). These tussocks have dry leaf tips, but the tussocks have a wet interior and are enriched with small particles of detritus. The slime molds *Lamproderma columbinum* (Figure 66), *L. sauteri* (Figure 72), and *Didymium melanospermum* (Figure 28) fruit here, the latter often at the bases of the rocks. The second sub-association occurs in thin water films and will be discussed below under the Wet Habitat Associations.

Figure 69. *Sanionia uncinata*, a species forming thick mats with dry tips but moist interiors and collections of detritus. It serves as substrate for the slime molds *Lamproderma columbinum*, *L. sauteri*, and *Didymium melanospermum*. Photo by Hermann Schachner, through Creative Commons.

Figure 72. *Lamproderma sauteri* sporangia that can occur on moss-covered rocks. Photo by The Eumycetozoon Project, DiscoverLife.org, with online permission.

Diderma lucidum seems to be restricted to mossy rocks (Brooks *et al.* 1977).

Few studies seem to have included the rock habitat. Schnittler and Novozhilov (1996), studying the boreal woodlands of northern Karelia in Russia, have contributed a number of records of slime molds that seemingly are able to live on rocks by using bryophytes as their immediate substrate. *Lamproderma columbinum* (Figure 66) occurred almost exclusively on moss-covered rocks, where it was often accompanied by *L. sauteri* (Figure 72) and *Colloderma oculatum* (Figure 73), but preferring drier and thicker moss tussocks than the substrate preferred by these two slime molds. *Lamproderma columbinum* forms large and conspicuous colonies on thick moss beds on rocks (as well as on moss-covered logs). *Lepidoderma tigrinum* (Figure 20) fruits in autumn after the first frosts and snowfalls, when it is visible in a rock association of very wet, thin liverwort and algae mats. In summer the plasmodia are visible.

Figure 73. *Colloderma oculatum* on bryophytes. Photo by David Mitchell, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Sand Dunes

Sand dunes are inhospitable habitats for both bryophytes and slime molds. But where there is a niche, some bryophyte will usually fill it. Hence, the slime mold *Physarum didermoides* (Figure 56; syn.=*Diderma spumarioides*) is common in sand dunes and often forms "plaques of sporangia up to a square meter" on carpets of the moss *Syntrichia ruralis* (Ing 1994).

Alpine and Polar

When investigating the alpine and Arctic/Antarctic areas, researchers have often been surprised at the low diversity of slime molds. They are both less abundant and exhibit fewer species than in other areas, but some rarer species elsewhere can be present more commonly in the Arctic (Stephenson *et al.* 2000).

Although the cold regions do not appear to be friendly toward slime molds, the most bryophyte-exclusive (perhaps leafy liverwort-exclusive) slime mold, *Barbeyella minutissima* (Figure 19) is a common alpine slime mold (Kowalski & Hinchey 1972). Similarly, Kowalski (1972) found that in the mountains of Washington, USA, *Licea*

hepatica seems to be restricted to leafy liverworts, a species that seems to be unknown from other substrata (Steven Stephenson, pers. comm. 1 June 2019).

This may cause us to be hopeful of special bryophyte associations high in the mountains, but beyond these two limited cases, that does not appear to be the case.

Elaeomyxa australiensis (Figure 74) is known from an alpine snowbank habitat in Australia (Moreno *et al.* 2009; Stephenson & Shadwick 2009). There it grows on litter in association with bryophytes, with only 3 collections out of 300 actually occurring on bryophytes (Stephenson & Shadwick 2009). In these Australian alpine areas, *Meriderma cribrarioides* (reported as *Lamproderma atrosporum*; Figure 75) also occurs on bryophytes.

Figure 74. *Elaeomyxa cf. australiensis*, an alpine snowbank species that grows with litter in association with bryophytes. Photo by Sarah Lloyd, with permission.

Figure 75. *Meriderma cribrarioides* sporangium, a species that sometimes occurs on bryophytes in alpine areas of Australia. Photo by Alain Michaud, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Stephenson *et al.* (2000) set out to determine what factors limit slime mold distribution in high-latitude and cold-dominated regions in the Northern Hemisphere. They collected 938 specimens and cultured 1453 substrate samples from 12 study areas in Iceland, northern Russia, Alaska, and Greenland. They identified 150 species, with 33 being widely distributed in at least five study areas. With only 41 species having a frequency greater than 1%, most of the species seemed to have only limited distribution or low frequency. Although the Arctic species seem to have a depauperate representation of species known from the temperate region, as already noted, some species that are considered rare in temperate areas are common in the Arctic, supporting the conclusion that the Arctic slime mold communities are different from those in temperate regions.

Novozhilov *et al.* (1999) reported 56 species of slime molds from the Taimyr Peninsula in north-central Siberia. Among these, only two species apparently were found ever associated with bryophytes. *Didymium melanospermum* (Figure 28) typically occurs on mossy coarse woody debris. *Mucilago crustacea* (Figure 76) is even less associated, occurring in a moss- and grass-rich, open patch of the forest tundra. It is notable that slime mold species numbers decrease progressively from the northern taiga, northward to the tundra subzone. This study supports the contention that the tundra is represented by an impoverished flora from the northern taiga subzone.

Figure 76. *Mucilago crustacea*, a species that occurs in moss-rich habitats in the forest tundra. Photo by Alexey Sergeev, with permission.

Stephenson *et al.* (1991) expressed their disappointment at the small number of species they were able to find on the soils of the Alaskan tundra. After collecting from nine different study sites, their cultures yielded only *Dictyostelium mucoroides* (Figure 77; *Dictyosteliomycetes*) and *D. sphaerocephalum* (Figure 78). The total number of slime mold colonies per gram of wet soil averaged more than 100 for all samples and was more than 200 at three of the four Arctic tundra sites. These values are similar to those they found for forest soils in two spruce study sites of interior Alaska.

Figure 77. *Dictyostelium mucoroides* (Dictyosteliomycetes) plasmodial slug, a tundra species. Photo by Dmitry Leontyev, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Figure 78. *Dictyostelium sphaerocephalum* fruiting body, sometimes the only slime mold present in the Alaskan tundra. Photo by Andy Swanson, with permission, image provided by Steve Stephenson.

The report from Stephenson *et al.* (1991) is similar to that of Benson and Mahoney (1977). But the latter authors considered *Dictyostelium mucoroides* (Figure 77) to be conspecific with *D. sphaerocephalum* (Figure 78). They found the latter inclusive species to be dominant above 1700 m in Southern California.

Cavender conducted a number of studies in Arctic and high altitude locations. He found a new Alaskan tundra species of *Dictyostelium*, *D. septentrionale*, along with *D. mucoroides* (Figure 77), *D. sphaerocephalum* (Figure 78), and *D. giganteum* in that tundra habitat (Cavender 1978). He considered *D. sphaerocephalum* and *D. mucoroides* to have sufficiently large populations to play a role in tundra ecology. When Cavender (1983) sampled slime molds in the Rocky Mountains, USA, he found that the soil slime molds were 29.5% *Dictyostelium sphaerocephalum* and

68% *D. mucoroides* when appearing in cultures. Cavender (1980, 1983) concluded that the altitudinal distribution of slime molds is similar to that of latitude. In the Appalachian Mountains, eastern USA, Cavender (1980) found that the dictyostelid slime molds predominate, with 15 species. The greatest *Dictyostelium* richness occurred at 590 - 820 m.

Landolt *et al.* (1992) found *Dictyostelium mucoroides* (Figure 77) and *D. sphaerocephalum* (Figure 78) to be overwhelmingly dominant in the Kantishna Hills of Denali National Park (formerly Mt. McKinley), Alaska, USA, with the number of clones per gram of wet soil ranging 0-1203. Some of these sites were restoration sites; the natural sites had far greater slime mold density. The mean number of clones per gram of wet soil was 259 clones for the 14 study sites, with the seven natural sites having a mean of 430. *Dictyostelium mucoroides* was the dominant species (59-98%) in the natural sites. In the restoration sites, *D. sphaerocephalum* was dominant (50-100% of all clones) in the six restoration study plots where slime molds were found.

But none of the preceding studies reported any *Dictyostelium* species on bryophytes.

Emphasizing the paucity of species in these cold habitats, Kanda and Sato (1982) were unable to find any cellular slime molds in the alpine tundra of Mt. O-Akan, Hokkaido, Japan. Hence, we should not be surprised that most of these polar and alpine studies did not report any slime molds growing on bryophytes.

In the Carpathians of Poland, other species emerge as nivicolous species (Ronikier *et al.* 2008). These include 18 species, of which 10 are reported for the first time in Poland. *Diderma niveum* (Figure 79), *Lepidoderma chailletii* (Figure 80), and *Lamproderma ovoideum* (Figure 81) are very abundant, particularly in the spring in glades and shrub communities. *Diderma alpinum* (Figure 82) and *D. niveum* occur on mosses.

Figure 79. *Diderma cf. niveum* sporangia on mosses. Photo by Tom Thekathyl, with permission.

Figure 82. *Diderma alpinum* sporangia, a species that occurs on mosses in the Carpathian Mountains. Photo by The Eumycetozoon Project, DiscoverLife.org, with online permission.

Stephenson *et al.* (1992) noted the paucity of reports of slime molds from Antarctica and the subAntarctic islands. Several genera occurring there are known from bryophytes elsewhere, but many of the Antarctic species are different. *Diderma effusum* (Figure 9) is known from mosses in the Antarctic (unpublished record from Steven Stephenson, pers. comm. 1 June 2019).

Lepidoderma crustaceum (Figure 83) is among the bryophyte dwellers found on the subAntarctic Macquarie Island in the Antarctic region (Stephenson *et al.* 2007a). *Lamproderma ovoideum* (Figure 84) similarly occurs on the leafy liverwort *Lepidozia* sp. (Figure 22) on Macquarie Island (Stephenson *et al.* 1992). But most of the species in the Antarctic region are **nival** (subject to actions of snow and ice) species, and their fruiting is associated with winter snow packs. *Lamproderma ovoideum* is typical of such habitats in alpine areas. Whereas only 6 slime mold species were known in 1990 from the Antarctic region, 32 were known from Iceland and 54 from Greenland (Götzsche 1989, 1990). In an intensive study, Stephenson *et al.* (2007b) located 22 species on Macquarie Island.

Figure 83. *Lepidoderma crustaceum* sporangia, one of the bryophyte dwellers on Macquarie Island. Photo from Myxotropic, through Creative Commons.

Figure 84. *Lamproderma ovoideum* sporangia, a late snowmelt species in alpine areas, sometimes occurring on bryophytes. Photo by Alain Michaud, The Eumycetozoon Project, DiscoverLife.org, with online permission.

Stephenson *et al.* (2007b) reported a more diverse slime mold fauna on Macquarie Island, including several that occurred on bryophytes. These bryophyte dwellers included 6 of 80 collections of *Trichia verrucosa* (Figure 85), 1 of 78 of *Diderma alpinum* (Figure 86-Figure 87), 2 of 59 of *Craterium leucocephalum* (Figure 88), 2 of 48 *Didymium cf. dubium* (Figure 89-Figure 90), 7 of 15 *Lamproderma arcyrrioides* (Figure 91-Figure 92), and 13 of 68 of all other species. *Diderma radiatum* (Figure 93-

Figure 94) had a higher ratio, but poor representation, with 1 of the 3 collections being on bryophytes. *Lamproderma ovoideum* (Figure 84) is considered **nivicolous** (associated with snow), but the only collection of this species was on bryophytes. *Lepidoderma crustaceum* (Figure 84) also was reported from bryophytes. The most common bryophytes serving as slime mold substrates on Macquarie Island are the mosses *Brachythecium salebrosum* (Figure 95), *Achrophyllum dentatum* (Figure 96-Figure 97), and the leafy liverwort *Lophocolea bidentata* (Figure 98).

Wet-Habitat Associations

Lindley *et al.* (2007) remarked on the paucity of information on slime molds in aquatic habitats. They found that the distributions of slime molds above and below the water level were different.

Ravines

Krziemiewska (1934) reported *Colloderma oculatum* (Figure 73; as *C. dubium*) from wet wood covered with mosses and liverworts in her study in the Zarocelak forest, eastern Carpathians. But studies that concentrate on ravine slime molds are still very limited.

One reason for the lack of study in this interesting habitat is that they can only be identified during their fruiting season. In most habitats, bark and other substrate samples can be taken to the lab and cultured. But Novozhilov *et al.* (2000) lamented the difficulty of culturing the slime molds that prefer the trickling water of humid ravines. This lack of success forces researchers to be in the field when the slime molds are producing sporangia, noting that this is predominately in the late autumn, a time when most slime mold specialists, who are also academicians, are busy with their educational responsibilities. With all this difficulty in being at the right place at the right time, Novozhilov and coworkers estimate that less than 5% of the species occur in such habitats.

Whereas most of the slime molds seem to prefer rotting logs, some prefer more moist or even wet habitats. One reason for this may be the associated algae that can serve as a food source. Ing (1994) noticed that algae were typically abundant in association with the mats of bryophytes that served as substrate for slime mold fruiting bodies in cool, moist ravines of the western British Isles (Ing 1983). In another European study, Schnittler and Novozhilov (1998) reported the slime molds *Colloderma oculatum* (Figure 73) fruiting on wet, moss-covered rock surfaces that presented a continuous layer of algae.

Craterium muscorum (Figure 99; syn.=*Badhamia rubiginosa* var. *globosa*) and *Diderma lucidum* are rare Atlantic species that can be found on moss-covered rocks in wooded ravines (Ing 1982). *Lamproderma columbinum* (Figure 66) and *Lepidoderma tigrinum* (Figure 20), both species noted elsewhere from bryophytes, are characteristic of ravines. *Fuligo muscorum* (Figure 100) occurs in wet, terrestrial mossy habitats.

Figure 100. *Fuligo muscorum* on the moss *Hypnum*. Photo by Charles Hipkin, with permission from Barry Stewart.

Lamproderma sauteri (Figure 72) occurs on bryophyte layers on rocks and boulders where there is running water (Novozhilov *et al.* 2000). These occurrences seem to be mostly in association with the Arctic-alpine leafy liverwort, *Gymnomitrium concinnum* (Figure 101). *Colloderma oculatum* (Figure 73) and *Lepidoderma tigrinum* (Figure 20) seem to benefit from living on thin, slimy layers of liverworts under a thick cover of mosses and having a covering of water film.

Figure 101. *Gymnomitrium concinnum*, an Arctic-alpine leafy liverwort that serves as substrate for *Lamproderma sauteri*. Photo by Michael Lüth, with permission.

In his 1983 study of ravines in the UK, Ing found that slime molds were associated with the moist bryophytes near waterfalls and dripping areas that kept the mosses moist. Novozhilov *et al.* (2000) reported a similar relationship on wood and rocks near trickling water in humid ravines. In fact, *Lamproderma columbinum* (Figure 66; *Stemonitidaceae*) is an ecotype that is associated with mosses in such habitats. Ing (1983) found that sporangia of slime molds occur most commonly on the mosses *Cratoneuron commutatum* (Figure 102), *Dicranum majus* (Figure 103), *D. scoparium* (Figure 33-Figure 34), *Hyocomium armoricum* (Figure 104), *Hypnum cupressiforme* (Figure 105), *Isoetes myosuroides* (Figure 106), *Plagiothecium undulatum* (Figure 107), and *Rhytidadelphus loreus* (Figure 108), and the liverworts *Bazzania trilobata* (Figure 109), *Lepidozia*

reptans (Figure 22), *Plagiochila asplenoides* (Figure 110), *P. spinulosa* (Figure 111), *Saccogyna viticulosa* (Figure 112), and *Scapania gracilis* (Figure 113). The most common slime molds that occur on these ravine bryophytes are *Craterium muscorum* (Figure 99), *Diderma lucidum*, *D. ochraceum* (Figure 114), *Lamproderma columbinum* (Figure 66), and *Lepidoderma tigrinum* (Figure 20).

A very detailed study of slime molds in ravines and their associated bryophytes, using 127 small-scale relevés, is that of Schnittler *et al.* (2010) in sandstone gorges of Switzerland. They followed the methods developed by Holz (1997) for ravine bryophyte communities. Only five taxa account for 87% of the records, and all of these except *Lamproderma puncticulatum* (Figure 115-Figure 116) are reported elsewhere in this chapter from bryophyte associations: *Colloderma robustum* (Figure 117), *Diderma ochraceum* (Figure 114), *Lamproderma columbinum* (Figure 66), *L. puncticulatum* agg., and *Lepidoderma tigrinum* (Figure 20). They determined that the community is relatively unique, occurring only in the deep, narrow ravines on nearly vertical rocks, mostly on northern exposures. The substrate has a very acidic pH with a mean of 3.35. The fruiting season, in the beginning of October, has a very constant microclimate with nearly 100% relative humidity and ~10°C. Green algae, most commonly *Coccomyxa confluens* (Figure 118), were associated with all the slime mold collections. The mosses *Dicranodontium denudatum* (Figure 119) (59%) and *Tetraphis pellucida* (Figure 25) (50%) and leafy liverworts *Mylia taylorii* (Figure 120) (64%) and *Diplophyllum albicans* (Figure 121) (40%) had high indicator values for the community. Nevertheless, the five most common slime molds had high niche overlap values, but low niche width values, indicating their high degree of specialization. I have to wonder if these slime molds were cryptospecies because they are relatively well known outside ravines and are among species more frequently cited as associated with bryophytes. For example, Hoffmann (1795) originally described *Diderma ochraceum* from mosses. On the other hand, sufficient habitat information is often lacking.

Ing (1983) described a ravine slime mold community having a preference for bryophytes on rocks in numerous Atlantic locations in the British Isles. But the species differed somewhat from those in Switzerland: *Craterium muscorum* (Figure 99), *Diderma lucidum*, **D. ochraceum* (Figure 114), **Lamproderma columbinum* (Figure 66), and **Lepidoderma tigrinum* (Figure 20), with **species* being common in ravines of both countries. Later he (Ing 1994) recognized the ravine slime mold community as a distinct community.

Schnittler *et al.* (2010) did note that even when the inclination was suitable, pure turfs of *Tetraphis pellucida* (Figure 25) rarely had slime molds, but also tended to have less trickling water or algae. The leafy liverwort *Mylia taylorii* (Figure 120), on the other hand, is a good indicator organism for the presence of ravine slime molds. These researchers concluded that most of the ravine species are rare outside the ravines, citing *Colloderma robustum* (Figure 117) and *Diderma ochraceum* (Figure 114), two species closely associated with *Mylia taylorii*. *Lamproderma puncticulatum* (Figure 115-Figure 116) agg. was likewise closely associated with *M. taylorii*. Other common ravine species, specifically *Lamproderma columbinum* (Figure 66) and *Lepidoderma tigrinum* (Figure 20), occur elsewhere in forests with constantly humid conditions; in the British ravines they are closely associated with *Tetraphis pellucida* (Figure 25). As noted earlier in this chapter, they may be true bryophiles. *Diderma umbilicatum* (Figure 122) was always "in close neighborhood" with *Mylia taylorii* and *Dicranodontium denudatum* (Figure 119), suggesting that this slime mold preferred similar conditions to these two bryophytes. The moving plasmodia of *D. umbilicatum* were a conspicuous bright yellow. These segregate to form distinct sporangia on the tips of the bryophyte shoots, often forming a doughnut shape around the narrow leaves of *Dicranodontium*.

Other species preferring *Tetraphis pellucida* (Figure 25) in ravines include *Diderma lucidum* and *Lamproderma columbinum* (Figure 66), the latter occurring there in 73% of the *Tetraphis* turf records where green algae were present in Saxonian Switzerland (Schnittler *et al.* 2010). *Lamproderma puncticulatum* (Figure 115-Figure 116) prefers thicker bryophyte tufts [64% with *Mylia taylorii* (Figure 120), 56% with *Tetraphis*

pellucida]. *Lepidoderma tigrinum* (Figure 20) prefers *Dicranodontium denudatum* (Figure 119) (74% of all records) and *Mylia taylorii* (65%), but occurred several times on *Sphagnum* (Figure 128-Figure 129) tufts at the base of large rocks; *Diderma umbilicatum* (Figure 122) had a similar preference for these two species. *Physarum album* (Figure 123) was less common, with only three records on *Tetraphis pellucida* and one on *Dicranodontium denudatum*. Overall, the slime molds seem to prefer the closed turfs of *Mylia taylorii* and *Dicranodontium denudatum*, but not the common pure short turfs of *Tetraphis pellucida*.

Schnittler *et al.* (2010) agreed with Ing (1994) that nitrogen-fixing activity of the **Cyanobacteria** may be beneficial in some way to the slime molds, possibly as nutrients for their food source, or directly as a food source. But experimental evidence to support this is lacking. They in fact suggested that bryophilous slime molds may instead be phycophilous.

Wet Rocks

One of the early reports on slime mold-bryophyte associations in wet habitats is that of Lister (1918) in the UK. He found *Lamproderma scintillans* (Figure 11) on stones in a shallow stream. He surmised that they had migrated to these rocks from mosses and leaf litter on the stream bank.

Schnittler and Novozhilov (1996) described a granite rock community that is comprised of *Colloderma oculatum* (Figure 73) and *Lepidoderma tigrinum* (Figure 20). These two species fruit on very thin (< 0.5 cm), slimy layers of liverworts, covered with a water film. These microhabitat films are found at 1-3 m height on rocks that are provided with trickling water. The large moss tussocks on the upper margins of the rocks can function as a water reservoir. Both slime mold species produce sporangia directly on the water film of the liverworts. The researchers assumed that the plasmodia lived within the bryophyte layers because of their location on the rocks. The huge colonies, especially of *Colloderma oculatum*, suggest that moss layers are a normal microhabitat. The **Cyanobacteria** (Figure 124-Figure 127) present are a possible food source for the plasmodia. In the northern Ammergau Alps, Schnittler and Novozhilov (1998) also found *Colloderma oculatum* on wet rock surfaces where they were associated with mosses and a continuous layer of algae (probably including **Cyanobacteria**).

One such bryophyte dweller that may really be an algae/**Cyanobacteria** dweller is *Physarum viride* (Figure 14). This species occurs on two substrate types, one of which is on the moss and liverwort layers of rocks (Schnittler & Novozhilov 1996). It prefers medium-wet places between the pure slimy algae layers and the big moss tussocks.

One advantage to living on a wet rock is the presence of **Cyanobacteria**. Not only do the rocks present slimy layers of these nitrogen-fixing organisms, but so also do the bryophytes (Ing 1994). In the study by Ing, these encrustations are predominantly *Nostoc muscorum* (Figure 124-Figure 125) or *N. commune* (Figure 126-Figure 127). For the slime molds, these can be a food source, whereas for the bryophytes, they may improve the nitrogen availability. The beneficial aspects of this association are supported by the frequency with which this assemblage of species coincides with the *Nostoc* growths. In this case, the rocks are base-rich, and Ing hypothesized that the nitrogen-fixing activity of the *Nostoc*, enhanced by a high pH, may be beneficial for the slime molds. *Craterium muscorum* (Figure 99), *Lamproderma columbinum* (Figure 66), and *Lepidoderma tigrinum* (Figure 20) typically develop plasmodia that have close contact with the *Nostoc* on these wet rocks.

Sphagnum and peatland Dwellers

Sphagnum (Figure 128) offers both a habitat modifier that maintains a high moisture level, and a substrate. Carr (1939) provided an early record of *Didymium iridis* (Figure 6; as *Didymium nigripes* var. *xanthopus*) growing in abundance on *Sphagnum*.

Figure 128. *Sphagnum fallax* with capsules. Photo by David T. Holyoak, with permission.

Schnittler and Novozhilov (1996) noted species of slime molds that were in some way associated with *Sphagnum* (Figure 128) in the northern Karelia of Russia. Nevertheless, they observed that the *Sphagnum*-rich spruce (*Picea*; Figure 129) woodland, despite its nearly continuously moist environment, served as a poor habitat for slime molds. Only *Physarum virescens* (Figure 38-Figure 39) appeared to be adapted sufficiently to live on the large moss tussocks.

Figure 129. *Sphagnum* in spruce forest. Photo courtesy of Kim Barton.

In his examination of mosses of wet habitats, Ing (1994) found two slime molds that are mostly restricted to growing on *Sphagnum* (Figure 128). These are *Symphytocarpus trechispora* (Figure 130) and *Amaurochaete trechispora*. On the other hand, Salamaga *et al.* (2014) concluded that in Poland *S. trechispora* is acidophilic. Whereas it frequently occurs on *Sphagnum*, it is not restricted to that substrate. They reported it also from *Polytrichum* sp. (Figure 131) (growing with *Sphagnum fallax* – Figure 128). It is also known from *Sphagnum* in Scotland, England, and Germany (Ing 1999; Schnittler *et al.* 2011).

Figure 130. *Symphytocarpus trechispora* on moss. Photo by Thomas Laxton, through Creative Commons.

Figure 131. *Polytrichum commune*, a common substrate for *Symphytocarpus trechispora*. Photo by Christopher Tracey through Creative Commons.

In the same study, Ing (1994) found that two bryophiles, *Lamproderma columbinum* (Figure 66, Figure 132) and *Lepidoderma tigrinum* (Figure 20), occur on *Sphagnum* (Figure 128) as well as other bryophytes. *Diderma simplex* (Figure 133) is a moorland species that includes bog mosses among its substrates. Hagelstein (1941) reported *Paradiachea caespitosa* (Figure 134) growing on the tips of *Sphagnum*. But Ing (1994) concludes that in general, the low pH and low oxygen availability make many mires and bogs unsuitable for the growth of slime molds.

Figure 134. *Paradiachea caespitosa*, a species that grows at the tip of *Sphagnum*. Photo by Sarah Lloyd, with permission.

Cavender *et al.* (2005) reported a new species of cellular slime mold, *Dictyostelium quercibrachium* (*Dictyosteliomycetes*), from the margin of a small bog in Ohio, USA. Cavender and Vadell (2006) likewise reported the cellular slime mold *Acytostelium magniphorum* from the margin of a small bog in Ohio. Landolt *et al.* (2006) suggested that bog margins provide relict habitats that have been under explored for slime molds and therefore may hold more unknown species or range extensions.

In a more recent study in the Ukraine, Yatsiuk *et al.* (2018) found *Didymium ovoideum* (Figure 135) on *Sphagnum* (Figure 128). *Didymium melanospermum* (Figure 28) and *Stemonitis axifera* (Figure 136) occurred on species of *Sphagnum* and *Polytrichaceae* (Figure 131). *Didymium melanospermum* typically occurs on acid substrates, including mosses (Stephenson & Studlar 1985; Nannenga-Bremekamp 1991; Ing 1994). On the other hand, *Stemonitis axifera* does not appear to be bryophilous in most locations.

Figure 135. *Didymium ovoideum* sporangium on wood, a species that sometimes occurs on *Sphagnum*. Photo by Thomas Laxton, through Creative Commons.

Figure 136. *Stemonitis axifera* sporangia on decorticated log, a species that also occurs on *Sphagnum* and *Polytrichaceae*. Photo by Clive Shirley, The Hidden Forest, with permission.

In *Sphagnum* (Figure 128) bogs, *Badhamia lilacina* (Figure 137-Figure 138) seems to prefer aquatic areas, but their fruiting occurs on moss leaves (Tamayama & Keller 2013). Others, like the *Leocarpus fragilis* (Figure 139) in occur in peatlands but seem to avoid the *Sphagnum*. Only one tiny patch of this one is on the moss.

Summary

Habitats for the slime molds are arguably as diverse as those of bryophytes. Some of the "less important" habitats, in terms of number of species, are on epiphyllous leafy liverworts, on liverworts elsewhere, on leaf litter, on soil, on rocks, on sand dunes, in alpine and polar regions, in ravines, on wet rocks, and in peatlands, including on *Sphagnum*. These habitats contrast with the higher richness and abundance on bark and rotting wood. In all of these habitats, some slime molds exist on bryophytes. Our understanding of this slime mold-bryophyte relationship is almost non-existent. The presence of plasmodia on bryophytes is even less well understood than the presence of sporangia. In contrast to the bryophytes, the species richness and abundance changes of slime molds with increasing elevation mimic those seen for increasing altitude.

Alpine areas seem have some of the bryophiles, such as *Barbeyella minuta*. Polar regions, on the other hand, are often dominated by *Dictyosteliomycetes*. Records of bryophyte dwellers are rare or non-existent in the polar regions.

Ravines provide a unique assemblage of species, and many of these occur on bryophytes, probably in part because bryophytes provide a high cover there. *Craterium muscorum*, *Diderma lucidum*, *D. ochraceum*, *Lamproderma columbinum*, and *Lepidoderma tigrinum* are common on bryophytes there. The presence of *Mylia taylorii* is a good indicator organism for the presence of ravine slime molds, and many also occur on the moss *Dicranodontium denudatum*. The *Cyanobacteria* *Nostoc muscorum* and *N. commune* are common associates on wet rocks and may provide food for the slime molds. Slime molds occurring in peatlands in association with *Sphagnum* may be there because of the low pH.

Of the 79 genera of slime molds in the *Mxyomycetes*, *Dictyosteliomycetes*, and *Ceratiomycetes* listed by nomen.eumycetozoa.com as of 5 May 2019, 44 have at least one member that has been found on a bryophyte. I have found no records among the protostelids.

Summarizing this chapter raises more questions than answers. Do either the bryophytes or the slime molds, or both, benefit from their association? If so, how? Do the bryophytes and slime molds simply prefer the same environmental conditions? It seems likely that moisture is a major factor, but experiments are needed on a sponge or other non-biological material to provide moisture with no nutrients. Do some bryophytes inhibit the growth of slime molds? Do some provide food through the microflora and fauna of the bryophyte, and do others fail to provide it because of growing conditions or inhibitors? Are some slime molds inhibited while others are not by the same bryophyte species? Experiments with bryophyte extracts on cultures of slime molds could be illuminating.

Acknowledgments

Marianne Meyer and Isabelle Charissou were very helpful in providing me with pictures of slime molds on mosses and Marianne helped me with identification of some images contributed by others. Sarah Lloyd and Steve Stephenson were very helpful in providing images, references, and critiques.

The Invertebrate Fauna

Einstein is credited with saying that the most incomprehensible fact about nature is that it is comprehensible (Miller 1992). The invertebrate community associated with bryophytes, especially in terrestrial habitats, needs still to be comprehended.

Dendy (1895) coined the term **cryptozoic fauna** to describe "the assemblage of small terrestrial animals found dwelling in darkness beneath stones, rotten logs, the bark of trees, and in other similar situations." Although not specifically mentioned, bryophytes surely belong among the "other similar situations," as evidenced by the browsed patches on the liverwort in Figure 1. A comparable term for such bryophyte dwellers in the aquatic realm is **meiofauna**, defined as "**benthic** (living on the bottom of a body of water) animals that can fit a mesh size of 1 mm and be retained on a mesh size of 42 μm " (Brave New Biosphere 1999). Although living among bryophytes directly contradicts being on the bottom, the bryophytes do occupy the bottom, and one might think of the habitat they create as simply an extension of that bottom.

For many of the invertebrates, the bryophytes represent a moist island among the drier sites. Invertebrates living there because they are able to survive in interstitial collections of water droplets are considered **limnoterrestrial**, and this **limnoterrestrial habitat** houses many organisms better known in aquatic habitats, such as copepods, gastrotrichs, rotifers, and tardigrades (Thorp & Covich 2010).

The invertebrate fauna are likely to play an important role in nutrient cycling within the bryophyte community, thus facilitating return of detrital matter to ecosystem level nutrient cycling. Merrifield and Ingham (1998) suggested that the diversity of feeding strategies found in moss invertebrate communities provides evidence of within-bryophyte-community nutrient cycling. Studies by Davis (1981) seem to support this suggestion. He found that the moss turf community and the moss carpet community in the maritime Antarctic on Signy Island showed similar levels of productivity, trophic structure, and efficiencies of organic matter transfer, but they differed in **Collembola**

(springtails) and **Acari** (mites) standing crops, turnover of mosses, and accumulation of dead organic matter. Both communities [turf of *Polytrichum strictum* (= *P. alpestre*; Figure 2-Figure 3) and *Chorisodontium aciphyllum* (Figure 4-Figure 5) and carpet of *Calliergon sarmentosum* (Figure 6), *Calliergidium austro-stramineum* (Figure 7), *Sanionia uncinata* (Figure 8), and *Cephaloziella varians* – a liverwort (Figure 9)] had fauna of **Protozoa**, **Rotifera**, **Tardigrada**, **Nematoda**, **Acari**, and **Collembola**. Despite the diverse fauna, Davis found no evidence that the mosses would have been eaten. However, he based this on known feeding groups of the organisms and not on direct evidence. Nevertheless, it is likely that detrital matter and predation were primary food pathways, permitting nutrient cycling.

Nelson and Hauser (2012) examined what would seem to be a very different habitat from that of the Antarctic samples of Davis (1981) – epiphytic mosses and liverworts of the Pacific Northwest, USA. Despite that seeming difference in climate, the same six groups were dominant: Acari, Tardigrada, Collembola, Nematoda, and Rotifera, in that order. Protozoa were also abundant, but they did not quantify those. They found no differences in major groups between mosses and liverworts, but suggested that there may have been differences between species.

Figure 10. Mean percent and standard deviation of organisms for each of the five dominant taxa groups in epiphytic mosses and liverworts at Tryon Creek State Natural Area, 1, 7, and 17 October 2011, calculated for all samples together. Redrawn from Neslon & Hauser 2012.

In the Czech Republic, Božanić *et al.* (2013) attempted to elucidate the factors that determined which invertebrates inhabited bryophyte clumps. They examined the fauna on 15 bryophyte species (61 total samples) and identified 45 invertebrate species in 13 higher taxonomic groups. They found that the two most important factors determining the invertebrate fauna were the size of the moss clump (Figure 12) and the height above ground (Figure 13). The moss genus *Brachythecium* housed the most invertebrate taxa, with the species *Brachythecium curtum* (Figure 11) on rotten trees housing the most.

Figure 11. *Brachythecium curtum* on rotten wood, home for the most invertebrate taxa in a Czech Republic study. Photo by Janice Glime.

Millipedes preferred bryophyte habitats higher above ground, with *Nemasoma varicorne* (Figure 14) being the most abundant (Božanić *et al.* 2013). Mites (**Acarina**), pseudoscorpions (**Pseudoscorpiones**), and ants (**Formicidae**) were only in the lower levels. Interestingly, tree diameter also played a role in locations, with the isopods *Trichoniscus pusillus* (Figure 15) and *Porcellium collicola* (Figure 16) occupying mosses on smaller trees, whereas the isopod *Trachelipus rathkii* (Figure 17) and centipedes *Lithobius mutabilis* and juveniles of other *Lithobius* species preferred larger trees.

Dražina *et al.* (2011) examined the meiofauna of bryophytes in Europe. These included **Turbellaria** (flatworms), **Rotifera** (rotifers), **Nematoda** (nematodes), **Gastrotricha**, **Oligochaeta** (segmented worms), **Tardigrada** (tardigrades), and **Crustacea**, as well as small, immature insects. They found more than 100 taxa, with rotifers dominating (52 taxa) and nematodes second (27 taxa). In fast water, rotifers averaged an abundance of 219 individuals cm^{-3} . Velocity accounted for much of the variation in locations, with rotifers being most abundant in high velocity and gastrotrichs, tardigrades, and microturbellarians having a negative relationship to flow velocity.

Perić *et al.* (2014) studied the invertebrate drift and found that the meiofauna formed a "considerable" portion of it among moss-rich areas in a karst stream. They found 60 invertebrate taxa in the drift. Only six taxa, all in the annelid and arthropod meiofauna, comprised 35% of the total drift density. Most of the Macroinvertebrates were immature insects. The **Cladocera** (*Alona* spp.; Figure 19) comprised 26.7%, *Riolus* spp. (Coleoptera: Elmidae; Figure 20) comprised 13.2%, *Simulium* spp. (Diptera: Simuliidae; Figure 21) 12.2%, **Enchytraeidae** (Annelida; Figure 22) 10.4%, **Hydrachnidia** (mites; Figure 23) 6.3%, **Orthocladinae** (Diptera: Chironomidae; Figure 24) 3.9%, and **Naididae** (Annelida; Figure 25) 3.6%.

Drozd *et al.* (2009) conducted studies in bryophyte fauna in the forests of the submountain and mountain areas of the Czech Republic. They concluded that moisture, bryophyte presence, and surprisingly, bryophyte species were the important characteristics determining total abundance. Their study area bryophytes included the mosses *Polytrichum commune* (Figure 26), *Polytrichastrum formosum* (Figure 27), *Sphagnum teres* (Figure 28), *Sphagnum girgensohnii* (Figure 29), *Sphagnum fallax* (Figure 30), *Pleurozium schreberi* (Figure 31-Figure 32), *Eurhynchium angustirete* (Figure 33), *Oligotrichum hercynicum* (Figure 34), and the leafy liverwort *Bazzania trilobata* (Figure 35-Figure 36).

Sampling

Drozd *et al.* (2009) lamented the paucity of comprehensive studies, citing many studies that included only one taxonomic group. They studied the bryophyte fauna using 66 traps in three mountain ranges in the Czech Republic. These traps collected more than 55,000 individuals in 5 sites with a mean of 850 individuals per trap. Litter samples had higher arthropod abundance than did moss cushions. They suggested this was probably influenced by the behavior of the detritivorous arthropods that do not have to move about in search of food. They also suggested that the arthropods might use the bryophytes only as a temporary shelter against predators and desiccation.

Quantitative field sampling of bryophytes is a challenge, and what works for one species may not work for another. Hynes (1961) collected mosses by hand and stuffed them into a 180 cc jar until it reached capacity, a sample of ca 300 cm². But this may not work well for some large growths of *Fontinalis* spp and produces a large sample to be sorted. Furthermore, adding material from other locations in the clump or different clumps diminishes the ability to detect variability and prevents examining subtle effects of stream location. Pulling the moss from the water generally loses few animals because they are adapted to clinging within the moss mat, but pulling the moss apart to make a smaller sample to fit into 180 cc will dislodge even some of the best adapted. Cutting the moss into smaller segments would be less disruptive, but if no bases are samples, some organisms with preferences for bases may be missed. And increasing the sample size of all collections to one suitable for large clumps of *Fontinalis* (Figure 37) would create a prohibitive sorting size. I found that collecting a handful, preferably to fit into a baby food jar, worked well (Glime1994). The samples were quantified on the basis of moss dry weight after sorting by hand. Frost (1942) used 200 g wet weight for her moss sample size. Since many of the invertebrates disintegrate quickly, 90-95% ethanol should be added immediately. Lower concentrations become too dilute. This method worked well for insects, but may not be suitable for all the non-chitonous invertebrates. These methods will be discussed with the various groups.

Figure 37. *Fontinalis antipyretica*, a large aquatic moss that is difficult to sort through. Photo by Bernd Haynold, through Creative Commons.

Hynes (1961) solved the sorting problem by floating the organisms with a saturated solution of calcium chloride. Even with repeated stirring, those organisms with spines and clinging legs may remain in the mosses, as will those nestled at the bases of leaves that curl around them, creating a bias in the sampling.

Determining the faunal composition and community structure of these microhabitats is not an easy task. The most obvious method of sampling invertebrates is sorting them from the bryophytes under the dissecting microscope. But this method is tedious, very time-consuming, and often misses the smaller organisms (personal experience!). The method of wringing and squeezing is much less tedious and faster, a method used by Morgan (1977), but certainly many get left behind, and attached organisms are likely to be preferentially left behind, not to mention damage to larger organisms. To help in this time-consuming task, Paul Davison (pers. comm. 21 June 2006) modified the **Baermann funnel** (Figure 38) for extracting turbellarians (as well as nematodes, copepods, and tardigrades) from bryophytes. A piece of cheese cloth, muslin, or tissue paper is placed in a funnel to hold a sample (Tylka Nematology Lab 2005). This is usually supported by a piece of screening (Figure 38). Then water is run through the sample with rubber tubing clamped at the end of the funnel. After the sample sits overnight or longer, the water is released from the funnel and collected. The first few drops will have a concentration of nematodes, which are heavier than water.

Another method is use of the **Berlese funnel**, which does not have water, using a light and/or temperature gradient that separates mobile organisms such as **arthropods** and **annelids**, but that method leaves the non-mobile ones behind, and doesn't work for nematodes (ED-STEPP). If it is too hot, organisms die before they can drop.

Figure 38. Baermann funnel using moss sample. Water can be replaced with air for non-aquatic organisms, thus making it similar to the Berlese funnel. Modified from Briones 2006.

Nelson and Hauser (2012) discovered that the Berlese funnel and soaking in water gave very different results. For the water extraction, they placed the bryophytes in 200 mL water and allowed to settle for at least two hours, following the protocol for tardigrades described by Thorpe and Covich (2010). The sample was taken by sucking up sediment with a dropper and placing two drops on a depression slide. The Berlese funnel method has a strong bias toward arthropods, in this case mites (Acari), whereas the water method found at least 6 types of tardigrades and many algae and protozoa. They found "almost no taxa overlap" between the two extraction methods!

Kreutz and Foissner (2006) likewise used liquid extraction. They placed mud on a slide, but for bryophytes it is necessary to wash the bryophytes into water in something like a Petri plate. Detritus and unattached organisms will be dislodged if the bryophytes are stirred into the water. The precipitated detritus can be placed on a slide and separated using the slide-on-slide method described in Chapter 2-6, Protozoa Ecology.

Jennings (1979) used the Baerman funnel to extract invertebrates from mosses on Signy Island in the Antarctic. Fairchild *et al.* (1987) have taken advantage of the behavior of these invertebrates to develop an extraction method. By creating a vertical temperature and oxygen gradient in samples of *Sphagnum* (Figure 28-Figure 30), they were able to obtain an 85% efficiency. Merrifield and Ingham (1998) compared several methods of extracting invertebrates. In a study of *Eurhynchium oregonum* (Figure 39) in the Oregon Coast Range, USA, Merrifield and Ingham first verified extraction efficiency for **nematodes** and other invertebrates using the Baermann funnel. First, invertebrates were collected from the funnel

apparatus, then more were collected from the mosses on subsequent days, and finally more were collected by squeezing and agitation of the moss. More than 90% of cumulative final counts of the nematodes *Monhystera* spp. (Figure 40) and *Prionchulus muscorum* (Figure 41) were extracted by the Baermann funnel technique by day 4 of extraction. Tardigrade extraction was even more efficient, reaching 95% by day 4. Rotifers, however, were less efficiently extracted, with only 42% by day 4 and 55% by day 7.

Figure 41. *Prionchulus muscorum*, a nematode that is extracted effectively from bryophytes by a Baerman funnel. Photo by Peter Mullin, with permission.

Andrew and Rodgerson (1999) investigated diversity gradients of invertebrates on bryophytes on two mountains in Tasmania. They compared two extraction techniques for their effectiveness in representing diversity – Tullgren funnels and sugar flotation – with a new technique using kerosene phase separation. When using two samples bulked together, they found that the kerosene phase separation extracted more total individuals and more Acari (mites) and Collembola (springtails). When they compared single samples (1.5 cm x 2.5 cm), the abundance results were the same, but only three of the nine taxa found in the bulked samples were extracted from the single samples. They therefore recommended that two samples be taken and used as replicates (not bulked).

Preservation of Specimens

Ecologists take note. Simply identifying and counting the faunal organisms and getting someone to identify the bryophytes isn't enough! Whereas you may be confident that your expert has identified everything correctly, it is likely that the expert is less confident and has provided you with the "best" determination possible with the material provided. But ecological specimens typically lack reproductive organs, are not well preserved, and may not even be the whole organism. Systematists always pay careful attention to keeping specimens and publishing their location. Ecologists and physiologists should also. Both the bryophytes and the fauna should be preserved and their locations in permanent, reputable herbaria and museums should be part of any publication based on the data. Furthermore, the specimens should be clearly labelled as voucher specimens, referencing the study.

Species concepts change; often physiological and ecological properties are not uniform among members of the earlier species concept. In the absence of a specimen, the data become useless. Yet, in 1950, Fosberg examined 270 ecological publications with discussions of species. Locations of preserved specimens were provided in only five of these publications! I decided to see if the situation had improved by using a much smaller sample size of three recent ecological journals and three recent bryological journals. In the 15 papers I examined from ecological journals, there was no mention of preserving or keeping specimens. In the three bryological journals, all 15 papers dealing with systematics or checklists provided the herbaria locations. However, even among this group of biologists who share the same journals, none of the six ecological papers in the same issues mentioned any preservation of specimens from the species included in the study. This practice of providing no preserved reference material defies the concept that scientific data must be verifiable.

I disagree with Fosberg (1950) when he pokes fun at stating the source of the nomenclature. Unlike his concept that this is presented to "verify" the identity of the organism, the source of nomenclature demonstrates the species concept used and provides a link to a source where a description may be found. Thus, if one uses *Drepanocladus* from Crum 1973, we know that a broad concept of the genus is used and that *Sanionia*, *Warnstorfia*, or other genus might now apply instead.

Community Patterns

When only aquatic vs terrestrial are considered, we find a difference in groups dominating the bryophytes. In terrestrial habitats, arthropods dominate (Kinchin 1992). Nevertheless, few arthropods spend their entire life cycle among mosses (Kinchin 1990a). The aquatic fauna, Kinchin (1992) contends, is dominated by nematodes, tardigrades, and rotifers. It is not clear if he includes the peatlands in this aquatic grouping, but I have examined the preserved fauna of stream bryophytes, where I have found **insects** to be the dominant organisms (Glime 1994). I must admit, however, that my bias was to describe the insect communities.

A particularly good reference for the identification of species in *Sphagnum* pools (Figure 42), particularly in Germany, is that of Kreutz and Foissner (2006). However, those on mosses are not distinguished from those in open water.

Terrestrial/Limnoterrestrial

Kinchin (1992) reviewed the invertebrate fauna among bryophytes in the British Isles and provided us with a summary of the "moss" habitat. He found that acrocarpous cushions support a richer fauna than the more loosely packed pleurocarpous mosses, attributing this to the greater ability of acrocarpous cushions to hold water. He demonstrated this ability experimentally, showing that at 100% saturation a cushion of the acrocarpous *Bryum argenteum* (Figure 43) held 277% of its "dry" weight in water. The pleurocarpous moss *Hypnum cupressiforme* (Figure 44), on the other hand, held 1496%. *Bryum argenteum* held 85% of its dry weight as soil trapped among the rhizoids, whereas *H. cupressiforme* has less than 1%. But perhaps most importantly, *B. argenteum* required 180 hours to reach steady dryness, whereas *H. cupressiforme* required only 132, and this was in a moss starting with more than 5X as much water!

Figure 43. *Bryum argenteum* showing its compact habit. Photo by Dick Haaksma, with permission.

Figure 44. Mat of *Hypnum cupressiforme*. Photo by Dick Haaksma, with permission.

Slow drying, as you will soon see, is a prerequisite for survival in many of these faunal organisms. Supporting his argument, Kinchin found that the *Bryum argenteum* (Figure 43) fauna was much richer than that of *Hypnum cupressiforme* (Figure 44). Interestingly, he found that mosses such as *Tortula muralis* (Figure 45) and *Grimmia pulvinata* (Figure 46) with long hair points have particularly rich fauna, which might again result from a mechanism for slow drying.

Figure 45. *Tortula muralis* in a rock crevice. Photo by Michael Lüth, with permission.

Figure 46. *Grimmia pulvinata* on boulder. Photo by Michael Lüth, with permission.

The wonderful fauna of bryophytes led Gadsby (1926) to publish his paper, "Meanderings 'mong mosses." Even after a fire bryophytes such as *Funaria hygrometrica* (Figure 47) and *Ceratodon purpureus* (Figure 48) accumulate organic matter and dust, permitting invertebrates to colonize (Clément & Touffet 1981). Others are quick to colonize areas of harvested peat (Curry *et al.* 1989). Even glacial land in the Antarctic (Schwarz *et al.* 1993) and geothermal areas of Iceland (Elmarsdottir 2003) and Ireland (Fahy 1974) sport their own bryophyte invertebrate fauna, most likely facilitated by the ameliorating effect of the microclimate within the bryophyte clone. In the Antarctic, Sohlenius *et al.* (2004) found highest invertebrate densities where there were moss communities.

In addition to the protozoa already discussed, these leaves are home to large numbers of rotifers, nematodes, and oribatid mites, and the associated bacteria, fungi, and algae provide their sustenance. Some of the species, particularly *Sphagnum* (Figure 41) inhabitants, are not found elsewhere. Many live as epiphytes on the leaf, but some live as endophytes, gaining entrance to the cells through pores in *Sphagnum* leaf and stem cells. These specialists are often elusive by standard sampling techniques. Nevertheless, Hingley showed that 50% of the taxa were present in a single drop of water!

Jones *et al.* (1994) described mosses as ecosystem engineers that provide living spaces by providing a suitable physical structure. Although *Sphagnum* (Figure 42) is the most cosmopolitan engineer, bryophytes create habitats for invertebrates in many ecosystems. Sayre and Brunson (1971) compared the moss inhabitants in a variety of habitats to determine what faunal taxa were most common (Figure 49).

One of the primary determinants of faunal inhabitants is the film of water surrounding moss leaves, especially *Sphagnum* (Hingley 1999). Bryophyte habitats generally influence the faunal community structure based on their moisture availability. Five classes can be recognized (Hofmann 1987; Hofmann & Eichelberg 1987):

- I Submerged mosses
- II Mosses that are permanently moist
- III Mosses that are only rarely dry
- IV Mosses that are frequently dry
- V Exposed mosses that are often dry for long periods

In desert cryptogamic crusts, bryophytes seem to be important to the soil fauna (Brantley & Shepherd 2004). Among these invertebrates are **arachnids**, **mites**, **nematodes**, **springtails**, **tardigrades**, and other small **arthropods**. Mixed lichen and moss patches supported 27 taxa at sites in New Mexico, whereas mosses had 29 taxa. Abundance and diversity were higher in winter than in summer, most likely due to a lower water stress. Even the moss *Syntrichia ruralis* var. *pseudodesertorum* (Figure 50) may have its own invertebrate community (Kaplin & Ovezova 1986; Ovezova 1989).

In **Vaccinium heaths**, the moss litter is difficult to break down (Frak & Ponge 2002). The invertebrate fauna process the litter, convert it to animal feces, and transform the soil to mor.

Figure 49. Mean population numbers of faunal groups from 3 2.5-cm diameter cores per moss sample, plotted on a logarithmic scale. Samples represent a variety of habitats from 26 locations in Maryland and Virginia, USA. Redrawn from Sayre & Brunson 1971.

Figure 50. *Syntrichia ruralis* var. *pseudodesertorum* may have its own invertebrate community. Photo by Paul Slichter, with permission.

In the Antarctic, the structure of the mosses [*Calliergon sarmentosum* (Figure 51), *Drepanocladus* sp. (possibly *Sanionia uncinata*)] provides a complex community where epiphytic algae and invertebrates form a higher diversity than the surrounding algal community (Priddle & Dartnall 1978). For example, *Calliergon sarmentosum* provides the site of most abundant algae in leaf axils. Six stem zones result from deterioration of basal portions. Benthic invertebrates move actively among these mosses. Six species of **rotifers** are common in the middle stem zones where there is the greatest abundance of epiphytes. Of these, two colonize the bare underside of leaves whereas four live mostly in leaf axils. Wind-induced mixing in the summer provides transportation for at least some of the epiphytes from the shallow portions of the lake. **Rotifers** settle there as larvae.

Figure 51. *Calliergon sarmentosum*, a common component of the moss-invertebrate community in the Antarctic. Photo by Michael Lüth, with permission.

The invertebrate representation can be more limited in the Antarctic than in many other parts of the world. Schwarz *et al.* (1993) found that the moss-dominated flushes near the Canada Glacier supported a community where **Protozoa**, **rotifers**, **worms**, and **tardigrades** dominated, with all but the **Protozoa** occurring at 5-10.83 mm depth in the moss. Following melt, more of the organisms were found in the upper 5 mm of the moss habitat. **Mites** occurred in lesser quantities and **Collembola** were nearly absent. On the other hand, a catenulid **flatworm** in that habitat was a rare find; **microturbellarians** are quite rare in Antarctica.

Bryophytic epiphytes are important habitats for invertebrates. Kellar (1999) and Milne and Short (1999) demonstrated this for *Dicranoloma* in the cool temperate rainforest of Victoria, Australia. Nadkarni and Longino (1990) have demonstrated this for the neotropics.

Lobules as Habitat

As discussed in the chapters on micro-organisms and rotifers, the water-holding lobules of some leafy liverworts may house a variety of invertebrates. In fact, these invertebrates seem in some cases to be attracted to the plants and readily enter the lobules (Hess *et al.* 2005). In the leafy liverwort *Pleurozia purpurea* (Figure 52-Figure 53), the fauna include **Ciliata**, **Rhizopoda** (protozoans), **flatworms**, **nematodes**, **annelids**, **rotifers**, **tardigrades**, and **copepods**. A detailed discussion of the "trapping" mechanism of the lobules is in sub-Chapter 2-6 on protozoa. Whether these invertebrates are truly trapped and consumed by the liverworts remains unknown. Decaying inhabitants provide food for other members of the community and provide a proximal source of nutrients for the liverwort leaves. These organisms form a unique faunal community where organisms live, consume, die, and decay.

Aquatic

Bryophytes can offer communities that mimic those of riffles, or house very different communities. In her study of the River Liffey, Ireland, Frost (1942) found that the

numbers of organisms found in 23 bryophyte samples differed little between an acid (ca 282,000 organisms) and an alkaline (ca 306,900 organisms) stream, but the composition of the organism differed. On the other hand, Elgmork and Sæther (1970) found that at least some species exhibited larger numbers of individuals at locations with moss cover on the stones than those without mosses, suggesting that the mosses could accommodate a much larger number of invertebrates.

Figure 53. **Left:** Worm, probably an *oligochaete*, from the lobule of the leafy liverwort *Pleurozia purpurea*. **Right:** Lobule of the liverwort, *Pleurozia purpurea*. Photos by Sebastian Hess, with permission.

In a study of Doe Run, Meade County, Kentucky, USA, Minckley (1963) found that the invertebrate abundance in beds of the moss *Fissidens fontanus* (Figure 54) "strongly reflected the fauna of unvegetated riffles." This seems to be almost a contradiction since the same study demonstrated that the closely matted *F. fontanus* created a "pool environment in the midst of riffles."

Minckley suggested that those animals that were relatively scarce in the moss beds but much more abundant in the rubble of smaller riffles may have been driven there by the preference of crustaceans for the mosses. Inhabiting the riffles permitted the smaller invertebrates to avoid being dinner for the crustaceans.

Kinchin (1992) considered the faunal inhabitants to grade from unspecialized among the submerged mosses to more specialized, drought-resistant or drought-tolerant toward the dry end. Carpenter and Lodge (1986) found that submerged plants, including bryophytes, affect the physical environment through light extinction, temperature modulation, hydrodynamics, and substrate. They alter the chemistry by providing oxygen, altering inorganic and organic carbon, and sequestering nutrients. Nevertheless, some habitats, while appearing suitable, are not colonized by any species.

Aquatic bryophytes in streams generally house the largest and probably the most diverse fauna among the various stream communities (see *e.g.* Percival & Whitehead 1929; Frost 1942; Badcock 1953; Hynes 1961; Minckley 1963; Thorum 1966; Stern & Stern 1969; Michaelis 1977; Cowie & Winterbourn 1979; Carpenter & Lodge 1986; Suren 1988, 1991a, b; Vlčková *et al.* 2001/2002; Paavola 2003). Amos (1999) described the torrent among the *Fontinalis* branches (Figure 55) in a poetic fashion: "All was quiet at the bottom of the torrent moss world, despite the storm of rushing water overhead." Here one could find zones of algae – diatoms, desmids, and filamentous species. Inhabitants included **round** and **segmented worms**, **rotifers**, **gastrotrichs**, **water fleas**, **copepods**, **scuds**, and a variety of larval **insects** as well as adults of tiny species. The **mountain midge** larva anchors there with suction cups that are even better than those of the squid and octopus. Yet Kinchin (1990b, 1992) paints a different picture of the waterfalls in Ein Gedi Nature Reserve, Israel, where the fauna is relatively poor.

Figure 55. *Fontinalis antipyretica* houses a wide range of invertebrates in streams and lakes, giving them a refuge from rapid flow and predators. Photo by Michael Lüth, with permission.

Specificity for particular bryophytes may be more a result of the habitat where each bryophyte lives. Paavola (2003) attempted to show the relationship between bryophytes, macroinvertebrates, and fish, with a goal to show concordance and usefulness in predictive power. Bryophytes and macroinvertebrates showed a weak congruence with weak predictive power, but neither had a good congruence with fish. Cowie and Winterbourn (1979) found distinct preferences for certain bryophyte species among the invertebrates in a New Zealand stream, but these differences also reflected habitat differences such as position in stream. *Fissidens rigidulus* occurred in the torrential water in mid channel. *Pterygophyllum quadrifarium* occurred where it was water saturated by the inner spray zone of a waterfall. *Cratoneuropsis relaxa* grew in the outer spray zone. Cowie and Winterbourn suggested that the invertebrates responded to differences in water saturation, flow rates, and detritus-trapping ability by the mosses, the latter also relating to flow rate but including aspects of the moss morphology.

In aquatic habitats, bryophytes are particularly important in contributing to faunal diversity (Priddle & Dartnall 1978; Suren & Winterbourn 1992a). In the Antarctic, these faunal groups are dominated by **Protozoa**, **Rotifera**, **Nematoda**, **Turbellaria**, **Tardigrada**, **Oligochaeta**, and **Acari** (Ingole & Parulekar 1990). In alpine streams of New Zealand, bryophytes provide shelter with reduced flow (Suren 1991b) and catchment for algae and detritus, thus creating a habitat with both shelter and food (Suren 1992), and in some cases materials for constructing larval cases (Suren 1987). Among 23 invertebrate taxa, 14 were found with bryophyte fragments in their gut, but their presence in the gut was only common in several of the aquatic insects (Suren & Winterbourn 1991). Bryophytes contained more indigestible compounds than did other plants, making them less nutritious. Rather, it appears that detritus and periphyton were the primary food sources (Suren & Winterbourn 1992b).

In these New Zealand streams, the bryophyte faunal communities were greater in streams above the treeline (Suren 1993). Greater invertebrate density occurred within bryophyte communities with periphyton than those with detritus (Suren 1993). Bryophyte communities were dominated by aquatic **insects** and **Nematoda**, **oribatid mites**, **Hydracarina**, **Copepoda**, and **Ostracoda** (Suren

1988). When artificial mosses were used in place of real ones, similar invertebrate communities developed, but some, e.g. **Nematoda**, **Acarina**, **Tardigrada**, **Ostracoda**, seemed to suffer from loss of the food supply (Suren 1991a).

Linhart *et al.* (2002) examined the fauna of *Fontinalis antipyretica* (Figure 55) growing on rocks used to stabilize a side channel of the Morava River in the Czech Republic. The means of moss-dwelling meiofauna were $253,917 \pm 178,335$ (\pm SD) per 10 g dry weight of moss and $7,160,461 \pm 5,029,047$ per 1 m² of the bottom area during October 1999–November 2000. **Bdelloidea** (rotifers) formed the dominant group (76%), followed by **Monogononta** (rotifers) (11.23%), **Nematoda** (6.38%), **Chironomidae** (midges) (4.08%), and **Oligochaeta** (worms) (1.06%). Linhart and coworkers (2002) considered that fine particulate matter trapped by the mosses would serve as both a habitat and a food source. They found that about 4% of the trapped matter was coarse matter (500–1000 μ m), 14% medium (10–500 μ m), and 82% fine (30–300 μ m). Only 10% of the trapped matter is organic. The size and content of the trapped matter were significantly correlated ($P < 0.05$) with densities of **Oligochaeta** (segmented worms), **Hydrachnidia** (mites), **Cladocera**, **Copepoda**, and **Chironomidae**. They reported that the bryophyte habitat houses considerably greater numbers of meiofauna compared to the stream gravel bed. Table 1 computes the numbers of moss-dwelling organisms in streams.

Even in the Antarctic, bryophytes are important habitats for invertebrates. In the flushes of meltwater, moss-dwelling invertebrates are dominated by protozoa, rotifers, nematodes, and tardigrades that live at moss depths of 5–10.8 mm. The upper 5 mm of the moss housed more members of all groups in post-melt samples than in pre-melt samples. Mites were less important than in more temperate climates. On the other hand, a flatworm, which is rare in the Antarctic, occurred there.

Altitudinal Gradients

Altitudinal gradients are often followed by community and diversity gradients. But surprisingly, the greatest diversity often occurs at mid altitudes rather than decreasing toward the summit. Andrew *et al.* (2003) investigated diversity gradients of invertebrates on bryophytes on mountains in Tasmania and New Zealand. Although they found altitudinal relationships, these were not consistent among the four mountains they studied. Rather, there were strong geographic differences. Mt. Field in Tasmania had the highest invertebrate and bryophyte diversity at 750 m, whereas Mt. Rufus had low diversity of both throughout its entire altitudinal gradient. In New Zealand, Otira had the highest bryophyte and invertebrate diversity at low altitudes, but Kaikoura had the highest invertebrate diversity at the highest altitude where the bryophyte diversity was lowest.

Food Webs

The aquatic food web is quite complex. It appears that detritus and periphyton may play a major role in the presence and abundance of invertebrates on the bryophytes (Percival & Whitehead 1929). Suren (1988) experimented with artificial bryophytes made of nylon cord woven into a

4 mm mesh mat. In the stream where the mat was highly colonized by periphyton and detritus, the invertebrates were far more abundant than in the stream with little periphyton and detritus on the mat. There was little difference between the number of invertebrates on the artificial and real mosses. But some groups were significantly reduced on the artificial mosses: **Acarina** (mites), **Collembola** (springtails), **Tardigrada** (water bears), **Dorylaimoidea** (nematode worms), and **Ostracoda**, possibly due to the loss of the bryophytes as a food source. It appears that the **aquatic insects** do not depend on the bryophytes for food, but some of the other invertebrates do. Aquatic insect relationships will be discussed in the chapter on aquatic insects, since they are major players in the aquatic bryophyte realm.

Much less is known about the terrestrial food webs in bryophyte microcosms. Sayre and Brunson (1971) pointed out that these ecosystems have the same four basic food units as larger ecosystems described by Odum (1963):

abiotic, producer, consumer, and decomposer. In fact, there are often secondary consumers and even some tertiary consumers.

The **abiotic** portion of the habitat includes dust and other particles gained from the atmosphere, organic leachates from the bryophytes (and host trees for epiphytes), decaying bryophyte parts, and the remains of dead inhabitants. The water film enveloping the bryophytes is essential to their survival in active states, but like the bryophytes, most of the organisms living here are capable of dormancy when the water dries up. They gain the advantage that the bryophytes dry slowly compared to most other available substrata.

The bryophytes themselves are **producers**, but they often also have algae on them (yes, even those on trees) and may have lichens associated with them, both of which add to the carbon fixation.

Table 1. Comparison of numbers of invertebrate organisms in moss collections from streams. **NR** means not reported.

The **consumer** component of the bryophyte community has seldom been investigated. We know that **tardigrades** are often specifically adapted to sucking contents from bryophyte cells and may be the primary consumers (Pennak 1953; LeGros 1958). However, many **tardigrades** are also carnivores; Sayre and Brunson (1971) suggest that most of those in their study were secondary consumers, *i.e.* predators/carnivores. Higgins (1959) suggested **rotifers** were a food source for **tardigrades**. As one of the two most abundant invertebrates in samples of Sayre and Brunson (1971), **rotifers** are a good source of food. **Tardigrades** also feed on **nematodes** (Sayre 1969).

As in other habitats, fungi and bacteria break down the debris that accumulates among the bryophytes. The bacteria and the by-products of their decomposition provide food for **nematodes**, **rotifers**, and **oligochaetes** (Sayre & Brunson 1971). Hence, one could hypothesize a simple food web (Figure 56).

Frost (1942) considered the mosses in some habitats to be a fallback substrate. She thought that those organisms that reach large numbers on other kinds of plants could colonize the moss when the other plants became overcrowded. This would increase the importance of the mosses in the food web. In other cases, they provide a winter substrate when tracheophytes are dormant.

Figure 56. Theoretical food web involving mosses and lower invertebrates. **Mollusks**, **insects**, and other **arthropods** could form secondary and tertiary consumers in this web.

Pollution

One predicted consequence of acidification is a shift from tracheophytes to bryophytes, especially in lakes (Carpenter & Lodge 1986). This may also be so in slow streams, whereas fast streams are typically dominated by bryophytes from the start. A consequence of this shift is likely to be a decrease in rates of decomposition in the sediment and an increase in the diffusion of phosphorus, iron, and possibly other metal ions into the water column. These chemical changes relate to the inability of bryophyte rhizoids and shoots to oxidize the sediments. These changes are likely to result in changes to the faunal community, but the interactions are too complex to make good predictions.

Mosses are well known for their ability to monitor and indicate pollution. But it appears that their fauna may also be important indicators of the assault by heavy metals and other air pollutants (Steiner 1994a, b, c). Zullini and Peretti (1986) found that lead pollution affects **nematodes** living among mosses. Species richness declines and communities become more uniform as pollution levels rise, especially for the **oribatid mites** (Figure 58) (Steiner 1995a). Moss communities of **nematodes**, **rotifers**, and **tardigrades** change composition in response to SO₂ fumigation (Steiner 1995b). Both **nematodes** and **tardigrades** were greatly reduced in numbers by the highest SO₂ levels (0.225 ppm), particularly the nematodes *Chiloplectus cf. andrassyi* and *Paratripyla intermedia*. Nevertheless, the tardigrade *Macrobiotus persimilis* (Figure 57) actually increased with increasing SO₂ levels. More attention should be paid to these organisms whose population numbers can serve as suitable indicators of pollution.

Figure 57. *Macrobiotus cf. furciger*, a tardigrade that seems to thrive in higher SO₂ levels. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Although the **arthropods** in aquatic systems have often been used as indicators, in terrestrial moss communities they seem to be less sensitive to pollution than **nematodes** and **tardigrades** (Steiner 1995b).

Harvesting Dangers

It would be irresponsible to include this and the succeeding chapters without reminding the readers of the dangers lurking in harvested mosses. Such mosses, like their living counterparts, harbor numerous invertebrates

(Peck *et al.* 1996), many that can become dormant for extended periods of time. The danger is not one to your safety, but to safety of ecosystems that may be disturbed, first in one from which you remove the bryophytes, and second to one to which they are transported.

Muir (2004) reported 81 million pounds of moss per year, the equivalent of about 10,500 semi-trucks, harvested in the Pacific Northwest. This massive harvest on logs can take 10-23 years to recover (Peck 2006). Most likely a greater recovery time is needed for epiphytes.

Using a Berlese funnel for extraction, Peck and Moldenke (1999) identified 125 invertebrate taxa from 200 moss mats in Oregon, USA. Greater overall numbers were present at shrub bases than at tips. However, this pattern did not exist for all organism groups (Peck & Moldenke 1999). **Coleoptera** (beetles) and **Thysanoptera** (thrips) exhibited greater numbers per gram at the base, as did detritivores in general, but spiders and predators in general were actually lower in numbers at the bases. Turtle-mites characterized basal samples [*Ceratoppia* sp. (Figure 58), *Hermannia*, and *Phthiracarus* sp. (Figure 60)], whereas microspiders (**Micryphantidae**) and springtails (*Sminthurus*; Figure 61) were typical of tips.

Figure 61. *Sminthurus viridis*; *Sminthurus* is typical of bryophytes at the tips of shrub branches in Oregon, USA. Photo by AfroBrazilian, through Creative Commons.

Moss harvesting therefore creates two problems. At first it creates the possibility of endangering specific inhabitants that thrive only among bryophytes. Secondly, transport of harvested mosses will undoubtedly also transport the invertebrate fauna, providing the possibility for these creatures to invade areas where they did not exist before, most likely altering their new ecosystem, often to the detriment of the native fauna and flora. Details of harvesting will be discussed in a different volume.

Summary

The invertebrate fauna living among bryophytes can be variously categorized as **cryptozoic fauna** (hidden animals), **meiofauna** (retained on a mesh size of 42 μm , and **benthic** (living on the bottom of a body of water). The non-arthropod fauna include primarily **nematodes**, **rotifers**, **tardigrades**, and **annelids**, generally in that order of abundance. Their diverse feeding strategies engage them in nutrient cycling.

Sampling can be difficult and often requires extraction by hand or use of a **Baermann or Berlese funnel**. Whenever possible, specimens should be preserved in a recognized museum and that location published along with any studies involving them.

In aquatic habitats, the bryophytes provide a safe site away from torrents and large predators, where invertebrates are known to number as much as 25,400 per g dry weight of *Fontinalis*. Detrital matter trapped by the moss is a ready food source. In prairies and desert regions, bryophytes may provide the most important suitable habitat. In the Antarctic, epiphytic algae provide food for the meiofauna.

Most of the organisms do not eat bryophytes and depend on adhering detritus and bacteria for food (**rotifers & nematodes**). **Tardigrades**, however, may also eat bryophytes.

Because of their ability to respond to heavy metals and other pollutants, the invertebrates provide a suitable group to monitor air pollution, along with their bryophyte habitat.

On one hand, harvesting of bryophytes can remove endangered invertebrate species, and on the other may distribute species to new areas where they may become invasive or disruptive to new ecosystems.

Acknowledgments

Thank you to Aldo Zullini for pointing me to the interesting paper by Sayre and Brunson. María Jesús Iglesias Briones was helpful in many ways in the preparation of this chapter. Bryonettors have been wonderful in making their photographs available to me and seeking photographs from others.

CHAPTER 4-2

INVERTEBRATES: SPONGES, GASTROTRICHS, NEMERTEANS, AND FLATWORMS

Figure 1. This planarian, *Polycladus gayi*, is navigating a mat of the liverwort *Lepidozia cordulifera*. The planarian is a native of Valdivian rainforests of southern Chile, where it hunts for food on bryophytes and other substrata. Photo courtesy of Filipe Osorio.

Cnidaria

Members of the **Hydrozoa** (hydroids) are not common among bryophytes, but they can occur there. Jones (1951) reported *Hydra viridissima* (Figure 2) from *Fontinalis antipyretica* (Figure 3) on bedrock in the River Towy, Wales.

Figure 2. *Hydra viridissima*, occasional bryophyte dweller. Photo from Proyecto Agua, with permission.

Figure 3. *Fontinalis antipyretica* growing in a stream where it can offer a protected substrate for a number of invertebrates. Photo by Andrew Spink, with permission.

Porifera – Sponges

Sponges don't seem to have any particular appreciation of bryophytes, being unknown from that habitat. However, it appears that the moss genus *Fissidens* has a special fondness for sponges. I know of no other bryophyte genus

that finds this a suitable habitat, but *Fissidens fontanus* (Figure 4) in Europe is epizootic on **sponges** (Sowter 1972) and *F. brachypus* lives only on freshwater sponges in the Amazon (Buck & Pursell 1980). *Fissidens* seems to like animal habitats, living on the openings of wombat holes, termite mounds, and in this case, on a sponge.

Although a moss-sponge combination in nature is rare, humans seem to have found this combination useful. A patent application by Albert G. Morey, dated 13 October 1968, for an "improved mattress" extols the virtues of placing a large **sponge** (mattress) over a layer of only slightly spongy material such as moss. A three-layer mattress is considered to be superior, with the lower layer of moss sustaining the middle layer of woody fiber or excelsior, again with a layer of elastic **sponge** on top. It appears that this was a real sponge (or lots of them) and predates the use of cellulose sponges. The improvement seems to have been the addition of the moss and fibrous layers.

Figure 4. *Fissidens fontanus*, a species that can be epizootic on **sponges**. Photo by Michael Lüth, with permission.

Gastrotrichs

These small animals with "hairs on their stomachs" use them to beat against such surfaces as moss leaves to glide forward (Figure 5-Figure 11; Hingley 1993). They lack a coelom, like flatworms, and move in a similar motion. Like nematodes, rotifers, and tardigrades, freshwater **gastrotrichs** are all **parthenogenetic**, producing viable unfertilized eggs. Adults are unable to go dormant, but when unfavorable conditions arise, they produce larger eggs with heavier shells that survive not only desiccation, but also low and high temperatures. They adhere using cement glands in two terminal projections (Gastrotrich 2009). One of the glands conveniently secretes a de-adhesion to release them.

They may be found occasionally on aquatic bryophytes. The *Dichaeturidae* is a rare family that has been found in cisterns, in underground water, and among mosses (Remane 1935-1936; Ruttner-Kolisko 1955). In the Czech Republic, Vlčková *et al.* (2001/2002) reported 2823 of these invertebrates on 100 ml of the aquatic moss *Fontinalis antipyretica* (Figure 3) in Bystřice, whereas in Mlýnský náhon there were only 371 per 100 ml. In

Bystřice the mosses held a food source of organic matter in the size range of 30-100 μm . Linhart *et al.* (2002) found that abundance was negatively influenced by flow velocity in both of these streams, and the gastrotrichs were significantly fewer in riffles, suggesting that bryophytes could act as refugia in areas of high flow. On the other hand, sediment also was reduced in areas of high velocity, resulting in more available food in sediments in low velocity areas.

In a peatland complex in northern Italy, Balsamo and Todaro (1993) identified 21 species of **gastrotrichs**. Hingley (1993) found the following gastrotrichs among the peatlands mosses in her study of the British Isles:

<i>Chaetonotus heterocanthus</i>	<i>Chaetonotus zelinkai</i>
<i>Chaetonotus maximus</i>	<i>Heterolepidoderma ocellatum</i>
<i>Chaetonotus ophiogaster</i>	<i>Ichthydium forcipatum</i>
<i>Chaetonotus polyspinosus</i>	<i>Lepidodermella squamatum</i>
<i>Chaetonotus voighti</i>	<i>Stylochaeta fusiformis</i>

Nemertea – Ribbon Worms

The ribbon worms are an unknown phylum to most of us. But those nemertines that live on land have learned about bryophytes. In 1915, Dakin described one of these as a new species *Geonemertes dendyi*, later moved to

Argonemertes dendyi (Figure 12), from Western Australia. Anderson (1980) reported this species from Ireland, where it can be found among a thin layer of mosses on branches. Later, Anderson (1986) reported it from mosses and under bark in Ireland. Ribbon worms are clandestine species that one can rarely find in the open (Winsor 2001, pers. comm. 29 February 2012).

Argonemertes dendyi (Figure 12) is among the small fauna, measuring only 15 mm (Dakin 1915). It has multiple eyes, numbering as many as 30 or 40. As descendants from marine organisms, one of the major adaptations required by terrestrial nemerteans was a way to maintain sufficient hydration (Moore & Gibson 1985). The physiological mechanisms are not well understood but seem to involve mucous glands, blood and excretory system, and modulation of osmotic properties. These worms often travel with potted plants, and consequently they can be found in far-flung parts of the planet (Gibson 1995; Moore *et al.* 2001). Their hermaphroditic reproduction makes establishment of these travellers more likely to succeed.

Figure 12. *Argonemertes dendyi*. Photo by Malcolm Storey through Creative Commons.

Leigh Winsor (pers. comm., 16 February 2012) is an avid seeker of terrestrial flatworms, but occasionally he also finds nemertines (Winsor 1985). He reports finding *Argonemertes australiensis* (Figure 13) under a thick mat of moss where it resided on a rotting log in a closed forest in southwest Tasmania. That is impressive for a worm that is 40 mm long (Hickman 1963; Moore 1975; Mesibov 1994). The egg capsules typically occur in rotting logs in August and March (Winsor 1996/97). These eggs are clear, jelly-like, and oblong, ca 10 mm long X 3 mm diameter.

Figure 13. *Argonemertes australiensis* extracted from moss on a log. Photo by Leigh Winsor, with permission.

This strange nemertine uses its proboscis to escape. When in a hurry, the worm quickly everts the proboscis and uses it as a muscled anchor to pull its body forward rapidly

as the proboscis once again returns to its internal lodging (Figure 14). This rapid proboscis also out-paces its Collembola and other prey, permitting the worm to capture its dinner. This species comes in three very distinct color varieties (Mesibov 1994), most likely permitting it to survive in its diverse habitat where different predators may lurk in different locations, a phenomenon we will discuss later for tropical frogs.

Figure 14. *Argonemertes australiensis* with an extended proboscis. Photo by Leigh Winsor, with permission.

Platyhelminthes – Flatworms

Most of us in the pre-DNA-biology generations learned about flatworms in high school because it was easy to do experiments with *Dugesia* (see *e.g.* Saló & Baguñà 2002), known to most of us as *Planaria*. This animal has a distinguishable head with two eyes, and it was relatively easy to cut the head in half and watch two heads develop. This novel exercise opened discussions about development and other topics and provided a memorable experience that endeared the flatworms to us for life.

Most of the **turbellaria** (Figure 1), formerly a class within the phylum **Platyhelminthes**, are nocturnal and free-living, and it is among this group that one finds a small number of bryophyte-dwellers. The group is not monophyletic and is no longer recognized taxonomically, but the concept of **turbellaria** is useful for our purposes as all the bryophyte dwellers are in this group of non-parasites. The **turbellaria** lack a true body cavity and are shaped like a large ciliate protozoan and actually have a covering of cilia that permits them to glide (Hingley 1993). But they are multicellular, somewhat flattened, as their phylum name implies, where *platy* means flat and *helminth* means worm. This flattening permits them to obtain oxygen throughout their bodies, which lack circulatory and respiratory organs. They sport a simple digestive system, nervous system, and excretory system, and they seem to lack any sort of physiological or anatomical adaptations for conserving water, but they may be able to conserve water through alternative biochemical excretory pathways (Winsor *et al.* 2004). They even have eyespots and a simple brain (Hingley 1993).

Reproduction in the phylum may be by simple division (fission), whereas almost all turbellarians are **simultaneous hermaphrodites** (have both sexes at the same time). Among the family Typhloplanidae, the eggs may be thin-shelled in summer and hatch within days of being laid, but winter eggs are often thick-shelled and may be dormant (Pennak 1953; Domenici & Gremigni 1977; Hingley 1993). In the Typhloplanidae, these thick-shelled eggs can survive

desiccation, whereas mature individuals might migrate to more moist, deeper levels. In other terrestrial flatworms, egg shells are typically thick (Figure 15), but the process of laying down the shell is different from those of the Typhloplanidae, and their ability to survive harsh conditions is unknown. These process differences may relate to differences between freshwater and terrestrial triclads (Winsor 1998a).

Bryophyte Habitat Constraints

Leigh Winsor, who has spent more than 40 years studying terrestrial flatworms, says that in wet forests the bryophytes are generally too adherent to the substrate to permit the (large) flatworms to move beneath the moss (Leigh Winsor, pers. comm. 16 February 2012).

Furthermore, unlike many of the invertebrates that seek mosses to maintain moisture, the flatworms seek a fairly smooth surface to which they can adhere their ventral surface, thus minimizing water loss. I would suggest further that the hygroscopic mosses might actually absorb surface water from the flatworms in drying conditions, further drying them. Nevertheless, the bryophyte mats do offer a substrate where the flatworms can pursue their prey (Leigh Winsor, pers. comm. 16 February 2012). And some seem to solve the problem of water loss by twisting into a knot that glues the ventral surface to itself (Figure 16). On the other hand, in excessively wet conditions, the terrestrial flatworms may use mosses to prevent getting too wet by crawling up into the moss and away from **frank water** (obvious pools of water).

Figure 16. *Australopacifica* sp. in knot on moss in New Zealand. Photo by Alastair Robertson and Maria Minor, Massey University, Copyright SoilBugs, published by permission.

Following Schultze (1857), who suggested that terrestrial planarians are likely to exhibit a rich fauna concealed in damp mosses, under stones, and other habitats where moisture is sufficient to maintain them, Davison *et al.* (2008, 2009) report on bryophilous microturbellarians from northwest Alabama, USA. These smaller versions are able to live among mosses on tree trunks and rocks.

The terrestrial flatworm *Tasmanoplana tasmaniana* (Figure 17), a species widespread in a variety of habitats throughout Tasmania, has also been found beneath moss in a temperate rainforest near Fourteen Mile Creek, SW Tasmania (Leigh Winsor, pers. comm. 16 February 2012). The area was very wet and the bryophytes and logs were saturated with water.

Figure 17. *Tasmanoplana tasmaniana*, a flatworm that lives in mosses in Tasmania. Photo by Leigh Winsor, with permission.

Bryophytes provide a moist habitat where zoospores of such parasites as the **chytridiomycosis** fungus *Batrachochytrium dendrobatidis* can survive (Dewel *et al.* 1985). This fungus can be lethal to some amphibians. One must wonder how bryophytes may play a role in harboring other parasites, or conversely, in providing antibiotics that deter them.

One mossy habitat that may be suitable for larger planarians is on leaves covered with epiphylls, as seen in *Pseudogeoplana panamensis* (Figure 18). The surface is relatively flat, and the mosses, liverworts, and other epiphylls can maintain greater moisture levels than a "clean" leaf surface. This relationship remains unstudied.

Figure 18. This flatworm, possibly *Pseudogeoplana panamensis*, is on a palm leaf covered with lichens. Photo by Brian Gratwicke through Creative Commons.

Food Sources

When active, **microflatworms** feed on **protozoa**, **nematodes**, **rotifers**, **tardigrades**, **insect** larvae (Figure 19), and **algae** (Kolasa 1991; Davison *et al.* 2008) with which they share their mossy home. As suggested by Davison, it appears that one attraction for these **flatworms** in moss communities is the available **tardigrades** (Figure 20). **Flatworms** are known to eat **mosquito** larvae (Figure 19), so it is likely that they are able to eat **Chironomidae** (**midge**) larvae that live among the leaves of aquatic mosses and liverworts. Some **microturbellarians** are known to house green **algae** as symbionts (Kolasa 1991), presumably contributing to oxygen, but possibly also contributing carbohydrates. Such a relationship is unknown among moss-dwellers, but certainly it would be worthwhile to search for such symbionts. We do know that some of the tardigrades eat diatoms, a group of algae common on bryophytes, even in some terrestrial habitats, making algae part of the food chain (Bartels 2005).

Figure 19. **Flatworm** feeding on a **mosquito** larva. Photo by Paul G. Davison, with permission.

Figure 20. **Flatworm** eating **tardigrade**. Photo by Paul G. Davison, with permission.

Davison *et al.* (2009) experimented with prey choice among flatworms from epiphytic mosses in Alabama, USA. The flatworms had a strong preference for the rotifer *Philodina roseola* (Figure 21) over the nematode *Panagrolaimus*, both of which occur on bryophytes (Hirschfelder *et al.* 1993; Shannon *et al.* 2005). They either ingested these prey or sucked the contents out.

Figure 21. *Philodina roseola*, a preferred prey organism for some flatworms. Photo from Proyecto Agua, with permission.

Protection or Predation?

The terrestrial flatworms seem to be relatively well protected from predation. Vertebrates seem to avoid them, most likely due to their mucous secretions when disturbed (Arndt & Manteufel 1925; McGee *et al.* 1996; Cannon *et al.* 1999). *Arthurdendyus triangulatus* (Figure 22) invokes violent reactions in earthworms when they make contact (Blackshaw & Stewart 1992 in Winsor *et al.* 2004). The flatworm wraps itself around the earthworm and secretes strong enzymes that turn the poor earthworm into soup! But then, earthworms are their primary source of food (Winsor *et al.* 2004). When this species is unable to find any food, it can survive more than 15 months at 12°C by digesting its own tissues – and shrinking (Blackshaw 1992, 1997; Christensen & Mather 1998a, 2001). However, at 20°C it dies within three weeks without food (Blackshaw 1992), so its presence at warmer temperatures needs to be timed with availability of a food source.

Figure 22. *Arthurdendyus triangulatus* on a bed of damp mosses. Photo © Roy Anderson, with permission.

Mosses can deprive the stoneflies of their flatworm prey. Wright (1975) found that flatworms in streams of North Wales were scarce on the undersides of stones and spent their lives confined to patches of mosses. Those that emerged from the mosses to venture to the undersides of rocks became easy prey for the stonefly *Dinocras cephalotes*.

Watch Out for Invasive Species

Arthurdendyus triangulatus (New Zealand flatworm, formerly *Artioposthia triangulata*; Figure 22) lives in damp terrestrial habitats such as those under logs, decaying wood, mosses, and leaves (Willis & Edwards 1977). *Arthurdendyus triangulatus* is a flatworm about 50 mm long, but can extend to 200 mm when in motion. Unlike the lab planaria with two large eyespots, *Arthurdendyus triangulatus* has a row of tiny black eyes extending down the pale-colored margin. These, as in planaria, are light sensitive and aid the animal in its navigation.

Arthurdendyus triangulatus (Figure 22) originated in New Zealand, but most likely hitch-hiked its way to Ireland among nursery plants, where it was able to spread to Scotland and Britain (Willis & Edwards 1977; Christensen & Mather 1998b; Baird *et al.* 2005). A member of this genus has also found its way to Macquarie Island in the subAntarctic (Winsor 2001). With its ability to travel at the rate of 28 cm per minute (Mather & Christensen 1995) and migrate as much as 20 m (Mather & Christensen 1998), there is concern about its spread in the British Isles where its habit of eating earthworms may be detrimental to their role in aerating the soil (Willis & Edwards 1977; Blackshaw 1990, 1997; Christensen & Mather 1995; Boag & Yeates 2001; Mather & Christensen 2001; Baird *et al.* 2005). One individual can eat about 1.4 *Eisenia foetida* earthworms each week (Blackshaw 1991) and has no species preference among earthworms. Furthermore, *Arthurdendyus triangulatus* thrives better in habitats with more earthworms (Mather & Christensen 2003).

Baird *et al.* (2005), concerned with its potential to drastically reduce the earthworm populations, studied the survival strategies of *Arthurdendyus triangulatus* (Figure 22) and its reproductive behavior under multiple conditions. As noted, planarians can survive for long periods of time without food, utilizing reabsorbed body tissue instead (Calow 1977; Ball & Reynoldson 1981). This permits them to survive winter and even allows them to lay eggs during that season (Baird *et al.* 2005). Whereas Christensen and Mather (1995) demonstrated that these flatworms could survive at least 15 months at 12°C without food, at lower temperatures (8°C), there was even less weight loss. In the lab, they had 100% survival under starvation for 4 weeks at 10°C, but at 15°C, 30% died during that time (Blackshaw & Stewart 1992). This greater loss of weight at temperatures above 14°C and the reduced survival at the warmer temperatures explains the greater spread seen in the northern compared to southern parts of the UK (Blackshaw 1992; Boag *et al.* 1993, 1995, 1998; Baird *et al.* 2005).

Because of these low temperature requirements, it is often necessary for these flatworms to burrow into the soil or travel down tunnels made by other invertebrates. The presence of bryophytes is likely to enhance the habitat by moderating the temperature and maintaining a greater level of moisture, but such bryophyte linkages have not been explored.

This species is a **K strategist** and is a hermaphrodite. Baird *et al.* (2005) demonstrated that *Arthurdendyus triangulatus* (Figure 22) could lay nine egg capsules in four months, with a mean of 4 eggs per capsule, producing 45 eggs per individual per year. It is able to store sperm after copulation (Baird 2002). Individuals cultured alone

were able to produce eggs for up to eight months, indicating that sperm could be stored at least that long (Baird *et al.* 2005).

At temperatures above 10°C, there was a considerable decrease in hatching success, but eggs took longer to hatch at 10°C (Baird *et al.* 2000, 2005). These eggs, like the adults, can easily travel with potted plants from one country to another, and although the nursery trade is highly regulated, internet sales usually escape this close scrutiny.

Desiccation Tolerance

If there is a niche, there is most likely an organism to fill it. And eventually, there is most likely a biologist to study it, but for moss-dwelling **flatworms**, this has been a long time in coming. Although **flatworms**, known to most of us as human parasites and freshwater organisms, can be quite abundant among bryophytes, their presence there is barely known (Paul Davison, pers. comm., 8 August 2007).

Unlike rhizopods and other kinds of protozoa, moss-dwelling **microflatworms** are not known to enter a state of **cryptobiosis**. Davison has collected several *Bryoplana xerophila* (Figure 23) from mosses on a concrete wall and taken them to room-dry conditions, then revived them (Figure 24). These relatively unknown members of the bryophyte community do form cysts and resistant eggs (Figure 25-Figure 26) that permit them to survive the alternating wet and dry conditions found among bryophytes, especially those on tree trunks, despite the thinness of their mucous covering (Davison *et al.* 2008, 2009; Van Steenkiste *et al.* 2010). But for the Australian and New Zealand fauna, these cysts do not seem to occur on the bryophytes (Leigh Winsor, pers. comm. 16 February 2012). Winsor considers the bryophyte habitat there to be too exposed for the cysts or eggs and young to survive.

Figure 23. *Bryoplana xerophila*, a moss-dwelling microturbellarian from Alabama. Photo by Paul G. Davison.

But for *Bryoplana xerophila* (Figure 23-Figure 26) survival on rocks is facilitated by the ability to encyst (Van Steenkiste *et al.* 2010). The cysts typically occur in concavities between moss leaves and the stem connection where interstitial water slows water loss. Once rewet, they begin moving within the cyst and within minutes (up to 15 minutes) break through the cyst wall and are on their way to an active life once again. They further ensure survival of the species by laying one or two eggs as they go into encystment.

Figure 24. Recently excysted terrestrial flatworm, *Bryoplana xerophila*, and empty cysts. The dark brown eggs formed during encystment provide a second means of surviving. These flatworms were living in the moss *Entodon seductrix* (Figure 44) from a concrete block wall in Florence, Alabama, induced to encyst on a glass slide, then brought back to an active state. Terrestrial (Limnoterrestrial)

Fletcheria sugdeni (Sugden's flatworm, also known as **canary worm**; Figure 27-Figure 28) is a native of wet and dry forests in Victoria and Tasmania, Australia

(Winsor, 1977; Ogren & Kawakatsu 1991), where it can sometimes be found among bryophytes. Dendy (1890) noted that *Fletcheria sugdeni* was "remarkable for its habit of wandering about in broad daylight." That is truly remarkable for this bright yellow planarian. But the bright color might actually be a warning color that would be more useful in daylight.

The bright yellow *Caenoplana citrina* (*C. barringtonensis* syn.; Figure 29) is known from mosses at Barrington Tops, New South Wales (Wood 1926). It resembles *Fletcheria sugdeni* (Figure 27-Figure 28), but has two stripes down its dorsal surface.

Wood (1926) noted that *Caenoplana coerulea* (Figure 30-Figure 31) was the commonest species collected near the Barrington River, New South Wales, being found on rocks, damp moss, the trunks of trees, and under rotten logs. Its thick-walled egg is in Figure 32.

Elsewhere in Great Britain, McDonald and Jones (2007) compared habitat and food preferences for two species of *Microplana*, a terrestrial flatworm. The habitat choices in the experiment were not germane to bryophytes, but in addition to the artificial cover, they did find cocoons at a 7 cm depth in *Sphagnum* in the garden. This genus is likely to occur among bryophytes elsewhere and thus should be sought there. The food preferences of *Microplana terrestris* (Figure 33) were gastropods [*Arion hortensis* (slugs, Figure 34) and *Discus rotundatus* (snail, Figure 36)]. *Microplana scharffi* (Figure 37) preferred earthworms but also ate slugs. Both of these species avoided eating live animals and instead fed on damaged animals (see Figure 35). McDonald and Jones suggested that centipedes may contribute to that damage in nature.

Leigh Winsor (pers. comm. 16 February 2012) reports that some terrestrial flatworms have a "most unpleasant taste" (he tasted some species!) that may have a repugnatorial function. Whether brightly colored Australian flatworm species have a repugnant or toxic taste to birds or other predators is not presently known, but the yellow coloration could serve as either Batesian or Muellerian mimicry.

Hyman (1957) reported the planarian *Gigantea cameliae* (identified at that time as *Geoplana cameliae* and moved to *Gigantea* by Ogren & Kawakatsu 1990) on wet mosses at night in Trinidad. This 25 mm, up to 50 mm (Hyman 1941), planarian is larger than most moss dwellers, especially among the terrestrial taxa. This species is also present in Panama (Hyman 1941), but there seem to be no reports of it from bryophytes there.

One mossy habitat where these **microturbellarians** seem to be quite rare, however, is in the Antarctic. Nevertheless, Schwarz *et al.* (1993) did find one **catenulid flatworm** inhabiting the mosses of flushes near the Canada Glacier on continental Antarctica.

Epiphyte Dwellers

The **microturbellarians** are those free-living flatworms (Platyhelminthes) generally <1 mm in length (e.g. Figure 23; Davison *et al.* 2008). They typically live in water films, making them essentially aquatic (**limnoterrestrial**). Bryophytes can provide such water films, so it is no real surprise that they (**Rhabdocoela**,

Typhloplanidae are common 1-2 m above ground among epiphytic mosses. Davison *et al.* (2008) sampled longleaf pine-mixed hardwoods, *Juniperus* in limestone cedar glades, northern hardwoods above 1600 m elevation, dwarf oak forest, upland hardwoods-pine, and planted roadside pecan trees in the southeastern USA. They found that the tree trunk dwellers are rare in cool, mossy stream ravines, where one might have expected them, but are common in areas prone to rapid drying following rainfall – mosses on tree trunks fit this need well. In such locations, Davison *et al.* have found that flatworms are quite common in association with mosses on hackberries and other trees in Florence, Alabama, USA. These mosses include *Leucodon julaceus* (Figure 38) on *Cornus florida* and *Clasmatodon* (Figure 39) on *Paulownia tomentosa*, all at least 0.3 m above ground, as well as on trees of open, urban habitats, including *Catalpa* sp., *Celtis* sp., *Cornus florida*, *Fraxinus* sp., *Liquidambar*, *Magnolia grandiflora*, *Quercus* spp., and *Ulmus* spp. They survive these habitats by forming thin-coated transparent mucous cysts, a mechanism not familiar in other habitats.

Figure 38. Epiphytic *Leucodon julaceus*, a known habitat for flatworms. Photo by Janice Glime.

Figure 39. *Clasmatodon parvulus* with capsule, a home for flatworms. Photo by Paul G. Davison, with permission.

Davison later collected **flatworms** from mosses on two white oaks in northern Tennessee, suggesting that they may be widespread, at least in these south temperate areas (Paul Davison, pers. comm. 12 January 2008). The collections were from the mosses *Forstroemia trichomitria* (Figure 40) and *Haplohymenium triste* (Figure 41) growing 1.7-2 m above the ground. Although these had 10 and 6 turbellarians, a sample of *Hypnum curvifolium* (Figure 42) from the tree base produced only one flatworm. Davison suggests that the **water bears** (tardigrades) are important determinants of the location of the **flatworms** as a food source, and **water bears** were much less abundant at the tree base.

Figure 40. *Forstroemia trichomitria* on a tree trunk, providing a suitable habitat for flatworms. Photo by Janice Glime.

Figure 42. *Hypnum curvifolium* on bark at base of tree, a habitat unsuitable for tardigrades and flatworms. Photo by Robert Klips, with permission.

Although **flatworms** are known from dry mosses on rocks, these observations by Davison and coworkers (2008, 2009) appear to be the first discovery of their living among epiphytic bryophytes. There is at least one report of moss-dwelling turbellarians (on *Eurhynchium oreganum*, Figure 43) on a wet log (Merrifield & Ingham 1998), but that is hardly similar to the dry habitat of a tree trunk. The **flatworms** are seldom abundant, with four or fewer from a clump being common. However, they can be as abundant as 20 in a palm-sized patch of moss. Although they are not abundant, they are frequent, despite the apparent dispersal problems they are likely to have.

Figure 43. *Eurhynchium oreganum*, sometimes home to flatworms. Photo by Matt Goff, with permission.

Epilithic Dwellers

The **epilithic** (rock) dwellers, like the epiphytic dwellers, must tolerate frequent drying on a very xeric habitat. For these limnoterrestrial microturbellarians, a bare rock is a challenge beyond their means. But bryophytes hold moisture and accumulate soil, making this austere habitat more turbellarian friendly. It was from this habitat that Van Steenkiste and co-workers (2010) described the new genus – *Bryoplana*. They appropriately named the new species, the first in the genus, *Bryoplana xerophila* (Figure 23-Figure 26). This one was found among mosses, including *Entodon seductrix* (Figure 44), and soil on a concrete wall in northern Alabama, USA. Not only is it a new genus, but it is the first limnoterrestrial member of the **Protoplanellinae** to be found in North America and is among only a few rhabdocoels from a dry habitat. This species is easy to miss, measuring only 0.4-0.5 mm long.

Figure 44. *Entodon seductrix*, a moss where the flatworm *Bryoplana xerophila* is known to encyst. Photo by Robert Klips, with permission.

These particular **microturbellarians** had guts filled with **bdelloid rotifers**, common inhabitants of mosses (Van Steenkiste *et al.* 2010). They ingested small ones within a minute, but for larger rotifers, they drained them instead, using a sucking action by the pharynx.

Other genera and species of limnoterrestrial turbellarian moss-dwellers include *Acrochordonoposthia*, *Adenocerca*, *Chorizogynopora*, *Haplorhynchella paludicola*, *Olisthanellinella*, *Olisthanellinella rotundula*, *Perandropera*(?), and *Rhomboplanilla bryophila* (Van Steenkiste *et al.* 2010). Association of *Acrochordonoposthia conica* with mosses seems to be particularly well documented (Reisinger 1924; Steinböck 1932; Luther 1963). *Rhomboplanilla bryophila* is even named for its preference for a bryophyte habitat. The absence of images of these taxa on the internet is a testimony to how little we know of them.

Aquatic Bryophyte Habitats

Most of the non-parasitic **flatworms** (formerly **Turbellaria**) are known from aquatic habitats. Stern and Stern (1969) found numbers among cold springbrook mosses (*Fontinalis antipyretica*, Figure 3) in Tennessee to be similar to those on stones, ranging 1-5 per 0.1 m² on stones and 1-4 per 0.1 m² among the moss-algae associations. Frost (1942) found the fauna of **turbellarians** among mosses [mostly *Fontinalis squamosa* (Figure 45), *F. antipyretica*, and *Platyhypnidium riparioides* (Figure 46)] in her River Liffey Survey, Ireland, to be less than 0.1% of the non-microscopic fauna. Berg and Petersen (1956) reported *Schmidtea lugubris* (formerly *Planaria lugubris*; Figure 47) and *Dendrocoelum lacteum* (Figure 48-Figure 49) from beds of *Fontinalis dalecarlica* (Figure 51) in Store Gribbsø Lake, Denmark. **Turbellarians** are not generally a dominant component of the aquatic bryophyte fauna.

Figure 45. *Fontinalis squamosa*, a common habitat for stream fauna, including flatworms. Photo by Michael Lüth, with permission.

In a springbrook in Meade County, Kentucky, USA, flatworms were very abundant at one sampling station on the flattened moss *Fissidens fontanus* (Figure 52), ranging from ~92 per 0.1 m² in June to ~1200 in January, but at another station, the same moss had numbers ranging from ~7 to ~300 in November and March respectively. In the marl riffles, the highest number was 1, and in rubble riffles it was not found. The flatworm *Phagocata velata* (see Figure 53) was the most abundant flatworm on *Fissidens fontanus* as well as under flat stones, logs, twigs, and debris, always in fast currents.

Figure 51. *Fontinalis dalecarlica*, suitable home for the flatworm *Dendrocoelum lacteum*. Photo by Janice Glime.

Figure 52. *Fissidens fontanus*, showing the flat fronds. Photo by Michael Lüth, with permission.

The well-known planarian *Dugesia dorotocephala* finds "moss and sand quite acceptable," preferring them over silt, but less than rocks or leaves (Figure 54; Speight & Chandler 1980). *Phagocata gracilis*, a moss-preferring species, selected temperatures of 4-22°C, preferring 14.8°C on rocks and 12.6°C on moss. I have to wonder if that was oxygen-related, with mosses taking up oxygen at night. *Phagocata velata*, on the other hand, preferred living on rocks and migrated mostly to a temperature range of 16.0-20.5°C, with a temperature preference of 17.8°C.

Figure 53. *Phagocata vitta*. Photo by Malcolm Storey through Creative Commons.

Figure 54. *Dugesia* sp. in its rock habitat, which is usually preferred to mosses. Photo by Janice Glime.

In a New Zealand springbrook, *Neppia montana* (Figure 55) seemed to have a preference for the *Achrophyllum quadrifarium* (= *Pterygophyllum quadrifarium*; Figure 56) over the other two mosses in the stream (*Fissidens rigidulus*, *Cratoneuropsis relaxa*) (Cowie & Winterbourn 1979). The *A. quadrifarium* occurred in a zone extending from the stream margins on up the banks where it received spray from the rapidly moving water. This is a large, pleurocarpous moss with flattened branches.

Extraction and Observation Techniques

The flatworms represent a little known fauna of terrestrial bryophytes. Brigham (2008) suggests that one reason for this may be the lack of a satisfactory extraction technique. She compared the traditional beaker extraction method with a Baermann funnel method modified by Paul Davison (see Vol 2, Chapter 4-1). Using the beaker

method, she was unable to find any **microturbellarians** among the mosses. However, she found them in multiple samples using the modified Baermann funnel.

Since these organisms are too small and too numerous for quantification in the field, they must be transported to the laboratory for extraction. Examination of live organisms makes them both easier to locate and easier to identify (Kolasa 2000). Warm temperatures and lack of oxygen quickly become lethal, not to mention confined but hungry predators, so samples must be kept in a cooler (Stead *et al.* 2003) and processed within a few hours of collection. Preserved animals usually cannot be identified.

Winsor (1998b) suggests narcotizing the flatworms with 10% ethanol, then preserving them with a formaldehyde calcium cobalt fixative. They can be cleared for examination in terpineol, imbedded in paraffin wax, and serially sectioned. The sections can be stained to make internal systems more visible. Long-term storage may require 80% ethanol, and those for DNA extraction should be fixed in 100% ethanol.

Slowing down live animals for identification can be challenging, but Thorp and Covich (1991) recommend placing them in a small volume of water on ice. Alternatively, they can be anaesthetized with a mix of 7% ethanol, 0.1% chloretone, and 1% hydroxylamine hydrochloride.

One trick to help in identification of soft-bodied taxa when time is at a premium is to use a video camera on a sample under appropriate microscope magnification (Stead *et al.* 2003). Davison and Kittle (2004) suggest making a miniature aquarium using microscope slides as a housing for both culturing these organisms and examining them (Figure 57-Figure 59).

Figure 57. Method for constructing a microchamber for observing flatworms and other small invertebrates. Modified from Davison 2006.

Food choices in the lab may differ from those in the field where a wider array of choices is available. Gut analyses are used for larger organisms to determine diet in the field. But obtaining samples for gut analysis in flatworms and other tiny invertebrates is a bit more tricky than that used for insects and larger invertebrates. One

can't pull or dissect the gut from the animal. Instead, Young (1973) sacrificed the animals another way. He squashed them with a coverslip on a glass slide. But first the flatworms had to take a bath by crawling around in tap water to remove adhering items that might look like food in the squash. Then they were placed on the "squash" slide, all within an hour of collection to avoid extensive digestion of the food items.

Figure 58. Filling completed microchamber built by above construction. Photo by Paul G. Davison from Davison 2006.

In 1979, Feller *et al.* demonstrated the usefulness of immunological techniques for identifying major taxonomic groups in the guts of these small organisms. Young and Gee (1993) used the precipitin test, a serological technique, to identify major taxonomic groups in the gut. Schmid-Araya *et al.* (2002) first anaesthetized the organisms with CO₂ to prevent regurgitation, although it was not clear if this method was used to identify flatworm gut contents. More recently, DNA extraction and amplification provide a means of identifying gut material from such small meiofauna (Martin *et al.* 2006), providing a potential tool for flatworms.

Figure 59. Occupied microchamber (with flatworms and moss). Image modified from Davison 2006.

Summary

Fissidens fontanus and *F. brachypus* can grow epizootically on sponges. Humans may enjoy a mattress made with mosses and sponges.

Gastrotrichs survive the dry stages of mosses by producing larger eggs that survive due to heavier shells. They seem to prefer lower velocity areas where sediments can accumulate and can be relatively common in peatlands.

Microflatworms are mostly from aquatic habitats where they are known from *Fontinalis antipyretica*, *F. squamosa*, and *Platyhypnidium riparioides*. They survive winter and dry periods like the **gastrotrichs**, as thick-shelled eggs, but they can also form cysts, particularly among epiphytic mosses. They are actually more abundant on tree trunks that are prone to drying out than they are in cool, mossy stream ravines. These terrestrial species seem to be most abundant among the mosses where they can find **tardigrades** to eat. The triclad flatworm *Phagocata gracilis* actually prefers moss habitats.

A Baermann funnel seems to work best for extracting microturbellarians from terrestrial mosses.

Acknowledgments

Paul Davison kept me informed of new finds, which were especially important for these groups where so little is known of their bryophyte relationships. Filipe Osorio added information on tropical Platyhelminthes. Sarah Lloyd has kept me in mind as she finds new invertebrates and takes pictures for me, including the canary worm. Yuuji Tsukii gave me permission to use his wonderful collection of images. Leigh Winsor has been invaluable in helping me to identify the flatworm and nemertine worm pictures, to understand these species better, and to review the revised chapter (February 2012). Thank you to Larry Williams for catching some of my errors and notifying me.

CHAPTER 4-3

INVERTEBRATES: NEMATODES

Figure 1. Nematode taken from epiphytic bryophytes. Photo by Paul G. Davison, with permission.

Nematoda – Roundworms

The failure of many soil biologists to distinguish between bryophytes and what the rest of us think of as soil (*i.e.* not including bryophytes) has made researching the bryophyte-dwelling nematodes and annelids particularly difficult. Although we usually think of the nematodes (roundworms as soil organisms, they join the many other invertebrates in living among bryophytes as well (Allgén 1929; Overgaard-Nielsen 1948, 1949; Zullini 1970, 1977; Wood 1973; Yeates 1979; Caldwell 1981a, b; Zullini & Peretti 1986; Kinchin 1989; Merrifield 1992; Steiner 1994a, b, c, 1995a, b; Gadea 1964a, b, 1995; Linhart *et al.* 2000a, b, 2002a). Even the pendant moss *Barbella asperifolia* (see Figure 2) can be inhabited by nematodes (Noguchi 1956). The most common moss-dwelling nematodes worldwide are *Plectus* (Figure 3) (named for its twisted excretory tract) and *Eudorylaimus* (Figure 4; Overgaard-Nielsen 1948; Brzeski 1962a, b; Gadea 1964b; Eliava 1966, Spaul 1973).

Figure 2. *Barbella* sp., demonstrating the aerial habitat of some nematodes, with another pendant moss, *Meteorium* sp. Photo by Janice Glime.

Figure 3. The tail end of the nematode genus *Plectus*. Photo by Peter Mullin, with permission.

Figure 4. Head of *Eudorylaimus* juvenile from Costa Rica. Photo by Melanie Raymond, with permission.

Most of the nematodes that inhabit mosses are less than 1 cm in length (Poinar 1991). Their digestive tract has a. mouth and anus, and it is the structure of this tract that determines many species differences in these animals. They get their gases by simple diffusion, and thus living deep in mosses can present a problem. The head possesses sensory papillae. Reproduction may be sexual or by parthenogenesis. No known species is hermaphroditic.

Densities and Richness

Kinchin (1992) claims that nematodes are common in most moss samples and are easy to see while they are alive due their thrashing movements. Fantham and Porter (1945) reported up to 480 per gram of moss. In their survey of Canadian moss fauna, they considered them to be the most abundant of the (terrestrial) metazoan fauna. Frost (1942) reported a mean of 56 and 38 individuals per stream sample (200 g). These represented only 0.41 and 0.3% of the fauna, respectively. In a high mountain brook, in the Colorado Rocky Mountains, Elgmork and Sæther (1970) reported that nematodes, primarily from the family Tylenchidae, were most abundant in the locations where there were mosses, but were not necessarily on the mosses – they were in all locations in the stream.

Despite the large numbers, not many species are known from bryophytes. Hingley (1993) reported that only 30 species were known from *Sphagnum* (Figure 5), despite 30,000 species known from soil or fresh water. One reason for the small number of species known is that they are quite

difficult to identify. Table 1 indicates species richness of nematodes in a number of locations, demonstrating several habitats.

Habitat Needs

Some of the mossy habitats, especially in streams, might make it easy for a nematode to become dislodged. Kinchin (1989) points out that many of the moss taxa have a caudal adhesive organ that permits them to anchor themselves.

Moisture Requirements

The moss cushion is not homogeneous. Generally, one can identify a leafy canopy layer, a stem layer with reduced leaf cover, and the rhizoid layer (Kinchin 1989). Many nematodes are able to migrate vertically through these layers diurnally to escape the dry upper canopy in the daytime (Overgaard-Nielsen 1948, 1949). Overgaard-Nielsen recognized three ecological groups, based on their behavior in dealing with moisture needs:

1. Members of the largest group, including *Plectus* (Figure 3), migrate from the rhizoid layer to the canopy layer when the moss is damp.

2. Worms such as *Aphelenchoides* (Figure 6) with modest migrations move only from the rhizoid layer to the stem layer and only when the moss is saturated.
3. Non-migrating worms such as *Dorylaimus* (Figure 7) never venture from the rhizoid layer, regardless of the moisture level.

Figure 6. *Aphelenchoides* sp., a moss dweller in the rhizoid layer. Photo by Peter Mullin, with permission.

Figure 7. *Dorylaimus* sp. Photo by Aldo Zullini, with permission.

Moist mosses have more nematode species than dry ones (Kinchin 1989). Mosses that experience frequent desiccation episodes tend to have a more specialized moss fauna. In the ones that are dry most of the time, the fauna is primarily comprised of *Plectus rhizophilus* (Figure 8), a species that does not occur in the soil beneath the moss (Overgaard-Nielsen 1948, 1949). **Acrocarpous** moss cushions typically have more nematodes than **pleurocarpous** feather mosses (Kinchin 1989). Kinchin suggests that the water content in cushions is more favorable for movement.

Figure 8. *Plectus rhizophilus*, a nematode that specializes in dry moss habitats. Photo by Peter Mullin, with permission.

As in most non-arthropod invertebrates, water can be a limiting factor for nematodes. Womersley (1987) (in Wharton 2004) considered most of the moss-dwelling nematodes to be slow-dehydration strategists, whereas other nematodes may tolerate rapid dehydration of the habitat by having mechanisms that make their own dehydration slow. Hence, despite their need for water, they can be common in cryptogamic crusts. In just one of its faunal genera, the Konza Prairie crusts support 16 species in the genus *Plectus* (Figure 3; Figure 8). Beasley (1981) and Kinchin (1990) suggested that some nematodes actually require a dry phase in their life cycle.

Food Supply

Food supply may at times be an overriding factor in determining locations of moss-dwelling nematodes. Several researchers have suggested that food supply was a major controlling factor for nematode density in soil (Bunt 1954; Winslow 1964; Yeates 1967). Spaul (1973) suggested that food was likely to also be a determining factor in the moss community, at least in the Antarctic. Predominant food strategies of bryophyte-dwelling nematodes include predators (Barbuto & Zullini 2006) and bacteriovores (Lazarova *et al.* 2000) and food includes bacteria, algae, and protozoa (Poinar 1991). Mosses usually collect detrital matter that provides suitable habitat for Protozoa and bacteria.

Quality of Food

However, it is possible that it is the quality of food that matters. Spaul (1973) found that nematode abundance was not related to water content on Signy Island, but correlated with a low ratio of C:N (favoring bacteria) in the soil (including mosses), seemingly explaining the greater numbers associated with the grass *Deschampsia antarctica*, where C:N ratios were the lowest. Hingley (1993) indicated that the peatland nematodes did not eat the moss *Sphagnum* (Figure 5). Rather, they are likely to eat bacteria, protozoa, and small invertebrates.

Warming Effect among Bryophytes

Spaul (1973) and Holdgate (1964) consider the warming effect of solar radiation within the upper portion of the moss mat to determine activity of nematode moss dwellers. But this influence is only important near the surface, with its influence diminishing with depth (Longton & Holdgate 1967; Cameron *et al.* 1970). Nevertheless, bryophytes buffer the temperature of the soil beneath them, keeping it cooler in summer and insulating it against an early frost or cold when there is no snow cover.

Unusual Bryophyte Dwellings

It appears that some nematodes have found a cozy niche in **antheridia** of mosses (Figure 9). Lars Hedenäs (pers. comm. Aug. 2007) has found such nematodes in old perigonia of *Homalothecium lutescens* (Figure 10) collected in France by Gillis Een with one actually inside the spent antheridium. Could this be a common niche for some nematode taxa, or was this just an opportunist and rare occurrence?

Substrate Preferences

Barbuto and Zullini (2006) found that despite highly variable densities of nematodes between samples and substrate of the mosses, the diversity and trophic group structure varied little. Predators dominated in these Italian samples. Soil as a substrate for the mosses seemed to favor a greater species richness and biomass, particularly for large species such as *Aporcelaimellus obtusicaudatus* (Figure 11-Figure 12; most likely a species complex; Mike Hodda, personal communication). In their study, *Tripylella intermedia* seemed to occur exclusively on mosses on rocks, but any other relationship to substrate was not clear. On the other hand, Eyualet-Abebe *et al.* (2006) reported it as a species of both mosses and soil. As in many other geographic areas, Barbuto and Zullini (2006) found that the two most common species were *Prionchulus muscorum* (Figure 13) and *Plectus acuminatus*, occurring in nearly all samples. The greatest differences among European communities seemed to be between continental and Mediterranean communities.

Figure 13. *Prionchulus muscorum*, one of the two most common species among mosses in an Italian study. Photo by Peter Mullin, with permission.

Lazarova *et al.* (2000), in comparing nematode communities on the moss *Hypnum cupressiforme* (Figure 14) in Bulgaria, likewise found that abundance was quite variable among substrata (soil, stone, & tree trunks) and samples, and these likewise were similar in diversity, trophic group structure, and generic composition. They did, however, vary in species composition. Contrasting to the predatory dominance of nematodes in the broader range of European mosses studied by Barbuto and Zullini (2006), they found that the most abundant *H. cupressiforme* nematodes were bacteriovores. The proportion of predatory and omnivorous nematodes was quite low. They also found no clear substrate dependence of any species except for *Chiloplectus andrassyi* (Figure 15), which was most abundant among *H. cupressiforme* on stone.

Motility Constraints

Merrifield and Ingham (1998) considered that low densities of nematodes in some mosses may result from interference by the moss with the motility efficiency of the nematodes. Kinchin (1992) commented that live nematodes in mosses were easy to locate because of their thrashing movements. Overgaard-Nielsen (1948) described the genera *Aphelenchoides* (Figure 6), *Monhystera* (Figure 16), *Plectus* (Figure 8), *Prionchulus* (Figure 13), *Teratocephalus* (Figure 17), and *Tylenchus* (Figure 18) as moving by swimming (a rare event for most nematodes),

thus requiring an accumulation of large quantities of water, but more likely they crawl in a thin film of water (Mike Hodda, personal communication). Nematodes are heavier than water and thus sink. The members of *Eudorylaimus* (Figure 19) are "powerful benders" that can move in a thin film of water. Although *Eudorylaimus* species are unable to inch or swim where they live on the moss, their bending ability permits them to attain a patchy distribution (Merrifield & Ingham 1998). The genera *Monhystera* and *Plectus* move like inchworms, using their caudal and labial gland adhesives (Overgaard-Nielsen 1948). But *Tylenchus*, lacking the caudal glands, cannot creep, and basically becomes confined to its original location.

Drought Strategies

As one would expect in a diverse group of organisms, the strategies for survival in a widely varying environment are also diverse. Like their mossy substrate, nematodes are able to go dormant for long periods of time (McSorley 2003). The record seems to be that of *Tylenchus polyhypnus* (literally meaning many sleeps). This moss-dweller became active again after 39 years of sleeping on a moss herbarium specimen! (Figure 18; Steiner & Albin 1946).

Eggs have a long longevity that permits them to remain quiescent until favorable conditions for growth and development return (Hingley 1993). They can survive drought, lack of oxygen, and a series of freeze-thaw cycles. Sex ratios can change to provide a more favorable ratio for the conditions at hand. And worms can cluster together in great aggregations in the soil, although I know of no reports of this phenomenon within moss habitats. Even adults can survive long periods of **anhydrobiosis**, a dormant state in which some invertebrates can survive desiccation. The lack of water prevents all enzymatic metabolic reactions (Clegg 1973; Barrett 1982).

Panagrolaimus (Figure 20) is known from a wide range of niches, including bryophytes, and they are bacterial feeders, a strategy that suits them well for dwelling among bryophytes (Shannon *et al.* 2005). They furthermore have the ability to survive extreme desiccation by entering the dormant state of **anhydrobiosis**, thus being able to dry as the bryophytes dry. Many of the *Panagrolaimus* species require preconditioning through slow desiccation. *Panagrolaimus superbus*, on the other hand, has a fast desiccation strategy in which it can survive rapid desiccation, but whose chance of survival increases with preconditioning. Just as found for freezing tolerance (Crowe *et al.* 1984), there is a high correlation between **trehalose** induction and desiccation/anhydrobiosis survival (Shannon *et al.* 2005). It is therefore not surprising that *P. superbus* maintains a high level of trehalose even in its fully hydrated state, *i.e.*, 10% of its dry mass! It is possible, then, that it is this ready supply of trehalose that preadapts this species to survival of desiccation.

Figure 20. *Panagrolaimus davidi*. Photo by Smithsonian Institution, National Museum of Natural History, Invertebrate Zoology through Creative Commons.

Panagrolaimus (Figure 20) species also exhibit behavioral adaptations to drying. They coil their bodies (Figure 21) and clump with other nematodes, both of which reduce the surface area from which water can be lost (Shannon *et al.* 2005).

Figure 21. This moss-dwelling nematode is attempting to move with its longitudinal muscles. Coiled positions like this also reduce the rate of water loss as the habitat dries. Photo courtesy of Andi Cairns.

Both moss-dwelling nematodes and bryophytes have been described as **poikilohydrous**, meaning their water content will vary with that of the environment (Proctor 1979). Like most mosses, some nematodes can enter an anhydrobiotic state or become dormant. Unlike *Panagrolaimus superbus*, most nematodes must dry slowly to survive (Crowe & Madin 1974) and eventually lose most of their water. *Plectus* (Figure 3), a common moss dweller, is a notable exception, being known as a "quick drier" (Mike Hodda, personal communication). Coiling their bodies (Figure 21) helps many nematodes to slow the water loss (Demeure *et al.* 1979), but Kinchin (1989) indicated that there are no observations to indicate whether or not this behavior is present in moss inhabitants. Fortunately, Andi Cairns has photographed a moss-dwelling nematode doing just that (Figure 21).

Habitation of mosses themselves is a survival strategy. Mosses, especially cushions, dry slowly. A boundary layer of still air forms over the cushion. Evaporation must occur through this boundary layer. Thicker layers mean slower evaporation rates. The nematodes are nestled in the axils of leaves, so those in a cushion experience slower evaporation than those in more open habitats (Richardson 1981).

Some mosses may contribute to slowing evaporation not only of themselves, but also their inhabitants by curling their leaves, as in *Atrichum* spp. (Figure 22). Others, such as *Syntrichia princeps* (Figure 23) or *S. intermedia* (Figure 24), may wind their leaves helically around the stem.

Figure 22. *Atrichum undulatum* with moist leaves (upper right) and dry, curled leaves (lower middle). Curled leaves help to slow evaporation, permitting the nematodes to acclimate as they go dormant. Photo by Michael Lüth, with permission.

Kinchin (1992) observed that luxuriant growths of epiphytic bryophytes often had fewer species and reduced numbers compared to those bryophytes in lesser abundance. He suggested that the more open growth habit of these mosses in higher humidity were perhaps not suitable for the nematodes. He further suggested that some nematodes require alternate dry and wet phases in their life cycles, thus not faring well in the more moist dense moss growths (see also Kinchin 1990).

Succession

Moss age not only affects probability of arrival, but also influences the moisture of the habitat. The most specialized nematode species arrive first because they are adapted to the changing moisture regime. These include *Plectus rhizophilus* (Figure 25), a moss canopy species (Kinchin 1989). Members of the rhizoidal group (e.g. *Dorylaimus*, Figure 7) are the last to arrive because they require the more stable moisture climate of a larger cushion. Although *Dorylaimus* is an aquatic genus, it can survive on very wet mosses (Aldo Zullini, pers. comm. 18 March 2009). On the other hand, Mike Hodda (personal communication) considers that they may arrive last because they have long life cycles and are slow to breed, whereas *Plectus* (Figure 27) is short-lived, fecund, and moves much more quickly.

Figure 25. *Plectus rhizophilus*, a nematode found among roof mosses. Photo by Peter Mullin, with permission.

Nematode communities in moss cushions are so sensitive to moisture regimes that they can be used to ascertain the moisture history of the cushion (Kinchin 1989). Fewer species would be present in cushions that are frequently desiccated. Thus even among populations of the same species, communities will differ based on the moisture history of the cushion. Overgaard-Nielsen (1967) demonstrated this by comparing communities associated with *Ceratodon* sp. (Figure 26) on north- and south-facing sides of a thatched roof (Table 2).

Seasonal Changes

Seasonal differences among the moss-dwelling nematodes can be pronounced, as reported by Steiner (1994d in Boag & Yeates 2004) for the Swiss Alps. In a study of nematodes dwelling on *Eurhynchium oregonum* (Figure 30) in the Oregon Coast Range, USA, comparison indicated that the densities of *Eudorylaimus* spp. (Figure 19) and *Plectus* spp. (Figure 25, Figure 27) differed between sampling dates, but that densities of *Monhystera* spp. (Figure 16), *Prionchulus muscorum* (Figure 13), and *Tylenchus* spp. (Figure 18) did not differ, resulting in total densities of nematodes that varied little between dates (Figure 31; Merrifield & Ingham 1998). Nevertheless, *Monhystera* (Figure 16) species reached a mean of 35 individuals per gram in August, but only 1 or fewer in winter and spring. Members of other genera occurred sporadically in low numbers: *Aphelenchus* (Figure 32), *Acrobeles* (Figure 33), *Cuticonema*, *Ecphyadophora*, *Leptolaimus* (Figure 34), *Teratocephalus* (Figure 17), and members of the order **Cromadorida**. The number of nematodes per gram of dry moss ranged from 21 in February to 64 in July, a density somewhat lower than that found in other studies on moss-dwelling nematodes.

Figure 34. Head end of *Leptolaimus*, an occasional dweller on the moss *Eurhynchium oregonum* (Figure 30). Photo by Peter Mullin, with permission.

Merrifield and Ingham (1998) suggested peaks of *Eudorylaimus* (Figure 19) and *Plectus* (Figure 3) species in association with the moss *Eurhynchium oregonum* (Figure 30) in the Oregon Coast Range in late May, continuing until August, could indicate optimal conditions during that time of year (Figure 31). It is not clear if food is a limiting factor because feeding habits of some species are not clear. In fact, these nematodes are often polyphagous, with some switching food items from bacteria to prey items as they grow (Yeates *et al.* 1993; Mike Hodda, personal communication). Merrifield (1994) examined the relationship between spore production of the moss *Schistidium maritimum* (Figure 35) and the omnivorous nematode *Eudorylaimus* at Yachats, Lincoln County, Oregon, USA, in a year-long study. She found a lag of one month between the peak of mature sporophytes and the maximum density of nematodes. Since there were no other invertebrates to serve as food, she suggested that the spores might serve as a food source.

Plectus sp. (Figure 3), a bacteriovore, ranged from 4 to 12 per gram dry weight (gdw) of moss on the northwest slope of Mary's Peak, Oregon, USA, throughout most of an October 1990–October 1991 sampling period, but reached 25 per gdw in June (Merrifield 1992). *Monhystera* sp. (Figure 16), on the other hand, peaked in September with 35 per gdw, whereas it remained mostly below 1 per gdw throughout the Oregon winter. The possibly fungus and plant feeder *Tylenchus* sp. (Figure 18) had a bimodal seasonal distribution, with highs in November (35) and July (25). *Prionchulus* sp. (Figure 13), a predator, peaked at 6–8 in summer and winter, with fluctuations throughout the year.

Figure 35. *Schistidium maritimum* in a typical shoreline habitat. Photo by Michael Lüth, with permission.

Spaull (1973) likewise found a vertical migration of moss-dwelling nematodes on Signy Island. In the summer and first half of winter the nematodes remained in the 3 cm nearest the surface, but when the cold of winter set in, they could be found primarily in the 3–6 cm layer. Spaull speculated that the freeze-thaw cycle near the surface resulted in a decline in numbers there, but that the lower positions also experienced slightly higher daytime temperatures in the autumn. Despite earlier studies suggesting the importance of moisture (Tilbrook 1967a, b), there seemed to be no relationship between vertical position and moisture in the mosses (Figure 36).

Figure 36. Seasonal depth distribution of nematodes compared to humidity levels in *Calliargon* (Figure 37)-*Calliargidium* (Figure 38) cores on Signy Island, Antarctic region. Redrawn from Spaull (1973).

Figure 37. *Calliergon sarmentosum*, a known host of nematode-trapping fungi on Signy Island in the Antarctic. Photo by Michael Lüth, with permission.

Some moss-dwelling nematodes can respond to seasonal changes by migrating. Of course they can't travel long distances like birds can. Whereas some nematodes migrate vertically on a daily basis, others move vertically within the moss community to survive changing seasons (Wharton 2004). In the Antarctic, Caldwell (1981b) and Maslen (1981) found that a seasonal migration existed in moss carpets, wherein the nematodes moved deep into the carpet in autumn and returned to the surface in spring. But it is interesting that they found no similar migration pattern in moss cushion forms.

Freeze Tolerance

Nematodes range at temperatures from snow pools to hot springs, with a species of *Aphelenchoides* (Figure 28) occurring at 61.3°C (Hebert 2008). In fact, some Antarctic nematodes can withstand freezing at -80°C for more than six years (Newsham *et al.* 2006). On the liverwort *Cephaloziella varians*, there were more live *Coomansus gerlachei* nematode individuals than of *Rhyssocolpus paradoxus*. Nematodes had much greater survival (49%) than did tardigrades (13%) or rotifers (2%).

One factor that permits nematodes to succeed in climates of the Antarctic, alpine areas, and other areas with harsh winters is their ability to survive freezing conditions. But how does this tiny, watery worm do it? Several species in the genus *Panagrolaimus* (Figure 39-Figure 41) have been studied to reveal their freeze-tolerance secrets. Some day we may be able to freeze and thaw humans from what we learn about these moss inhabitants.

The transparency of the nematode body enabled Wharton and Ferns (1995) to discover that *Panagrolaimus davidi* (Figure 20) froze not only in its extracellular spaces, but also formed ice in living cells (Figure 39). They found that all body parts could experience freezing and thawing, including within cells (Figure 39). Freezing extends inward through body openings, mostly through the excretory pore. These nematodes, with intracellular freezing, can revive, grow, and reproduce, at least in culture (Figure 41-Figure 41).

Figure 39. Frozen female *Panagrolaimus davidi* that survives intracellular ice formation (Wharton & Ferns 1995). This female was frozen on a light microscope cold-stage. Freezing causes darkening in appearance, and ice can be seen throughout this nematode, except the egg, which remains unfrozen due to its protective shell. Photo by Melianie Raymond, with permission.

Figure 40. The same female *Panagrolaimus davidi* as in Figure 39, thawing from being completely frozen. Photo by Melianie Raymond, with permission.

But *Panagrolaimus davidi* (Figure 20) has more possibilities to survive freezing, and these may play a role in its desiccation story as well. These nematodes can avoid freezing by dehydration (Wharton *et al.* 2007). If nucleation of their surrounding medium occurs at a high subzero temperature, *e.g.* -1°C, the nematodes dehydrate instead of freezing. This occurs as a result of difference in vapor pressure between ice and super-cooled water at the same temperature. When they are cooled slowly, there is sufficient time for them to lose enough water to prevent freezing. It is only when they are cooled rapidly or at a

lower nucleation temperature that they actually freeze internally, but still survive. These multiple strategies permit them to survive the harsh Antarctic environment.

Figure 41. The same female *Panagrolaimus davidi* as in Figure 39, after thawing from being completely frozen, but undamaged. Photo by Melanie Raymond, with permission.

However, when these nematodes are in water, they are seeded by exogenous ice nucleation, a process in which a dust particle, protein, or other small particle (the "nucleus") forms the center for ice crystallization – the same process used for making artificial snow. Even under these conditions, some of the nematodes of this species do survive. One reason for their survival is that the formation of the ice seems to be restricted to the **pseudocoel** – the "false" body cavity. A major danger from ice crystallization is that the crystals are sharp and poke holes in cell membranes, or distort them, changing permeability. However, the pseudocoel is fluid and **acellular**, thus avoiding that danger.

Thermal history and age are important in determining which individuals survive (Wharton & Brown 1991). In arthropods, supercooling and freeze tolerance are thought to be mutually exclusive, but in nematodes, that is not the case. In the Antarctic, sub-zero temperatures can occur on any day of the year, making tolerance a necessity for survival. Even in the summer, moss temperatures can go down to -8.4°C (Block 1985). The moss environment is usually saturated with water (Pickup 1990a, b), requiring that the nematodes either prevent ice nucleation or survive exogenous nucleation and subsequent freezing.

Panagrolaimus davidi (Figure 20; Figure 39-Figure 42) freezes when it is seeded by exogenous ice nucleation and is freezing tolerant (Wharton & Brown 1991). In the moss habitat, nematodes will usually experience low water loss rates; hence, an interaction between water loss and cold tolerance may occur under some conditions. This slow water loss rate may be a vital factor in its choice of the moss as a habitat (Wharton *et al.* 2003). When nucleation begins at subzero temperatures near -1°C, this nematode dehydrates (Wharton *et al.* 2003). The difference in vapor pressure of ice and supercooled water, at the same temperature, drives the water loss from the nematode. If the process is slow enough, the nematode loses enough water to prevent freezing (Figure 42). It is likely that **trehalose**, an important molecule during dehydration, also acts to prevent or reduce freezing within the worm (Wharton 2003).

Figure 42. *Panagrolaimus davidi* showing cryoprotective dehydration. *Panagrolaimus davidi* can also survive exposure to freezing conditions by undergoing cryoprotective dehydration (Wharton *et al.* 2003). This photo shows a nematode encased in ice, unfrozen but dehydrated. Photo by Melanie Raymond, with permission.

To further combat its frigid environs, *Panagrolaimus davidi* (Figure 20; Figure 39-Figure 42) produces **ice-active proteins** (Wharton *et al.* 2005a). These proteins seem to have the ability to stabilize the ice after freezing by preventing **recrystallization** during minor freeze-thaw temperature fluctuations within the organism. Wharton *et al.* (2005b) examined the survival of these nematodes under several freezing scenarios. At sub-zero temperatures near 0°C, three patterns of ice formation were evident: no ice, extracellular ice, and intracellular ice (Wharton *et al.* 2005b). In a slow-freezing regime (at -1°C) mainly extracellular ice (70.4%) formed, with most of the ice in the pseudocoel. Cryoprotective dehydration accounted for ~25% of the individuals with no ice within their bodies. However, under a fast-freezing regime (at -4°C) both intracellular (54%) and extracellular (42%) ice formed. Fortunately, the intracellular ice only formed in the cytoplasm of cells, while organelles remained in unfrozen spaces between the crystals. Nevertheless, those nematodes that experienced the fast freezing had only 53% survival compared to 92% for those that underwent slow freezing.

We have also learned that the Antarctic *Panagrolaimus davidi* (Figure 20; Figure 39-Figure 42) is able to survive freezing temperatures by supercooling when it is in air that permits it to be free of surface water (Figure 42) (Wharton & Brown 1991; Wharton *et al.* 2003). But, in these conditions, it is intolerant of freezing. In fact, it can survive better at sub-zero temperatures than other individuals of the species that have been kept at 15°C in 99% relative humidity – not unlike the moisture relationships of bryophytes and their tolerance to temperature extremes.

The importance of mosses to the life cycle of *Panagrolaimus davidi* (Figure 20; Figure 39-Figure 42) is evidenced by the nematode's optimum temperature range of 25-30°C (Brown *et al.* 2004). Population growth ceases at about 6.8°C. Fortunately, egg incubation requires only 4.1-7.6°C. This bacteriovore is **r-selected** (typically short-lived with lots of offspring like bacteria), more like temperate nematodes than its Antarctic compatriots. However, the

cold polar environment forces it to become dormant for long periods of time and to grow in spurts; such longevity is more like that of **K-selected** organisms (long life span and few offspring, like humans), but is it right to count that dormancy period as part of its longevity?

Scientists have known about freezing of juveniles and eggs of other nematodes for some time, but the mechanisms were not understood. In some species (*Trichostrongylus colubriformis*), a sheath protects at least some juveniles from formation of exogenous ice nucleation, although this species also survives freezing (Wharton & Allan 1989). Worms of *Ditylenchus dipsaci* and the eggs of *Globodera rostochiensis* are able to survive freezing in wet conditions, but the researchers were unable to distinguish between survival of freezing and prevention of ice nucleation (Wharton *et al.* 1984; Perry & Wharton 1985).

But not all cold temperatures are in the high elevations and latitudes. In peatlands, freezing is common, yet nematodes survive. Some protection is afforded by their behavior of coiling (Hingley 1993). But the greater protection is most likely their chemical alteration. As unfavorable conditions approach, they decrease their concentrations of **fats**, **glycogen**, and **glucose** and increase **glycerine** and **trehalose** (Crowe *et al.* 1984). In addition to its probable role in preventing or reducing freezing (Wharton 2003), trehalose is able to stabilize dry membranes, a consequence of freezing as well as drought conditions (Crowe *et al.* 1984).

Gall-formers

Some of bryophyte-dwelling nematodes are free-living and some are parasitic on the bryophytes (Gadea 1977, 1978a, b; Duggal & Koul 1985; Georgievska 1990). Nematode galls on bryophytes have been known since before 1905 (Dixon 1905; Marchal 1906). Dixon reported that others had found them on *Warnstorfia fluitans* (Figure 43), *Drepanocladus aduncus* (Figure 44), *Hypnum cupressiforme* (Figure 14), and several species of *Dicranum* (Figure 45). Dixon himself found them on *Thamnobryum alopecurum* (Figure 46). After reading the descriptions of others, he concluded that he had also seen them on *Eurhynchium hians* (Figure 47) as well. These galls typically occur at the shoot and branch apices. Dixon observed numbers up to 50 adorning a single stem of *Thamnobryum alopecurum*.

Figure 47. *Eurhynchium hians*, a species that can be home to gall-forming nematodes. Photo by Michael Lüth, with permission.

Schiffner (1906) noted that the nematode galls were typically associated with the apices where one should find sporophytes (Figure 48). But those shoots with galls did not produce sporophytes. Kitagawa (1974) observed apical galls in leafy liverworts and concluded that the nematode gallers induced a protective appendage resembling a perigynium or marsupium. This structure originally enveloped a young sporophyte and he concluded that the nematode galls are associated with the sporophytes of the liverwort.

Figure 49. *Orthotrichum* nematode galls showing their position where the sporophyte should be. Photo courtesy of Martin & Rosie Godfrey.

Akiyama (2010) found nematode galls on the leafy liverwort *Lejeunea tuberculosa* in the upper montane forest of northern Thailand. The galls consisted of tightly gathered abnormal leaves at the apex of shoots. Unlike Dixon's suggestion that all the moss galls were the same species, Akiyama determined that two nematode species could be found within a single gall. The numerous one of these was filamentous and lacked any ornamentation. The other was much thicker, had curved tails (see Figure 1), a vent, and ring-like ornamentation at the terminal position. This second species occurred in only small number. Eggs were present, and because of their size, Akiyama considered them to belong to the former, filamentous species. But he also suspected that those nematodes with the curved tails might not be a gall-forming species, but rather a usual bryophyte dweller.

Figure 50. *Lejeunea tuberculosa*, a species that can host nematode galls. Photo courtesy of Gaik Ee Lee.

Many kinds of nematodes induce the formation of galls (Sheldon 1936; Horikawa 1947) on both mosses [e.g. *Racomitrium lanuginosum* (Figure 51) and *R. heterostichum* (Figure 52) (Deguchi 1977), *Thuidium delicatulum* (Figure 53) (Sheldon 1936; by *Anguina askenasyi*, Steiner 1936, 1937), *Phascopsis rubicunda* (Stone 1980 in southern and western Australia), *Dicranum* sp., *Thamnobryum alopecurum* (Figure 46), *Eurhynchium* sp., *Warnstorfia fluitans* (Figure 43), and *Hypnum cupressiforme* (Figure 14) (Dixon 1905, 1908; Gerson 1982) and liverworts [e.g. *Cheilolejeunea krakakammae* (Asthana & Srivastava 1993) and *Anastrophyllum minutum* (Figure 54; Kitagawa 1974)].

Dixon (1905) reported the nematode *Tylenchus davainii* (Figure 55) to form galls on *Thamnobryum alopecurum* (Figure 46), *Eurhynchium hians* (= *E. swartzii*; Figure 47), and *Hypnum cupressiforme* (Figure 14) in Great Britain. Hedenäs (2000) found 59 individuals of the moss *Abietinella abietina* (Figure 56-Figure 57) (6.6% of those examined) to have nematode galls in the apices of their vegetative branches. Typically, where one gall existed, numerous ones could be found.

Figure 60. *Bryum argenteum* gall. The cell walls are thickened and the leaves and stem apex have a different morphology from uninfected plants. Two C-shaped nematodes can be seen at left, collected near Temascalapa, Mexico. Photo courtesy of Claudio Delgadillo Moya.

Stone (1978) commented that nematodes produced similar galls on male plants of *Bryum pachytheca* in Australia, again resembling cleistocarpous capsules. Both

Stone (1980) for *Phascopsis rubicunda* and Delgadillo (Bryonet 1996) for *Bryum argenteum* (Figure 58-Figure 60) reported that the cell walls were thickened. Stone reported that the stems of *Phascopsis rubicunda* were hollow and necrosed, cell walls were reddened and glossy, and inner leaves were ecostate, and like Delgadillo, she considered the galls to resemble cleistocarpous capsules.

As I thought I was drawing this chapter to a close, a new report appeared in the Australasian Bryological Newsletter. Jolley and Hodda (2009) found nematode galls on a tiny Australian moss called *Stonea oleaginosa* (Figure 61-Figure 63), a fitting name commemorating Ilma Stone, who had reported nematodes in this moss under the moss name of *Tortula oleaginosa* (Stone 1978). This moss from the salt bush and mallee in Southern Australia is inconspicuous (<1 mm) as it hides among the sand grains, often nearly buried.

As in *Phascopsis rubicunda*, Stone (1978) had reported hollow, elongated stems, but she had not observed galls. Like Delgadillo and Stone for other species of moss, Jolley and Hodda (2009) described the galls as resembling cleistocarpous moss capsules (Figure 63). And as in *Phascopsis rubicunda*, the galls of *Stonea oleaginosa* (Figure 62-Figure 63) are modified leaves that are very broad, with thick cell walls. I have to wonder if some of those unidentifiable mosses I have seen in the field with what I thought were developing sessile capsules may have been bearing galls – did I really explore them thoroughly enough?

Figure 61. *Stonea oleaginosa*, a microscopic moss. Photo by Helen Jolley, with permission.

Figure 62. Gall leaf of *Stonea oleaginosa*, caused by the nematode *Nothanguina* sp. nov. Photo by Helen Jolley, with permission.

Figure 63. Leaf gall of the nematode *Nothanguina* from the moss *Stonea oleaginosa*. Note the encysted nematodes within. Photo by Helen Jolley, with permission.

Jolley and Hodda (2009) determined the nematode to be a species of *Nothanguina* (Figure 64), a species that occurs on several Australian moss taxa, including *Phascopsis rubicunda*, and was a species as yet undescribed. (That is coming soon.) The genus is known to house up to five female adults, usually about the same number of males, and numerous eggs and juveniles in one gall. But in galls on *Stonea oleaginosa* (Figure 61-Figure 63), only female nematodes are known.

In *Stonea oleaginosa* (Figure 61-Figure 63), the galls are placed amid the archegonia of the moss, possibly modifying archegonia to inhibit fertilization. By interesting coincidence, only female plants are known in this moss, and inhibition of fertilization seems unnecessary, unless galls were so frequent that useless males were lost through evolution. Rather, females produce upper leaves that are modified into propagules that are rich in oils and break off the plant easily (Stone 1978). Could it be that some hormone inhibits male development in the moss and subsequently in the nematode? It would be interesting to follow the development of the gall to understand how tissues are modified to make the gall tissues and propagules.

Figure 64. *Nothanguina* sp. nov. from *Stonea oleaginosa*. Photo by Helen Jolley, with permission.

Niklas Lönnell (pers. comm. 26 March 2012) described a nematode gall on *Microbryum floerckeanum* (Figure 65). This moss had a structure that looked like a strange capsule, but it proved to be a structure with a nematode resident.

Figure 65. *Microbryum floerckeanum* with capsules, home of a nematode gall. Photo by David Holyoak, with permission.

It appears that even *Buxbaumia aphylla* (Figure 66) may host nematodes. Misha Ignatov (Bryonet 7 April 2017) observed gametophytes that resembled sea urchins (Figure 67) and had no trace of sporophytes. Instead, a nematode was often present inside (Figure 68). These occurred in September when the temperature was *ca.* 10°C in their Middle European Russia location.

Figure 66. *Buxbaumia aphylla* showing nearly mature capsules. The gametophyte is merely a protonema (threadlike structure) and the leafy plants seen here belong to other mosses. Photo through public domain.

Unfortunately, few of the bryophyte gall-formers have been identified, so we don't know if they are unique to bryophytes. It is likely that at least some are. Ernie Bernard at the University of Tennessee is currently working with nematode galls from the moss *Hypnum* sp. (Paul G. Davison, pers. comm. 22 January 2012).

Terrestrial Moss Inhabitants

Hodda (2003) lists only three bryophytes as hosts for nematodes: *Barbula* sp. (Figure 69) – *Aphelenchoides* sp. (Figure 28); *Tortula* sp. (Figure 70) – *Aphelenchus* sp. (Figure 32), *Aphelenchoides* sp.; *Grimmia pulvinata* (Figure 71) – *Laimaphelenchus pini*. But Kinchin (1992) reported that nearly all moss samples from the British Isles contained nematodes, often in large numbers.

Figure 71. *Grimmia pulvinata*, a moss that hosts nematodes. Photo by Michael Lüth, with permission.

Eyualet-Abele *et al.* (2006) reported that *Tripylella arenicola* occurs on moss as well as in soil. Many aquatic taxa also are able to survive in the wet habitat provided by moisture held in capillary spaces among bryophyte leaves. I was able to document eighteen genera (Table 3) that have species known in and around moss clumps. There are most likely more that have never been identified, or even found.

Peatlands

Some of the ubiquitous nematodes reside in peat, but others are inhibited by the low pH. Glatzer and Ahlf (2001) found that the nematode *Caenorhabditis elegans* (Figure 72) was inhibited in growth in the sediments. When they tested eighteen different sediment combinations that mimicked those available, the optimum for growth and successful reproduction was a mixture with 5% *Sphagnum* peat (Figure 5), suggesting that this nematode may actually benefit from some characteristic of the peat. Nematodes such as the mycophagous *Aphelenchoides compositicola* and many saprophytic nematodes can be a problem in peat used for culture of mushrooms and must be eliminated with chemicals such as ethylene oxide (Nikandrow *et al.* 1982).

Figure 72. *Caenorhabditis elegans*, a nematode that seems to benefit from some properties of *Sphagnum*. Photo by Kbradnam, through Creative Commons.

Some individuals coil up inside the hyaline cells of *Sphagnum* leaves (Figure 73), and nematodes even deposit eggs within these cells (Hingley 1993). Eggs of these species survive long periods of drought, anaerobic conditions, and repeated freeze-thaw cycles. Even adult worms can survive unfavorable conditions by encysting and decreasing fats, glycogen, and glucose, increasing glycerine and trehalose, and assuming a coiled position (Crowe *et al.* 1984).

Figure 73. *Sphagnum papillosum* leaf cells. Nematodes may live in the hyaline cells. Photo by Ralf Wagner <www.drralf-wagner.de>, with permission.

As noted earlier, although there are about 30,000 species of nematodes worldwide, only about 30 species are known from *Sphagnum* (Figure 5) (Hingley 1993). Knowledge about specific taxa on other mosses is likewise limited (Table 3), but Coleman pointed out in 1971 that our knowledge about nonparasitic nematodes in soils in many parts of the USA is nonexistent. With the important role they are perceived to play in soil compared to mosses, it is hardly surprising that knowledge about those among mosses is somewhat scant.

Woodland peat mosses are a somewhat preferred community (Hingley 1993). Some of these worms feed on detritus while others are predatory, feeding on protozoa and small invertebrates. The herbivorous species apparently never feed on the mosses. Nevertheless, nematodes living in the microbiotic soil crusts of prairies are known to eat moss rhizoids, among other things (Bamforth 2003).

Global Warming

Global warming has been a concern for the peatland habitat at all levels. Sohlenius and Boström (1999a) investigated the effect a rise in temperature might have on nematode communities of peatlands by transplanting peat blocks from northern Sweden to nine warmer sites within that country. After one year, they found that in all but the northernmost transplant site, these transplants resulted in increased numbers, but had no influence on species composition. The most abundant of the 35 taxa were *Plectus* (Figure 3) and *Teratocephalus* (Figure 17) (Sohlenius & Boström 1999b).

Hence, it appears that temperature alone may not have a serious effect on nematodes, but they cautioned that other changes in the ecosystem could alter the nematode communities. Furthermore, tardigrades, known to prey on nematodes, also increased in numbers, possibly damping

the effect of temperature on the nematodes (Sohlenius & Boström 1999b). I would consider that one year is insufficient basis for a long-term assessment as the greater temperatures could lie within normal variation from year to year. Even Sohlenius and Boström (1999b) suggested that seasonal differences and the short duration of the experiment could be misleading. Numbers of nematodes increased in autumn, especially in warm sites, with a positive relationship between nematode numbers and temperature in November. Likewise, in spring there were more nematodes in warm sites than in cooler ones.

Population Size

In an ombrotrophic mire in northern Sweden, Sohlenius *et al.* (1997) found high densities of nematodes, especially in the moss surface layer. In fact, the nematodes dominated with a mean abundance of 9.4 million individuals per square meter. These were represented by 34 taxa. The surface layer was characterized by similar numbers of fungal vs bacterial feeders. By contrast, bacterial feeders dominated the underlying peat.

Aquatic Nematodes

In New Zealand alpine streams, nematodes were the most abundant moss-dwelling invertebrate (40.6%), exceeding **all** the insects (Suren 1993). This number was higher above the treeline (43.6%), but was exceeded by the Chironomidae (midges) below the treeline. In an unshaded alpine stream at Arthur's Pass National Park on South Island, NZ, Chironomidae were the most abundant (57.6%), with nematodes in second place (22.1%) (Suren 1991b). The same relationship existed in a shaded stream, but the Chironomidae became more dominant (63.4%) compared to only 12.5% nematodes. Numbers of nematodes were lower and their ranks dropped in the gravel in both streams. This was supported by the significant correlations of nematodes with bryophytes compared to gravels.

In the Czech Republic, Vlčková *et al.* (2001/2002) found similar percentages of nematodes among *Fontinalis antipyretica* (Figure 74) plants, with 38,350 per mL (14.6% of total meiofauna) in one stream and 31,813 per mL (6.4%) in another.

Some aquatic mosses have a somewhat unique fauna. In a comparison of communities associated with *Fontinalis antipyretica* (Figure 74) and those of associated gravel, Linhart *et al.* (2000b) found six genera only in mosses and five only in gravel. Nine genera occurred in both habitats. The most abundant genera were the same as many terrestrial genera and Linhart *et al.* (2000b) considered that their feeding strategy explained locations of dominant genera: *Plectus* (Figure 75) – bacteriophagous, in moss; *Mononchus* (Figure 76), *Tobrilus*, and *Tripyla* (Figure 77) – predators, in gravel; *Eudorylaimus* (Figure 78) – plant feeders, in moss; *Dorylaimus* (Figure 7) – omnivorous, both substrates. Table 4 lists taxa of nematodes known from aquatic bryophytes.

A study comparing artificial and real mosses [*Fissidens rigidulus* (Figure 79), *Cratoneuropsis relaxa*, *Bryum blandum* (Figure 80)] in New Zealand suggests that mosses may indeed have something unique to offer the nematodes (Suren 1991b). In three out of four trials, involving two streams, the artificial mosses made of nylon cord were poor mimics of the bryophyte habitat for the nematodes. Mosses had a mean of 84,000 & 90,000 (2 trials) per m² in mosses compared to 1560 & 2400 per m²

in artificial mosses in one stream and 9840 & 3780 per m² in mosses compared to 1760 & 1320 in artificial mosses in a second stream. While it is unlikely that the bryophytes themselves provided food, they are a good source of periphyton and detritus.

On the other hand, when Hynes (1961) used silk in place of mosses, the percentage of organisms that were nematodes associated with the silk differed little from that associated with the mosses.

Figure 79. *Fissidens rigidulus*. Photo by Bill and Nancy Malcolm, with permission.

Figure 80. *Bryum blandum*, a moss superior to artificial mosses as a nematode habitat. Photo by Jan-Peter Frahm, with permission.

In streams, mosses can serve as nutrient traps, collecting detrital matter that is readily available to tiny organisms such as these (Suren 1991a; Linhart *et al.* 2002b). Food availability may account for moss-dwelling (*Fontinalis antipyretica*; Figure 74) nematodes whose numbers more closely resembled those in the gravel in that Austrian study: 2,850 per m² in the moss and 2,135 per m² in the gravel. When Linhart *et al.* (2000a) considered all meiofauna, mean abundances were as follows: moss at locality 1 – 182,672 individuals per 100 mL of moss, gravel at locality 1 – 1,206 individuals per 100 mL substrate, moss at locality 2 – 390,057 individuals per 100 mL moss. Mosses had more than 150 times as great a meiofauna density compared to the nearby mineral substrate. Nematodes were only about 22% of this moss

meiofauna, but that is still greater than the entire meiofauna of the mineral substrate. Differences in fine particulate organic matter (FPOM, $>30\ \mu\text{m}$) may account for differences in nematode densities. At locality 1, mosses trapped 19 times as much FPOM as the gravel and 3 times as much as the moss at locality 2. Likewise, nematodes at locality 2 comprised only 11% of the meiofauna. Everybody has to eat!

Even aquatic habitats dry out from time to time. Aquatic moss-dwelling nematodes are among the dominant invertebrates and tolerate these drying events in a state of **anhydrobiosis** (Overgaard-Nielsen 1949; Gilbert 1974; Crowe 1975; Nicholas 1975; Wright 1991), a capability that is not typical of other aquatic nematodes (Merrifield & Ingham 1998).

The Antarctic

Mosses are an important habitat for nematodes in the Antarctic (Figure 81). But not all mosses are created equal, and biologists in the Antarctic have been very aware of these differences. Caldwell (1981a) compared nematodes in moss turf with those in moss carpet on Signy Island. These two ecosystems differ markedly, with the carpets averaging $220\text{--}236\ \text{mg m}^{-2}$ of nematode biomass and the turf $105\text{--}355\ \text{mg m}^{-2}$, showing a much greater variation. Despite these differences, the annual nematode population respiration was very similar: $1726.1\ \mu\text{L O}_2\ \text{m}^{-2}\ \text{d}^{-1}$ in the turf and $1761.0\ \mu\text{L O}_2\ \text{m}^{-2}\ \text{d}^{-1}$ in the carpets, accounting for 16% and 35% of metazoan respiration in the turf and carpet, respectively.

In Wilkes Land, East Antarctica, Petz (1997) found the highest abundance of soil microfauna occurred in mosses, with 513 nematodes per gram dry "soil" (moss). Distribution was non-random because the microfauna were often strongly correlated with each other and were related to water and organic matter. Air temperature and pH more likely had indirect effects through the food web, especially the detrital component.

Figure 81. Nematode from the terrestrial moss *Sanionia uncinata* on the Barton Peninsula of King George Island, Antarctica. Photo by Takeshi Ueno, with permission.

Spaull (1973) found 30 species in 19 genera among mosses on Signy Island, with summer population densities of $0.48 \times 10^6/\text{m}^2$ in the upper 6 cm of *Chorisodontium* (Figure 38)-*Polytrichum* (Figure 82) turf compared to $7.47 \times 10^4/\text{m}^2$ in soil beneath the grass *Deschampsia antarctica*. Nevertheless, in alpine areas in *Schistidium apocarpum* (as *S. grande*; Figure 83), Hoschitz (2003) and in the

Antarctic (Figure 84; Caldwell 1981a, b), bryophytes and lichens provide a protected shelter in which nematodes may survive. In the Austrian Alps, *Plectus* sp. (Figure 3) and *Eudorylaimus* sp. (Figure 78) survive the extreme conditions of the Alps. *Plectus murrayi* (Figure 85) is likewise a moss inhabitant at Victoria Land in the Antarctic (Melanie Raymond, pers. comm. 2008). *Teratocephalus tilbrooki* and *Plectus antarcticus* coexist in the shelter of moss cushions and mats (Pickup 1990b) and were the most abundant taxa on Signy Island in the Antarctic (Spaull 1973). However, on Signy Island *Plectus* (Figure 3) reaches its greatest abundance in moss carpets and *Teratocephalus* (Figure 17) in moss turf, suggesting that moss form plays a role, most likely in moisture relations, but possibly also in temperature relations.

Figure 84. Moss (reddish) and lichens. This photo shows a typical habitat for *Plectus murrayi* and occasionally *Panagrolaimus davidi* and *Eudorylaimus antarcticus*. The photo was taken near Gondwana Station, Terra Nova Bay, Victoria Land. Photo by Melanie Raymond, with permission.

Figure 85. Two individuals of *Plectus murrayi*, an Antarctic endemic that is often found in moss beds. Photo by Melanie Raymond, with permission.

The common presence of *Teratocephalus* (Figure 17) seems to be unique to the Antarctic, where it is abundant in the moss turf (Spaull 1973). It survives the frigid cold by a fast dehydration strategy that reduces damage by ice crystals (Wharton 2003). It would be interesting to determine how this fast dehydration relates to its choices of moss species/form. *Ditylenchus* sp. B occurs in more exposed aerial thalli of lichens (Spaull 1973). The latter species exhibits supercooling ability, whereas the moss-dwelling species both have bimodal supercooling point distributions. The high group supercools to $\sim 7^{\circ}\text{C}$ and the other at $\sim 22^{\circ}\text{C}$. Pickup (1990b) suggests that field temperatures are likely to reach even lower levels than that.

Spaull (1973) found *Teratocephalus*, *Plectus* (Figure 3), and *Eudorylaimus* (Figure 78) in all the bryophyte sampling locations on Signy Island, with the former two accounting for more than 50% of the nematodes among

mosses. Cushion-formers such as *Andreaea* (Figure 86) and *Grimmia*, on the other hand, had a nematode community where *Plectus* comprised less than 3%. A similar small percentage of *Teratocephalus* occurred in *Bryum*. *Eudorylaimus* is more abundant in moss carpets and cushions than elsewhere. *Eudorylaimus* sp. C, in particular, seems to prefer cushions of *Andreaea* (Figure 86), *Grimmia*, and *Tortula*, where it comprises 45% of the individuals in that genus, but it is rare elsewhere (Spaull 1973). *Antarctenchus hooperi* is less restricted, being common in cushions of *Andreaea* and *Tortula* and in carpet-forming *Calliergon* (Figure 37)-*Calliergidium* (probably *Warnstorfia austrostraminea*), but it is likewise rare or absent elsewhere. The tylenchids [*Antarctenchus*, *Aphelenchoides*, *Ditylenchus*, *Tylenchus* (Figure 18)] are more abundant in moss turf than elsewhere, whereas the monhysterids [*Monhystera* (Figure 16), *Prismatolaimus*] are less numerous in moss turf than in other bryophyte formations.

Figure 86. *Andreaea gainii* (blackish) in Antarctica, showing cushion growth where nematodes may lurk. Photo from Polar Institute through Creative Commons.

The genus *Eudorylaimus* is particularly common in the Antarctic. Melanie Raymond (pers. comm. 2008) found *Eudorylaimus antarcticus* (Figure 87) among mosses in the Antarctic. In the McMurdo Dry Valleys, *Eudorylaimus* species are unaffected by vegetation type, including bryophytes (Simmons *et al.* 2009). *Plectus* (Figure 3) species, although bryophyte dwellers, are more abundant in algae. Its abundance above ground and below ground were significantly correlated in both the microbial mats and mosses. That is, the above ground abundance was a good indicator of below-ground abundance. The ability of *Plectus* species to migrate vertically is likely to benefit it in this changeable and extreme climate (Overgaard-Nielsen 1948; Kinchin 1989).

Kito *et al.* (1996) found a new species of *Eudorylaimus* (*E. shirasei*), bringing the Antarctic total in that genus to seven. Some of the specimens for this new species were collected from moss clumps at Cape Ryugu on the Prince Olav Coast, East Antarctica. It is odd among the members of *Eudorylaimus* (Figure 78) in having multinucleate intestinal cells, a factor that could simply have been overlooked elsewhere, but that raises questions about the possible effects of the severe Antarctic climate in causing or selecting for this multinucleate state. New species of moss nematodes will most likely continue to be described, particularly in the Antarctic.

Sohlenius and Boström (2006) found that 64% of 91 moss cushion samples from nunataks in East Antarctica had nematodes in them. In this harsh environment, 8% of the samples had no microfauna (nematodes, rotifers, or tardigrades) at all. The researchers considered the patchy distribution of nematodes and other organisms among the mosses to be a product of patch dynamics where stochastic processes determined colonization. They further supported this notion with the fact that nematodes in different cushions had different developmental stages, but it is possible that these may reflect differences in temperature that would affect rate of development. Competition with tardigrades that share their food sources seems also to be a limiting factor within a cushion.

Figure 87. *Eudorylaimus antarcticus*, a common nematode among Antarctic mosses. Photo by Melanie Raymond, with permission.

In nunataks of Vestfjella, Heimefrontfjella, and Schimacher Oasis in East Antarctica, the faunal communities associated with mosses lacked organization and represented early stages of succession (Sohlenius *et al.* 2004). In these exposed nunatak moss habitats, species of *Plectus* (Figure 3) and *Panagrolaimus* (Figure 20) were the most frequent of the nematodes, occurring in 26% and 5% of the samples, respectively.

Dangers Lurking among Bryophytes

Fungal Interactions

Who would think that fungal treachery looms amid the mosses! Although nematode-trapping fungi are known worldwide, they were unknown in the Antarctic until 1973. In their examination of Signy Island mosses, Duddington *et al.* (1973) found nematode-trapping fungi on a number of moss species: *Brachythecium austrosalebrosum*, *Calliergon sarmentosum* (Figure 37), *Sanionia uncinata* (Figure 88) (all hydrophytic), and *Andreaea depressinervis* (mesophytic-xerophytic). These fungi sport rings (Figure 89) that are able to constrict around nematodes that wander through them, thus ensnaring them. Several specimens of the predatory *Thyronectria antarctica* var. *hyperantarctica* had indeed trapped nematodes within their mossy home. Spaul (in Duddington *et al.* 1973) also noted fungi with such loops in a sample of the leafy liverwort *Cephaloziella* sp. (Figure 90) mixed with the lichen *Cladonia metacorallifera* from Terra Firma Islands in Marguerite Bay (latitude 68°42'S).

Figure 88. *Sanionia uncinata*, common home of nematodes and nematode-trapping fungi. Photo by Michael Lüth, with permission.

Figure 89. Nematode-trapping fungus, possibly *Monacrosporium cionopagum*, isolated from the moss *Calliergidium cf. austro-stramineum* on Signy Island in the Antarctic. Redrawn from Duddington *et al.* 1973.

Figure 90. Leafy liverwort *Cephaloziella turneri*, member of a genus that is home to nematode-trapping fungi. Photo by Michael Lüth, with permission.

The Antarctic sports at least 18 taxa that either trap nematodes or become endozoic parasites of members of this phylum (Gray *et al.* 1982). Many of these have been found among the mosses. Among the Hyphomycetes that snare nematodes, *Monacrosporium ellipsosporum* and *M. cionopagum* were the most widely distributed. The most frequent of the endozoic taxa was *Harposporium anguillulae* (Figure 91). These fungi seemed to have some bryological preferences, with *M. ellipsosporum* preferring calcicolous mosses. In fact, it appears that acidic habitats might provide a safe haven - the nematophagous fungi were absent from permanently saturated moss carpets and the strongly acidic turf-forming mosses of Polytrichaceae.

Figure 91. *Harposporium anguillulae*, fungal parasite with conidiophores and conidia, on a dead nematode. Photo by George Barron, with permission.

These ensnaring fungi are not restricted to the Antarctic. Duddington (1951) considered the abundance of such fungi among mosses to result from the large amount of water among the shoots and leaves, making the environment favorable for both nematodes and fungi. In the Antarctic, the mosses provide the added benefit of being warmer than the air in summer.

Both nematodes and fungi live among *Sphagnum* (Figure 5). And here we also find nematode ensnaring fungi. In particular, the genus *Sporotrichum* (Figure 92), known for causing **sporotrichosis** in those who handle

Sphagnum, is able to trap the nematodes that reside there (Dollfus 1946).

Figure 92. The nematode-ensnaring fungus *Sporotrichum* sp. in action. This is the same genus known so well for causing sporotrichosis in people who work with *Sphagnum*. Image from Dollfus 1946.

Other fungal treachery looms, although not so dramatically. Several species of nematode-dwelling parasites await. Among these on Signy Island in the Antarctic are *Harposporium* sp. (Figure 91) and *Acrostalagmus* sp.

The widespread fungus *Catenaria anguillulae* (Figure 93-Figure 96) parasitizes nematodes (Sayre & Keeley 1969). Its **zoospores** (swimming spores) are attracted to the nematodes by exudates from the mouth, anus, or other opening of the nematode, including wounds. Once attached, the zoospores encyst, typically in clusters. These eventually germinate and penetrate through the nearby orifice to attack their host, the nematode. Success of the fungus is favored by high temperatures (optimum at 28°C) and moisture, the latter provided by bryophytes.

Safe Site from Predation

One advantage to living in a habitat with only small chambers is that large organisms don't fit. This affords some protection from predation, but nematodes are definitely not free from it. Some are preyed on by co-habiting tardigrades (Doncaster & Hooper 1961); under experimental conditions, one tardigrade, *Macrobiotus richtersi* (Figure 97), consumed 61 nematodes per day – no small threat (Sánchez-Moreno *et al.* 2008). Others must surely fall prey to insects. Even the protozoa may be a

threat (Yeates & Foissner 1995). The Testacea (amoebae) can ingest nematodes, attacking mostly from the tail. In New Zealand, it was the protozoa *Nebela* (*Apodera*) *vas* (Figure 98) and *Diffugia* sp. (Figure 99) that waged the attacks, mostly on *Dorylaimus* (Figure 7) and *Plectus* (Figure 3) species among common bryophyte inhabitants.

Figure 97. *Macrobiotus richtersi*, a moss-dwelling tardigrade that devours numerous nematodes. Photo through Creative Commons.

Pollution

Even aquatic organisms can suffer from air pollution. Steiner (1995b) tested responses of several groups of aquatic moss-dwelling invertebrates to SO_2 pollution. Nematodes, rotifers, and tardigrades changed their community composition. SO_2 at 0.225 ppm for 18 months significantly reduced the numbers of several nematode species. Responses were not so clear at 0.075 ppm, with some species increasing and others decreasing in numbers.

Lead can also considerably alter the moss-dwelling nematode community. Zullini and Peretti (1986) found that increased lead content in the moss resulted in a significant decrease in diversity, richness, and biomass, but not the density. The *Dorylaimina* suborder suffered the most by far.

Summary

Among the most common bryophyte-dwelling nematodes are members of the genera *Plectus* and *Eudorylaimus*. These nematodes are usually less than 1 cm in length and many are much smaller. Although bryophyte-inhabiting nematodes are rarely studied, they are common there and can reach 480 individuals in just 1 g of moss.

Many nematodes adhere to the mosses with an **adhesive organ**. Water is their most limiting factor. They can migrate vertically among the bryophytes to adjust their moisture level. Some migrate from rhizoids to canopy when the moss is too wet, some move from the rhizoids to the stems when the moss is saturated, and some never leave the rhizoids. The most specialized nematodes, such as *Plectus rhizophilus*, live in the bryophytes that experience the most events of desiccation, such as the epiphytes.

Members of *Plectus* are quick driers. Acrocarpous cushions are more favorable habitats than pleurocarpous feather mosses. Slow dehydration is important to their survival in a state of **anhydrobiosis**; some achieve this by **coiling**. Water is also necessary for their motility, where they can swim, crawl, inch, or bend to move. Some survive by living and reproducing inside the hyaline cells of *Sphagnum*. Eggs likewise have a long survival and can even survive lack of oxygen.

Food strategies are mostly bacteriovores and predators. Some are **mycophagous** or **saprophytic**. Woodland mosses often feed on the detritus. They seem to do best in habitats with a low C:N ratio in the food source. Stream mosses serve as nutrient traps that favor nematodes.

Bryophytes can provide a safe site against would-be predators. However nematode-trapping fungi and fungal parasites may loom there. Bryophytes can also make a safe site by buffering the temperature both in the bryophyte and in the soil beneath. Even antheridia can serve as habitat, and in other cases the nematodes nestle among archegonia to make nematode galls. Galls seem to occur on many species of bryophytes and house nematodes that are often less than 1 mm long.

Numbers usually are highest in summer and lowest in winter, with some species migrating to greater depths in winter. Some species among *Panagrolaimus* can freeze and recover. Others, such as one *Aphelenchoides*, can tolerate temperatures ranging from meltwater to 61.3°C. **Trehalose** can protect some from freezing damage as well as from dehydration damage, most likely by stabilizing membranes.

Acknowledgments

Jan-Peter Frahm helped me obtain the photographs of the nematode and *Pleurozia* locales. Aldo Zullini gave me a valuable critique of an early version, provided images, and suggested some older literature I would probably not have found otherwise. George Barron helped me sort out the fungal stories. Tom Powers provided me with additional sources of images, helped with nomenclature, and gave me permission to use the images on the <nematode.unl> website. Helen Jolley provided the story of nematode galls on *Stonea*. Melanie Raymond provided me with images and information to tell the Antarctic story. Bryonettors have been wonderful in making their photographs available to me and seeking photographs from others.

CHAPTER 4-4

INVERTEBRATES: ANNELIDS

Figure 1. *Aeosoma*, an aquatic annelid that sometimes inhabits mosses such as *Fontinalis*. Photo by Yuuji Tsukii, with permission.

Annelida – Segmented Worms

Among the bryophyte-dwelling **Annelida** are worms that qualify as **mesofauna** (Figure 1). These are organisms, also including **mites** (**Acari**) and **springtails** (**Collembola**), that can occupy pore spaces that have a diameter of less than 2 mm (Briones 2006). In other words, these are small annelids, primarily in the subclass **Oligochaeta**.

Among the annelids, the family **Enchytraeidae** is a worldwide but little known family that can be found among the bryophytes. They reach their greatest abundance in the moist temperate soils (Block & Christensen 1985). Unlike the large, pink-red earthworms, these worms are usually grey-white (Briones 2006). Their identification is based primarily on internal characters, hence making them unknowns to the casual observer. And they must be live to be identified because preservatives make them opaque. **Enchytraeids** are important consumers in the Arctic tundra sedge-moss meadow habitat (Ryan 1977).

Although annelids are not as common as some other invertebrates in bryophytic habitats, there are at least some notable exceptions. *Fontinalis* (Figure 2) has been known to house 67 **oligochaetes** and 5 **leeches** (**Hirudinea**) in a square meter (Berg & Peterson in Macan 1966). Moss balls of *Drepanocladus* (Figure 3) and *Fontinalis* also house these annelids. In New Zealand Suren (1993) found **oligochaetes** to occupy 12.3% of the bryophyte fauna.

Three of the most common Enchytraeids in peatlands are *Cognettia sphagnetorum*, *Marionina clavata*, and *Achaeta eiseni* (Figure 4; Briones *et al.* 1997; Briones pers. comm. 17 March 2009). Nevertheless, Standen and Latter (1977) demonstrated that the common *C. sphagnetorum* is less common among *Sphagnum* than it is among

Eriophorum or *Calluna* in a blanket bog at Moor House in Cumbria. *Marionina clavata* is aided in its survival by laying two types of eggs, one taking ~112 days and another taking ~271 days for the worms to reach maturity at 10°C, thus potentially providing them with two different sets of conditions (Springett 1970). A tolerance for low pH levels in *C. sphagnetorum* and *M. clavata* (2.9-4) suggests their suitability for peatland habitation (Graefe & Beylich 2003).

Figure 2. Brook moss, *Fontinalis duriaei*, where annelids can be common. Photo by Janice Glime.

In a Dutch Scots pine forest these three had a vertical zonation pattern in the same order, with *Cognettia sphagnetorum* (Figure 5) being the first to colonize new needle litter (Didden & de Fluiter 1998).

Water Relations

Very small annelids (**Enchytraeidae**) occur among *Sphagnum* plants. Springett (1970) found six species associated with peat. The moisture changes can result in diurnal vertical migrations (upwards at night), at least in *Cognettia sphagnetorum* (Springett *et al.* 1970; Hingley 1993; Briones *et al.* 1997), a widespread species known from aquatic habitats, *Sphagnum* peatlands, and on South Georgia in the Antarctic from *Polytrichum* (Figure 6) clumps (Block & Christensen 1985).

Cognettia sphagnetorum (Figure 5) has no cocoon stage, thus permitting it to take full advantage of the growing season in cold, wet climates of places like the Antarctic (Hingley 1993).

Several species of *Achaeta* (Figure 4) are morphologically adapted to drought by having a thicker cuticle. However, it appears that physiological adaptations to drought in the enchytraeids may be limited.

On the other hand, they seem also to be intolerant of too much water. In a study on the effects of drainage on the mesofauna of peatlands in Finland, Silvan *et al.* (2000) found that water-level drawdown resulting from peatland drainage caused an increase in the numbers of all the mesofauna studied, including the **Enchytraeidae**, with

numbers ten times as great after 60 years. Because of a proportionally larger increase in Collembola, the proportion of **Enchytraeidae** in the fauna dropped slightly. More than 60% of the **enchytraeids** occurred in the top 4 cm of the peat. Within two years after water was returned to a drained peatland, the numbers dropped abruptly to levels near that of pre-drainage.

Figure 6. Clump of *Polytrichum* that could house annelids. Photo by Michael Lüth, with permission.

Temperature Tolerance

In peatlands and elsewhere, the **Enchytraeidae** are sensitive to temperature, which seems to be a major differentiating factor for population size. *Cognettia sphagnetorum* increases its reproductive rate, most likely through its capability of fragmentation as a reproductive strategy, in response to warmer temperatures (Briones *et al.* 1997). Warming seems to result in greater numbers without a concomitant vertical migration. Despite this advantage, Briones *et al.* (2007) considered that an increase in temperature to a maximum mean annual threshold of 16°C could cause total loss of this species from some regions.

Achaeta eiseni, also a peatland species, is resistant to higher temperatures, increasing in numbers as temperatures increase, whereas numbers of *Cernovitoviella atrata* (Figure 7) are greatly reduced by higher temperatures (Briones 2006, pers. comm. 17 March 2009). The latter species is inhibited by its inability to avoid dry conditions, resulting in death at high temperatures (Briones *et al.* 1997).

Figure 7. SEM image of *Cernovitoviella atrata*. Photo by María Jesús Iglesias Briones, with permission.

Cognettia sphagnetorum and *C. glandulosa* (known from moss banks and elsewhere; Block & Christensen 1985) are also prepared for the seasonal inundation of the peatlands. They are able to produce red blood under very wet conditions (Healy & Bolger 1984) to survive the low oxygen conditions that arise. Healy and Bolger showed that 35% of the Irish taxa of **enchytraeids** preferred habitats that were submerged or frequently flooded.

Reproduction

Any successful inhabitant of mosses must have a life cycle that is coordinated with the moss habitat. One advantage to some **Oligochaetes** is their ability to reproduce by fragmentation. Christensen (1959) pointed out that the **Enchytraeidae** contrast with other Oligochaeta in their inability to reproduce by fragmentation. At the same time, he reported on asexual reproduction in three species among the 78 Dutch **Enchytraeidae** studied by that time. In fact, one species apparently had only asexual reproduction, by fragmentation. Honda *et al.* (2003) described fragmentation in *Enchytraeus japonensis*. This worm uses stem cells to accomplish its regeneration. Segments form as organs regenerate. They showed that cells with newly synthesized DNA appeared first as a ring in the tail area. The labelling then migrated, suggesting that the formation of segments occurs before organ regeneration. This regeneration cycle can take as few as ten days (Myohara *et al.* 1999; Nakamura 2004), and both ends of the worm can regenerate (Nakamura 2004). Nakamura (2004), in a six-and-a-half-year study, determined that the average fragmentation cycle length for the species was 20.4 days. The maximum number of fragmentation events in the life of the worm was 122, with an average of 35.3. The number of fragments in one event was 6.3. The cycle can repeat until the worm is starved or the population density is low, at which time it will differentiate gonads and reproduce once sexually (Honda *et al.* 2003). At this time I don't know how the number of annelid species using fragmentation relates to bryophytes as a habitat.

Food Relations

Springett and Latter (1977) experimented with various fungal diets on agar and found they could not keep many *Cognettia sphagnetorum* alive on the combinations they

tried. Exudates from the mycelia of Basidiomycetes proved most harmful, resulting in 100% mortality in 20 days. They concluded that micro-organisms did not form any part of the natural diet of moorland Enchytraeidae. Hingley (1993) considered peat to be a poor source for food (Hingley 1993), with the moss itself seemingly of poor quality for annelids; only stem material of *Sphagnum* has been found in gut analyses (Figure 8; Standen & Latter 1977). Nevertheless, these worms feed on items that are generally unpalatable to other animals (Hingley 1993). After these are processed by the **annelids**, the feces are colonized by fungi and bacteria, which are in turn ingested by **Protozoa**, **rotifers**, and **nematodes**. Hence a food web emerges and peat is processed.

Briones (pers. comm.) challenged the suggestion that peatlands offered poor food quality, stating that enchytraeids are known to consume bacteria and dead organic matter, both of which are associated with the peatlands. Briones *et al.* (2004) used ^{14}C to match the gut contents with the substrate and found that most of the assimilated food came from sediment that is 5-10 years old. Their vertical movements in response to changing moisture did not affect their food source, but at higher temperatures it seemed that they had altered their carbon source since there was a lower ^{14}C enrichment with depth.

Figure 8. Stem section of *Sphagnum contortum*, like those found in an annelid gut. Photo by Michael Lüth, with permission.

Guts from worms in substrata of *Sphagnum*, *Calluna*, and *Eriophorum* at Moorhouse, Great Britain, all contained mixed decomposing litter, including cellulosic or humified plant material, amorphous humus, and associated fungal mycelia, again suggesting equal nutritional availability in the peatlands (Standen & Latter 1977). The *Sphagnum* stem material extracted from the gut of *Cognettia sphagnetorum* (Figure 5) causes one to question if these stems provide nutrition or merely serve to help in grinding other foods, much like the role of sand. In any case, the very high numbers of worms reached in peatlands provides witness that these are not bad systems for **enchytraeids** (Briones pers. comm.).

In the blanket bog at Moor House, Great Britain, the numbers of *Cognettia sphagnetorum* were significantly less in *Sphagnum* than they were in *Calluna* and *Eriophorum*, suggesting that *Sphagnum* was not an ideal habitat. However, when these were converted to numbers

per gram dry weight of substrate, there were no significant differences among substrata. The species was in greatest numbers in association with older decomposing litter of *Eriophorum* and *Calluna* and with surface layers of *Sphagnum*. The numbers of worms correlated weakly with unstained fungi, cocci, and moisture.

Sampling

Annelids are generally extracted from core samples. Researchers typically use some modification of a Berlese funnel (Didden *et al.* 1997; See Chapter 4-1). For annelids, a wet funnel is the most common, as suggested by O'Connor (1955) and Overgaard-Nielsen (1948, 1949). The moss samples are placed in a water-filled funnel and the temperature is gradually increased to about 40°C (~3 hours). The high temperature causes the worms to vacate the mosses and drop down to the funnel. In organic soils, the efficiency is often 95% or more (Healy 1987), but can be less than 50% in some samples (Willard 1972 in Didden *et al.* 1997). Variations on this include soil cores in an earthenware cylinder suspended over a heated water bath (O'Connor 1955). The worms are driven upward to a layer of cool sand on top of the soil core. The worms are recovered by washing them from the sand.

An alternative method is to squeeze water from the mosses onto a microscope slide or into a Petri dish (Hingley 1993). Repeated extraction can be accomplished by soaking the moss in water and squeezing again, repeating this for a standard number of times. A paint brush or strip of filter paper can be used to transfer them to a drop of water on a slide. The sample could be transferred to a test tube, then centrifuged. A concentrated sample can then be removed from the bottom of the test tube with a long pipette.

Andrew and Rodgerson (1999) tested three methods of extracting invertebrates from Tasmanian bryophytes: Tullgren funnels, sugar flotation, and kerosene phase separation. When two samples were combined, the kerosene phase separation method extracted more total individuals, more **mites**, and more **Collembola**. Nevertheless, only three of the nine taxa were found in the single samples, suggesting that replicate samples are needed. Andrew and Rodgerson attributed this to differences caused by spatial scales. They further found that there is site scale variation at 2 km or less that may be more important than altitudinal variation.

Habitats

Aquatic

Aquatic bryophytes can serve as annelid (subclass Oligochaeta) habitat, especially for **Naididae**, reaching as much as 33% of the invertebrate fauna (1968 per dm²) in thick moss vegetation of streams in the West Riding of Yorkshire, UK (Percival & Whitehead 1929). Their numbers were exceeded only by the Chironomidae (midges). This is a sharp contrast to their apparent absence on *Potamogeton* in those streams. Brusven *et al.* (1990) found that annelids were the most common non-insect invertebrate in the South Fork of the Salmon River, Idaho, USA. In Brazil, Gorni and da Gama Alves (2007) collected *Fissidens* and *Philonotis* (Figure 9) in winter and spring. Bryophytes adhering to rocks in the rapids of the Jacaré

Pepira River, Brotas, São Paulo, Brazil, and to a vertical rock wall of a waterfall near the river provided a home for 191 Naididae individuals of *Nais communis*, *Pristinella jenkiniae*, and *P. menoni*. Among the identifiable species, *P. jenkiniae* was dominant, representing 96.8% of all individuals. This species occupied both the submerged mosses of stream beds and the rock wall mosses with little water. But often the annelids are not very common. In *Fontinalis antipyretica* in the Czech Republic, Vlčková *et al.* (2001/2002) found that only about 1.1% of the fauna were annelids in one stream and about 1.4% in another.

Figure 9. *Philonotis fontana*, representing a genus where *Nais communis*, *Pristinella jenkiniae*, and *P. menoni* dwell in Brazil. Photo by Michael Lüth, with permission.

Naididae occupancy of mosses may provide several benefits to these worms. Mosses provide a safe site where the current is reduced in fast water (Vlčková *et al.* 2001/2002; Habdija *et al.* 2004). This is important for a group of organism that lack any adaptations for clinging or anchoring. Abundance and diversity are likely to increase with an increase in moss biomass, and more biomass makes available more periphyton and detritus (Egglisshaw 1969; Suren 1993; Vlčková *et al.* 2001/2002; Linhart *et al.* 2002a, b).

Like Thienemann (1912), I rarely found oligochaetes among the bryophytes in Appalachian Mountain, USA, streams (Glime 1968). But Percival and Whitehead (1929) found that *Eiseniella tetrædra* was a frequent inhabitant among the mosses in shallow water (3-4 cm). Nevertheless, even in thick moss beds, it reached a density of only 6 per dm². The Naididae (*Nais elinguis*), on the other hand, reached as many as 12,000 per dm² among the thick moss beds. Thickness of moss growth, as well as time of year and recent history of river conditions, influenced the density of oligochaetes. Percival and Whitehead suggest that the much smaller numbers of these naidids in the loose moss mats may be due to "feeble" setae and no ability to attach to the moss.

Hynes (1961) compared the oligochaetes, including *Eiseniella tetrædra*, on mosses and silk in a Welsh mountain stream and found little difference in the percentage of organisms, suggesting that the moss need not be a living organism and might only provide a substrate, perhaps with trapped detritus as a food source.

Peatlands

Unlike many other kinds of animals, the annelids are not very diverse in peatlands. Hingley (1993) reported that

only three families of **Oligochaeta** occur in peatlands, with the most common being the **Enchytraeidae**. Duinen *et al.* (2006) found that in Estonia and The Netherlands, only *Cognettia sphagnetorum* occurred in ombrotrophic raised bogs, *i.e.*, in the most nutrient-poor situations. In Estonia, *Nais variabilis* (Figure 10), *Lumbriculus* (= *Lumbricus*) *variegatus* (Figure 11), and species with sexual reproduction occur only in more minerotrophic water bodies with a higher decomposition rate and consequent higher nutrient content. The lagg zone (marginal area around the bog where nutrients are often higher) fares somewhat better, having ten species of oligochaetes. This zone is absent in The Netherlands due to agriculture.

Figure 11. *Lumbriculus* (= *Lumbricus*) *variegatus*, an annelid that is used to feed pets and that lives in minerotrophic peatlands. Photo from Wikimedia Commons.

Prairie Worms

It is possible that mosses may provide refugia for one rare species. The giant **Palouse earthworm** (*Driloleirus americanus*; Figure 12), named because it can reach nearly a meter in length, is the subject of a petition to declare it an endangered species and afford it protection (Palouse Prairie Foundation 2007). Few recent reports of its presence exist. In one such report, however, near Moscow, Idaho, USA, two researchers found it in a somewhat mesic area under forest canopy. The area had abundant mosses and these researchers found several of the worms near the surface

under moss mats when looking for moss-feeding beetles in the Byrrhidae. In drier times it can burrow down as much as 5 m.

Figure 12. The giant **Palouse earthworm** (*Driloleirus americanus*), an endangered worm that seems to seek moisture under mosses in the Palouse Prairie. Photo by Yaniria Sanchez-de Leon, with permission.

Antarctic

As in the peatlands, the **Enchytraeidae** are common in the Antarctic bryophytes. Block and Christensen (1985) found *Cognettia sphagnetorum* in *Polytrichum* clumps and *C. glandulosa* in moss banks. On South Georgia and Signy Island, they found seven taxa in soil and peat, but suspected that five of those had been introduced by human activity on the islands.

Dispersal Agents?

The presence of bryophyte diaspores in earthworm castings suggests a possible dispersal mechanism (During *et al.* 1987). Van Tooren and During (1988) found various spores and vegetative diaspores in the guts of terrestrial earthworms [*Allolobophora caliginosa*, *A. chlorotica*, and *Lumbricus terrestris* (Figure 13-Figure 14)] in The Netherlands. Especially rhizoid tubers and spores occurred. However, it is not clear that these provided any nutritional value to the worms because some remained viable and grew new plants, suggesting digestion was not possible. Rather, they most likely were simply mixed in with the soil that was being consumed.

Figure 13. *Lumbricus terrestris*, the common earthworm, is able to transport various diaspores, thus being a potential dispersal agent for bryophytes. Photo by Michael Linnenbach through GNU Free Documentation.

Figure 14. *Lumbricus terrestris* wending its way in a clump of the moss *Rhynchosetegium confertum*. Photo by Serhat Ursavas, with permission.

From a bryological point of view, it thus appears that the worms might serve as dispersal agents, although it was spores, not the more easily established tubers, that remained viable after traversing the **earthworm** gut (Van Tooren & During 1988). Tubers seemed unable to survive the journey through the gut. Twenty-five species of mosses germinated from diaspores from gut contents, with *Pottia/Phascum* (Figure 15) being the most common. This compares to the presence of only eight species of mosses in the samples of **earthworms**, indicating transport from other locations. For buried diaspores, **earthworms** may facilitate their movement from beneath the surface to the castings above ground where they are exposed to light and able to germinate. On the other hand, *Bryum rubens* (Figure 16) is not known to produce sporophytes in this area and relies on vegetative diaspores. It is one of the most common species in the area, but is not common above ground. It was also rare in the worm samples, causing Van Tooren and During to suggest that mechanical and chemical processes in the gut cause high mortality of the rhizoidal tubers in this species.

Figure 15. *Pottia bryoides*, a member of one of the genera that had the highest germination in cultures from earthworm guts. Photo by Michael Lüth, with permission.

Earthworm Culture

Peatmoss is recommended as an additive to rich soil for rearing earthworms (Mascio 2006; How to Grow Your Own Earthworms 2009; Oliver 2009)

Most farmers seem to consider **earthworms** to be their friends because they reputedly aerate the soil. However,

they can also be a nuisance. One person complained that the earthworms were the largest deterrent to the establishment of a moss garden. The worms would "plow" up the surface and detach the moss from the soil. It appeared that they also chewed up the moss, but there seems to be only circumstantial evidence of that.

Figure 16. Clump of *Bryum rubens*, a moss that does not produce sporophytes and relies on dispersal of vegetative diaspores. Photo by Michael Lüth, with permission.

Polychaetes

I completely overlooked this mostly marine group when I wrote this chapter (Figure 17). It was only when two people posted pictures on Bryonet of strange organisms they found among bryophytes that I realized there are terrestrial polychaetes that may inhabit bryophytes. These Bryonet organisms were not polychaetes, but they did raise the question. However, I have been unable to find any published documentation that polychaetes ever occur on bryophytes.

Figure 17. Syllid polychaete undergoing epitoky – becoming sexually mature. Photo by Megan McCuller, through Creative Commons.

Storch and Welsch (1972) described adaptations to air breathing in polychaetes from the mangrove swamps of Sumatra. Their exterior is protected by a cuticle that varies in thickness. The gills have extracellular spaces that have blood lacunae in the epidermis in at least one species. But the terrestrial polychaetes seem to be poorly known.

Thank you to Bryonet and its wonderful subscribers! *Parergodrilus heideri* and *Hrabeiella periglandulata* are the only terrestrial European flatworms, where they live in forest soils (Dumnicka & Rozen 2002) and would seem to be likely candidates for bryophyte dwelling (Juan Larrain,

pers. comm. 29 February 2012). But both Larrain and I searched the web for links to bryophytes to no avail. Rather, Schläghamerský and Šídová (2009) examined the vertical distribution of a population in the Czech Republic of *Hrabeiella periglandulata* in soil and determined that they avoided the organic layer, which would include bryophytes. Perhaps the minute *Parergodrilus heideri* (Rota 1997) and *Hrabeiella periglandulata* (Rota 1998) are hiding among them somewhere with the right moisture conditions. But it is more likely that the temperature of their environment is modified by the presence of bryophytes at the surface.

Summary

Many bryophyte-inhabiting annelids (segmented worms) are **mesofauna**, *i.e.* able to occupy spaces with a diameter < 2 mm. The **Enchytraeidae** are among the most common. Bryophyte-dwelling annelids may form zones in the soil and bryophytes and some species may migrate up and down daily in response to changing moisture conditions. **Enchytraeids** have a wide tolerance to water, but have little adaptation to drought. Some species produce red blood to survive low oxygen conditions.

Although most **Enchytraeidae** cannot reproduce by fragmentation, some enchytraeids can reproduce by this method in a cycle of ~20.4 days. *Cognettia sphagnetorum* increases its reproductive rate when temperatures get warmer, but an annual mean above 16°C could cause annihilation. Some species thrive in higher temperatures, whereas others are seriously affected.

Neither mosses nor fungi seem to serve as food for the annelids, although *Sphagnum* stems have been found in guts. In peatlands, 5-10-year old sediments seem to be an important food source. Bryophytes in streams can provide safe sites where reduced current provides more debris for food. Despite their apparent distaste for bryophytes, annelids may disperse vegetative diaspores by eating them and depositing them elsewhere unharmed, indicating at least some are not digested..

Worms can be extracted from bryophyte samples using funnel systems. Smaller taxa can be extracted by squeezing water onto a microscope slide.

The **Palouse earthworm** (*Driloleirus americanus*) is a rare species that occurs under moss mats in the prairie.

Acknowledgments

María Jesús Iglesias Briones provided invaluable help in obtaining images, literature, and a critique of an early draft on the annelids. Bryonettters have been wonderful in making their photographs available to me and seeking photographs from others.

CHAPTER 4-5

INVERTEBRATES: ROTIFERS

Figure 1. Two **bdelloid rotifers** that commonly inhabit bryophytes. Photo by Paul Davison, with permission.

Rotifera – Rotifers

Rotifers, also known as wheel animals, are so-named because of the ciliated **corona** on the head. The corona creates a circular movement that is used to direct food to the mouth. Rotifers have up to five simple eyes (Figure 2) that are light-sensitive and often are red. This sensitivity to light permits some species to be **phototactic** (moving toward or away from light).

Rotifers are natural partners for organisms like bryophytes that often experience extended periods of drought. Pourriot (1979) considered the number of species that inhabit mosses to be over 200. The number is surely larger now.

Anthony von Leeuwenhoek discovered in 1702 that rotifers could tolerate months in a state of desiccation, hence marking the earliest studies on **cryptobiosis**, or life in a dormant state without water (Alpert 2000). This desiccation tolerance is particularly common in the class **Bdelloidea**. In this dry state, they are easily dispersed along with fragments of the mosses they inhabit.

Not much bigger than some protozoa (mostly 0.1-0.5 mm long, but up to 2 mm), they form a phylum of their own, the **Rotifera**, with at least 2000 species (Howey

1999). They are multicellular and even possess a primitive brain, at least in females (Hingley 1993).

Figure 2. *Brachionus quadridentatus* (**Monogononta**) showing red eyespot. Photo by Frank Fox, through Creative Commons.

Rotifers have a variety of means of protection. Some are encased in a **lorica** (rigid case or shell; Figure 3, Figure 13-Figure 14). Others build tubes or cases (Figure 53, Figure 82). Some have sharp spines (Figure 13). And some simply hide, many of which use bryophytes for hiding.

Figure 3. *Colurella adriatica*, showing location of the mastax and other prominent features. This one is sitting on the green alga *Spirogyra* sp., but it sometimes occurs among mosses. Photo by Michel Verolet, with permission.

Moss-dwelling rotifers have been around for a long time. Waggoner and Poinar (1993) reported on fossil habrotrochid rotifers from Dominican amber. These revealed microfossils from the bracts of a moss from the Eocene-Oligocene (circa 34 million years ago) in the northern Dominican Republic. It is interesting that these match the **thecae** (sheaths) of living moss dwellers in *Habrotricha*, being almost identical with *H. angusticollis* (Figure 4). These **parthenogenetic** (producing unfertilized eggs) bdelloid rotifers seem to have a well-adapted body plan that has persisted for 35 million years.

Figure 4. *Habrotricha angusticollis*, a moss inhabitant. Photo by Yuuji Tsukii, with permission.

It is likely that many species of rotifers remain to be described. The most likely habitat for these discoveries is

that of bryophytes. The bryophyte dwellers are often very small, rarely swim, and go dormant (see below) as a **tun** (Figure 61) or a **resting egg**, all characteristics that make them less likely to be noticed and more difficult to identify. Shiel and Green (1996) remarked that considerably more rotifers in New Zealand and the Australasian region remain undescribed. At that time the region had 388 valid species in 66 genera. Yet less than 5% of these were endemic to the Australasian region.

With the potential differences in physiology and biochemistry, it is also likely that DNA analysis will reveal many microspecies and perhaps even different species that are not recognizable based on morphology alone. Kaya *et al.* (2009) compared "DNA species" with morphological species of bdelloid rotifers from mosses in Turkey and the United Kingdom. They found that traditional identification methods underestimate rotifer diversity by factors of 2 at the local level and 2.5 at a regional level. Each moss sample had 3-9 morphospecies, but the DNA species ranged 8-12 per moss sample. These DNA species numbers indicated greater differences in diversity among locations (**gamma diversity**) than within samples (**alpha diversity**). Rotifer biologists consider that the number of cryptic species that can be revealed by DNA taxonomy may be overwhelming (Suatoni *et al.* 2006; Fontaneto *et al.* 2008).

This knowledge that the **Rotifera** include many **cryptic species** (species that look alike but can't interbreed), as demonstrated by DNA, is supported by a diversity of narrow ecological niches (see, for example, Fontaneto *et al.* 2011). This allows for physiological/biochemical differences that permit the species to survive in a wide range of cosmopolitan habitats. This diversity and cosmopolitan distribution has led to superfluous names in many of the rotifer genera. This chapter follows the nomenclature of Segers (2007); for species described after that publication it follows EOL <<http://eol.org/>>.

Reproduction

The lifespan of many rotifers is as much as 30-40 days, not counting their time in dormant states (Ricci 2001). But Wikipedia (2016) considers it to be much shorter for **Monogononta**, ranging 2 days to 3 weeks for females. And species of these animals can often be found in active or dormant states on both aquatic/wetland (Priddle & Dartnall 1978; Bateman & Davis 1980; Ricci 1983; Ricci *et al.* 1989; Linhart *et al.* 2002a) and terrestrial mosses (Bartos 1949; Ramazotti 1958; Overgaard-Nielsen 1967; Kukhta *et al.* 1990). Several species are even known from the harsh environment of mosses growing on roofs (Hirschfelder *et al.* 1993).

Rotifers (depending on the taxon) have three types of individuals: **mictic** (mixing) females, **amictic** females (not reproducing sexually), and males. Rotifer eggs may be attached to a substrate (Figure 5-Figure 6) or remain attached to the parent (Figure 7) (EOL 2016). The female rotifers themselves live only a few days to a few weeks. The males have no digestive tract, are often sexually mature at birth, and are short-lived, as you might expect when they don't eat. Hence, it is also understandable that males are much smaller than females (Figure 8).

Figure 6. Egg of rotifer on an algal filament. Photo by Michel Verolet, with permission.

Figure 7. *Brachionus* with 3 eggs. Photo by Jean-Marie Cavanilhac, with permission.

The female reproductive system of rotifers consists of one (**Monogononta**) or two (**Bdelloidea**) ovaries. Each ovary has a **vitellarium gland** (Figure 9) that supplies the eggs with yolk.

Bdelloidea

Bdelloid rotifers (class **Bdelloidea**; Figure 10-Figure 11), known as moss rotifers, are less species rich (over 450 described species) than the **Monogononta** (ca 1500 species). The **Bdelloidea** are the most common rotifers in peatlands (bogs and fens; Bielańska-Grajner *et al.* 2011) and other mosses (Sayre & Brunson 1971; Ricci *et al.* 2003b; Gilbert & Mitchell 2006). All known taxa are **parthenogenetic**, *i.e.*, they have only females that reproduce asexually, giving rise to more females (Hingley 1993). However, Danchin *et al.* (2011) analyzed the genome of one of these, *Adineta vaga* (Figure 12), a moss dweller, and found four genotype modifications that suggested rare events of sexual reproduction may have occurred.

Monogononta

The **Monogononta** is the second major class of rotifers, and by far the largest (ca 1500 species) (Wikipedia 2012a). Among these are members that have both sexual and asexual reproduction. The short-lived, uncommon males, however, serve only for reproduction and thus are much smaller than females. Some males are so reduced that they have little more than a bladder and a penis! One such monogonont is the mostly planktonic genus

Brachionus (Wikipedia 2011; Figure 2, Figure 7, Figure 13-Figure 14). In this genus, with some members occurring among bryophytes, increases in population density can induce sexual reproduction. The sexually produced eggs can become resting eggs that survive unfavorable conditions (Plewka 2014). It appears that at least in **Brachionus calyciflorus** (Figure 13) only one allele is needed to turn off sexual reproduction and force all reproduction to be parthenogenetic. **Brachionus urceolaris** (Figure 14) sometimes lives among bryophytes (Figure 7; Hingley 1993), but it is primarily a cosmopolitan planktonic species like the other **Brachionus** species (EOL 2016). It is mostly parthenogenetic, but it occasionally produces males.

Figure 13. **Brachionus calyciflorus**, a species that needs only one allele to turn off sexual reproduction. Academy of Natural Sciences in Philadelphia, through Creative Commons.

Figure 14. **Brachionus urceolaris**, a bryophyte dweller. Photo courtesy of Emily Toscana Guerra from Rotifer World Catalog, through Creative Commons.

In the **Monogononta**, two types of reproduction occur. In one type, females produce unfertilized eggs that develop into females, just as in the bdelloids (Hingley 1993). But in the second type, sexual females appear only when environmental conditions are unfavorable, such as drought or cold. These females produce a sexual egg that forms a thick-walled resting "egg" when fertilized (Figure 15). That resting egg develops into a female. If the egg is not fertilized, it develops into a male.

Figure 15. *Euchlanis triquetra* with expelled resting egg. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Bryophytes as Habitat

Moss-dwelling **rotifers** have attracted the attention of rotifer specialists for some time (Burger 1948). The family **Habrotrochidae** (see Lobule Dwellers below) seems to occur mostly on mosses but is also **benthic** (living on the bottom of a water body) (Wallace & Snell 1991). There are two species in the genus *Elosa* (Figure 16) that are common on *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112), and these are considered bog specialists (Pejler & Bērziņš 1993b).

Figure 16. *Elosa worrallii*, a *Sphagnum* dweller. Photo by Jersabek *et al.* 2003 from Rotifer World Catalog, through Creative Commons.

Rotifers occur with bryophytes in both aquatic and terrestrial habitats, with bryophytes often providing a water space in the latter. Duggan (2001) points out that the **periphytic** (living on plant surfaces) species of rotifers have received little attention compared to the **planktonic**

(drifting in open water) species. Bryophytes are among these **macrophytic** (referring to plants that are visible without a microscope) substrates that support the periphyton, but Duggan did not include them in his study, considering bryophytes to be a separate habitat. **Periphytic** rotifers seem to have preferences among macrophyte species based on differences in physical structure or complexity, food concentration or composition, chemical factors, macrophyte age, and differences in protection from predation they provide (Duggan 2001). The same factors are likely to control bryophyte choices as well.

Terrestrial and wetland rotifers crawl through the spaces among leaves and branches of bryophytes, living in the water film surrounding the plant (Hingley 1993). In her website on rotifers, Jean-Marie Cavanilhac (2016) considers *Rotaria rotatoria* (formerly *Rotifer vulgaris*; Figure 17) to be one of the most frequent rotifers on mosses, and as a free-living (unattached) rotifer, it moves like a caterpillar.

Figure 17. *Rotaria rotatoria*, a bdelloid rotifer from moss. Photo by Christian D. Jersabek, through Creative Commons.

The bryophyte dwellers feed on the bacterial and protozoan inhabitants, swim among the leaves, or nestle between the leaves and branches where they gain more protection against their predators (Hingley 1993). The same is true for those living in terrestrial habitats as well as in ponds, lakes, and waterways.

Habitat Characteristics

Although not restricted to these habitats, rotifers are common on mosses in alpine *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112) bogs and in wetlands. Bryophytes may be particularly useful to stream and other aquatic rotifers as a substrate. Pejler and Bērziņš (1989) contend that rather than any chemical attraction for a substrate, some substrates might be avoided, perhaps due to lack of periphyton. The genus *Lecane* (Figure 122) is a very large, widespread genus that has little preference for any particular substrate (Pejler & Bērziņš 1994). In fact, it furthermore seems to have good dispersal, as indicated by its rapid ease of colonization on an artificial substrate of cotton. Fontaneto and Ricci (2006) consider that rotifers are probably best dispersed in their dormant state (allowing them to be dispersed along with their bryophytic substrate).

The species on various macrophytes differ, even when a different species of macrophyte is growing in close proximity (Pontin & Shiel 1995; Duggan *et al.* 2001). Likewise, bryophyte species composition explains most of the variation in monogonont rotifers in springs and fens

(Hájková *et al.* 2011). Bryophytes form four functional groups, supporting the importance of plant form in their selection of the bryophyte substrate. Species composition of monogonont rotifers differs significantly ($P < 0.01$) among crawling dense [*Cratoneuron filicinum* (Figure 18), *Palustriella commutata* (Figure 19), *P. decipiens* (Figure 20)], crawling loose [*Brachythecium rivulare* (Figure 21), *Calliergonella cuspidata* (Figure 22), *Plagiomnium affine* agg. (*P. ellipticum* – Figure 23, *P. elatum* – Figure 24)], and *Sphagnum* tufts [*S. fallax* (Figure 25), *S. flexuosum* (Figure 26), *S. palustre* (Figure 109), *S. papillosum* (Figure 27)]. The fourth group is erect (mostly acrocarpous) species: *Bryum pseudotriquetrum* (Figure 28), *Fissidens adianthoides* (Figure 29), *Philonotis caespitosa* (Figure 30).

Hájková *et al.* (2011) demonstrated bryophyte-dwelling monogonont rotifers in springs and fens form communities that are strongly correlated with water pH and conductivity, Ca concentration, and *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112) dominance. The rotifers did not respond to silica, iron, or nutrients, despite the effects of these factors on amoebae, algae, and other microscopic food organisms. Rotifer species composition does not depend on water chemistry, except pH and calcium, at least in part because their *Sphagnum* substrate selects for these factors. For shell-forming species, these latter chemical factors are often more important.

Aquatic bryophytes may provide a refuge during particularly heavy stream flow. The number of rotifer species among bryophytes in Tatra streams increased during spring runoff from 18 in winter to 24 during runoff (Madaliński 1961). Other factors that contribute to substrate choice include temperature, oxygen content, trophic levels, chemistry, food availability, and predators (Pejler & Bērziņš 1989).

Abundance

An average of 700 rotifers can exist per gram on the soil-dwelling mosses *Ceratodon purpureus* (Figure 31) and *Polytrichum juniperinum* (Figure 32), rock-dwelling moss *Schistidium apocarpum* (Figure 33), and bog/fen

species of *Sphagnum* (Gerson 1982). Consider that a rough estimate for a handful of moss is about 10 grams.

Figure 33. *Schistidium apocarpum*, a common moss that can house 700 rotifers per gram. Photo by Michael Lüth, with permission.

Aquatic rotifers can occupy a significant portion of the meiofauna (minute organisms living in soil and aquatic sediments) of aquatic mosses such as *Fontinalis antipyretica* (Figure 34) (Vlčková *et al.* 2002). Out of 20 taxa, *Bdelloidea* formed the dominant group with about 76% of the total meiofauna numbers. Linhart (2000) found that clumps of *Fontinalis antipyretica* was inhabited by 151 times the densities of meiofaunal invertebrates

compared to adjacent mineral substrate. During winter in two streams in the Czech Republic, Linhart found 182,672-390,057 individuals per 100 mL of *F. antipyretica*. That's about a handful of moss. Rotifers (**Bdelloidea**) were the dominant organisms, occupying up to 74% of the meiofauna. The rotifers seemed to be reduced by high amounts of organic matter, whereas **Chironomidae** (Figure 35) benefitted. These differences account for the dominance of rotifers (**Bdelloidea**) in Mlýnský náhon (76% of the community), whereas in Bystřice, the dominant group was **Chironomidae** (34%) (Vlčková *et al.* 2002).

Although the aquatic moss *Fontinalis antipyretica* (Figure 34) often lives in relatively rapid water, it can house huge numbers of temporary and permanent meiofauna. In samples taken in October and November, Vlčková *et al.* (2002) found 261,660 individuals per 100 mL of this moss in Bystřice and 498,948 in Mlýnský náhon. More permanent residents contribute approximately 62% and 95% in these locations, respectively. At Mlýnský náhon, the **Bdelloid** rotifers form 76% of the community as permanent residents.

Aquatic mosses can contribute significantly to biodiversity by providing a 3-d habitat. Linhart *et al.* (2002a) and Vlčková *et al.* (2002) found that rock rip-rap

overgrown by aquatic mosses (*Fontinalis antipyretica*; Figure 34) in a side channel of the Morava River, Czech Republic, contributed both habitat and food source for the meiofauna. Both the habitat and the food source were realized through the fine particulate matter trapped by the mosses. In this habitat, **Bdelloid** rotifers dominated as 76% of the organisms among 18 meiofaunal taxonomic groups.

Sampling

When comparing numbers of nematodes, tardigrades, mites, and annelids to rotifers among bryophytes, Merrifield and Ingham (1998) found low numbers of rotifers, with no seasonal variation. They suggested that the low numbers of rotifers in moss samples may be due to the use of the Baermann funnel for sampling. This technique is not suitable for immobile organisms like periphytic rotifers, as indicated by comparison with subsequent squeezings and agitation of the moss.

Before we explore this group of organisms, we need to consider potential sampling bias and the effects it may have on the numbers of rotifers in various studies. Because of their tendency to attach, rotifers require different sampling techniques from tardigrades and worms. They do not extract well with the Baermann funnel used so commonly for other invertebrates (Merrifield & Ingham 1998). Merrifield and Ingham tested the efficiency of this funnel technique on the moss *Eurhynchium oregonum* (Figure 36) on the Oregon Coast Range, USA, by squeezing and agitating the moss after the funnel extraction and suggested that the sedentary habit of the rotifers might cause them to be under sampled.

Figure 36. *Eurhynchium oregonum*, a moss where the funnel technique might under-sample the rotifers. Photo by Blanka Shaw, with permission.

Fussmann *et al.* (2000) discussed the problems with using sedimentation chambers of **fixed** (preserved) organisms. These must be analyzed with an inverted microscope and the amount of work required becomes prohibitive. Even for **non-sessile** (unattached) rotifers, using a transparent filtering funnel with appropriate mesh screening misses a large portion of the population (Likens & Gilbert 1970). It is most likely worse for bryophyte dwellers living in the small interstitial spaces.

May (1986) suggests that sampling sediments can be done in one day and the dormant individuals or resting eggs

cultured to permit identification. But this method is not only time-consuming, it may not enable one to see those individuals hiding among the bryophytes, especially in pockets, folds, and cells.

Pennak (1962) reported results from a littoral sampling tube, but cautioned that this method was less effective in sampling rotifers from macrophytes than the use of nets (Pennak 1966). Others (Goddard & McDiffett 1983; Duggan *et al.* 2001) used removal of the macrophytes, a method also appropriate for bryophytes, but the sorting process is tedious and time consuming. For example, removing the rotifers from the surfaces can be accomplished with a syringe (Pontin & Shiel 1995), but for a quantitative study this can be a large project, considering the numbers cited above. It is also a destructive method, and the patchiness of rotifer species would require a large number of samples.

Artificial substrata are a possible alternative (Duggan *et al.* 1998; Duggan 2001), but that method presumes that the bryophyte is being used only as a substrate and that shape of substrate and other organisms in the community don't matter. And this does not seem to be the case – preferred food organisms may be absent and high densities occur in leaf axils and other restricted spaces that are not mimicked by the artificial substrate.

Green (2003) sampled periphytic rotifers with Hydrobios plankton nets, mesh 55 μm . These samples were preserved in formaldehyde, then thoroughly mixed and sub-sampled with a wide-mouthed pipette. The subsamples were mixed with a small volume of lactic acid and mounted on a glass slide for examination. But once again, I question how effective this is for rotifers hiding in pockets, lobules, cells, or attached.

The closest macrophytes to use as models for bryophytes might be sampling of the alga *Chara* and the flowering plant *Utricularia vulgaris* (Figure 38). Kuczyńska-Kippen & Nagengast (2006) sampled periphyton (adhering algae, protozoa, microinvertebrates) on these and other macrophytes by removing a 0.25 x 0.25 m square of the plants. These were first rinsed in distilled water. Then the periphyton remaining was removed manually with a knife and small brush and number of rotifers calculated per volume of water above the sampled area. This is another destructive technique and would be prohibitively costly in time.

Figure 37. *Chara vulgaris*, a potential model for bryophyte faunal communities. Photo by Mnolf, through Creative Commons.

Figure 38. *Utricularia vulgaris*, a potential structural model for bryophyte rotifer communities. Photo by Erastos Kampouropoulos, through Creative Commons.

Vlčková *et al.* (2002) attempted to sample the aquatic moss *Fontinalis* (Figure 34) quantitatively. They removed the moss and its associated fauna with a 30 μm mesh hand net. The associated fauna and detritus were then washed from the moss and sieved through a 1 mm mesh to remove the larger organisms and debris. The organisms that went through the net were retained on a 30 μm mesh filter. The sediment retained by this filter was diluted in a graduated cylinder and 1 ml samples were observed with a dissecting microscope and counted in a Sedgwick Rafter counting chamber. But even this extensive (and destructive) method can fail to sample attached or pocketed fauna.

These difficulties help to explain the paucity of quantitative ecological studies on bryophyte dwellers.

Extraction Techniques

To further complicate finding rotifers even under the dissecting microscope, rotifers respond to disturbance by retracting their corona and toes, appearing like a ball. In this condition, they are difficult to locate, even with a dissecting microscope. And imagine trying to identify these balls! You can place a branch of bryophyte in a Petri dish or watch glass and cover it with water (Fox 2001). Then let it sit quietly, preferably on the stage of a dissecting microscope, for 15-30 minutes until the rotifers become active again. They can then be removed with microforceps by removing several leaves on which you have observed rotifers. If they are placed on a glass slide or hanging drop slide, you can observe these with the compound microscope at 40X.

But some rotifers are too small for this technique and are likely to be missed. Peters *et al.* (1993) suggest a different method that appears to be a somewhat reliable quantitative technique. They tested it on 74 samples of mixed *Brachythecium rutabulum* (Figure 39) and *Ceratodon purpureus* (Figure 31), both terrestrial mosses. Their criteria for establishing a method were that it should not kill the organisms because some must be alive to be identified, it must be equally effective for all species, it must be quantifiable, and it should be economical in both equipment cost and time. Bryophyte samples 1 cm^2 should be shaken vigorously in a 70 ml vial with 20 ml rainwater

for 15 seconds. If the sample is dry, it should soak for 24 hours in rainwater first. After shaking, put the sample and water in a Petri dish with a grid. Then put the moss back in the vial. Rotifers can be counted with a dissecting microscope at 40-50X. This should be repeated nine more times with material from the same sample, using a new Petri dish each time. From each of these samples, take 50 rotifers at random and make a separate slide for each. These can be stored for weeks in a moist chamber. This method needs more testing to check for attached species, species bias, and reliability of quantitative measures.

Figure 39. *Brachythecium rutabulum*, a moss used for extracting rotifers by a shaking technique. Photo by J. C. Schou, with permission.

Sakuma *et al.* (2002) tested two methods (covering method; picking-up method) of obtaining epiphytic rotifers from lake vegetation (Figure 40). Their "covering method"

involved shaking a vegetation sample in a 2-L jar of filtered lake water (40 μ m mesh). The jar lid (cap) is placed on the jar and the jar is placed upside-down in the lake water. The lid is then removed under water and the submerged part of the bryophyte is gently covered from above. The bryophyte is cut with scissors near the lip of the jar and the jar lid is returned to cover the jar. The covered jar is shaken vigorously 50 times, which in testing recovered 90% of the rotifers. Shaking only 10 times recovered only 80%. The water in the jar is then filtered through a 40 μ m filter and fixed with sugar formalin (see Haney & Hall 1973).

In the "picking-up method" the jar of lake water is prepared as above (Sakuma *et al.* 2002). It differs in cutting the bryophyte in the lake and picking it up above the water surface. This bryophyte sample is then put in the jar. The epiphytic rotifers are then treated as for the "covering method."

The authors consider the "covering method" to be superior in estimating the abundance, but it requires both hard work in a boat and more time (Sakuma *et al.* 2002). The "picking-up method" (Figure 40) introduces errors in the abundance estimates. The rotifers *Lecane* (Figure 41), *Euchlanis* (Figure 42), and *Trichocerca* (Figure 43) are underestimated, whereas *Brachionus* (Figure 13-Figure 14), *Mytilina* (Figure 44), *Lepadella* (Figure 45), and *Colurella* (Figure 46) seem to be accurately estimated. Such differences provide misleading information on community structure. The shaking part of the "covering method" is not without its own creation of bias. *Lecane* (Figure 47) and *Collotheca* (Figure 48) remained on the plants (*Potamogeton* – Figure 49) at ca. 50% and 70%, respectively.

Adaptations

The **Rotifera** are cosmopolitan, including both tropical and polar environments. There is a large number of species, permitting them to occupy a wide range of habitats. This indicates that ecological barriers are more important than geographical barriers in determining their distribution (Pejler 1995). However, many of the species are **euryoecious** (able to live in a variety of conditions), whereas few have strong restrictions on their environments. When an environment has a large number of rotifer species, the species typically differ greatly in their morphology. Therefore, it is difficult to characterize adaptations for a given environment. It is thus not surprising that published literature provides little information about adaptations of **rotifers** to the bryophyte habitat.

Particle Feeders

Rotifers among bryophytes can feed on detrital matter and algae collected by the bryophytes.

Spines

Kellicottia longispina (Figure 50) is a common plankton species that may be well adapted for bryophyte living. It has very long spines on its case (**lorica**) that Madaliński (1961) considered helpful in attaching to bryophytes. Others understand them as serving as a flotation device (De Smet, pers. comm. 3 November 2016), certainly not an adaptation to bryophyte living.

Figure 50. *Kellicottia longispina* showing its long spines that permit it to attach to bryophytes. Photo by Philipp Trummer, through Creative Commons.

But Pejler & Bērziņš (1989) have somewhat different ideas about long spines. They claim these are generally found in clear water as a protection against visual predators. This is consistent with defense against predation by small fish as shown by Barnhisel (1991) for *Bythotrephes*, a cladoceran. Rather, Pejler and Bērziņš suggest that adaptations to bryophytic living involve the suitability of the foot, egg-carrying protrusions, and other lorical structures. Certainly diet plays a role, with some bryophytes being suitable food for detrital feeders, but mostly because of the collected detritus and other planktonic and periphyton organisms among the bryophytes.

Small Size

If you are tiny and soft-bodied, you certainly need some sort of protection or a place to hide. Otherwise, you will be somebody's dinner. Wilts *et al.* (2010) discovered one of the smallest rotifers known, *Bryceella perpusilla*, a new species, concealed on terrestrial mosses in Germany. It is likely that many other small bryophyte-dwelling species remain unknown.

Some rotifers, for example *Cupelopagis vorax* (Figure 51), are too large to live among bryophytes (Cavanihac 2004). Cavanihac (2004) considered that this size limitation may be, in part, because the bryophytes cannot house enough detritus and bacteria to meet the food needs of the large rotifers. For *Cupelopagis vorax*, a consumer of ciliates and smaller rotifers, this may not be the case. This species lacks prominent cilia to draw food toward its mouth (Edmondson 1940, 1949). Therefore, it benefits when it settles on larger leaves where smaller ciliate rotifers bring food into the vicinity of its mouth. On the other hand, Dumont *et al.* (1975) found that the rotifers among the periphyton (which includes most of those associated with bryophytes) tended to be smaller than those living as plankton (see also Ricci *et al.* 2003a).

Mobility vs Attachment?

Epp and Lewis (1984) demonstrated that speed of motion was related to size in rotifers. Using *Brachionus* (Figure 2, Figure 13-Figure 14) and *Asplanchna* (Figure 52), they demonstrated that *Brachionus* has little size variation during its development, whereas *Asplanchna* increases significantly in size as it develops. Nevertheless, both genera decrease their speed of movement significantly as their size increases. *Brachionus* uses 62% of its energy for ciliary movement. This is a very inefficient activity, so we might consider one bryophyte adaptation to be attachment instead by crawling, thus saving energy. To observe the rotifers in motion, let the wet moss sit for 30 minutes before observation to provide the rotifers sufficient time to become active.

Figure 52. *Asplanchna* sp., a species that increases in size as it develops. Photo by Wim von Egmond, with permission.

Living in tune with their mossy environment, **limnoterrestrial** (in habitat providing tiny water reservoirs in terrestrial environment) rotifers exhibit a seasonal dynamic that depends on water availability and air quality (Kukhta *et al.* 1990; Steiner 1994a, b, 1995a, b). Not only is water important for hydration, but it is necessary for locomotion. The bdelloid rotifers (Figure 11) have a contractile body that permits them to creep around on the moss (Sayre & Brunson 1971). And the cilia that form the corona create currents as they beat (Figure 53), directing food particles into the mouth while thrusting the rotifer forward (Hingley 1993). Thus, the corona also contributes to movement.

Figure 53. Wheels of cilia (**corona**) on *Floscularia* sp. Photo by Martin Mach, with permission.

Members of the periphyton often remain firmly attached to the substrate, be it rock, bryophyte, or other macrophyte. This attachment may use a cement, produced by the toes that have a cement gland (Baqai *et al.* 2000).

Protection

Habrotrocha sp. (Figure 54) secretes a mucus that makes it appear much larger (Figure 54). Wallace and Snell (1991) considered mucus to be an adaptation against predation in the rotifers *Conochilus* (Figure 55) and *Lacinularia* (Figure 56), but it would seem it would likewise contribute to protection of rotifers such as *Habrotrocha* against desiccation in a mossy habitat where some members of the genus are known to live. However, this has not been clearly demonstrated. Others, such as *Keratella* (Figure 57-Figure 58), are protected from both desiccation and predation by armor (Figure 57-Figure 58), with spines that may help against predation.

Having parthenogenesis is an advantage for rotifers that travel with a moss fragment and are likely to land where there is no male partner. This advantage is further assured by the predominance of females in the population. In addition to the reproductive adaptations, many adaptations may be physiological.

Dormant States

Of course, a major need for terrestrial moss dwellers is the ability to survive dry periods. The actual mechanisms that permit this survival have been elusive. Some early ideas lack sufficient support and have been discarded as a general mechanism. One such mechanism is the ability to secrete a mucus, as in *Macrotrachela natans* (Bryce 1929). But there is inconclusive evidence that the ability to produce this mucus actually protects the rotifer from the effects of water loss (Tunnacliffe & Lapinski 2003). Rather, it appears that most rely on physiological changes that occur during dehydration.

Physiological Adaptations

Anhydrobiosis

One reason for the abundance of bdelloid rotifers on bryophytes is that they share with the bryophytes the ability to enter dormancy (Gilbert 1974). In the **Bdelloidea**, the most common group of terrestrial rotifers, including those among bryophytes, this dormancy permits the adults to survive when frozen or desiccated. In **Monogononta**, dormancy is restricted to the fertilized resting egg. Hence, the predominant group of moss dwellers (**Bdelloidea**) has two methods of surviving desiccation.

The concept of **anhydrobiosis** was introduced by Giard in 1894 as a highly stable state of suspended animation that an organism enters as a culmination of desiccation (Tunnacliffe & Lapinski 2003). It differs from **desiccation tolerance**, which refers to the ability of a cell or organism to tolerate loss of water, although not necessarily reaching a resting state.

Cryptobiosis (anhydrobiosis) is one type of dormancy (Wallace & Snell 1991; Fontaneto & Ricci 2004). **Anhydrobiosis**, a dormant state caused by loss of water, permits some rotifers to live with the same water stresses to which bryophytes are subjected.

Van Leeuwenhoek was the first to recognize the state of anhydrobiosis in a rotifer, the bdelloid *Philodina roseola* (Figure 60) (Tunnacliffe & Lapinski 2003). Tunnacliffe and Lapinski (2003) argue that the term **anhydrobiosis** is inappropriate because the organism is not devoid of all water and that it has shut down to a state of suspended animation. They suggested the term **anhidrous cryptobiosis** because it implies the living but inactive state. Nevertheless, the term **anhydrobiosis** has been used for a long time and its intended definition is understood. Hence, I prefer not to introduce a new term and agree with Tunnacliffe and Lapinski that "as 'anhydrobiosis' is firmly established in the literature, it is unlikely that it can now be replaced."

Figure 60. *Philodina roseola*, a species that is able to regulate its net water balance during dehydration. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Changes During Anhydrobiosis

Desiccation Stages: Rotifers enter this state of anhydrobiosis in stages (Ricci & Melone 1984). First they contract into the compact shape known as a **tun** (Figure 61) (Marotta *et al.* 2010). During this contraction, the cephalic and caudal extremities are withdrawn into the trunk. Presumably, this reduces the rate of water loss and minimizes water loss in the dormant state. The tissues and cells become packed, preserving their integrity (Ricci 2001). This preparation requires several hours, and a shorter period can reduce the recovery success (Caprioli & Ricci 2001).

Figure 61. Tun of a rotifer, *Pleuretra brycei*, a moss dweller. Photo by Michel Verolet, with permission.

Ability to contract and fold seems important to the survival of *Macrotrachela quadricornifera* (Figure 62) (Ricci *et al.* 2004). Upon drying, the rotifer contracts, drawing its foot and head into the body trunk (Figure 63) (Ricci & Melone 1984). Starved rotifers of this species survive better than those fed on concentrated food, with food remaining in the gut when the latter form the **tun** (Figure 64) (Ricci *et al.* 2004). This is in contrast to the loss of survival in *Philodina roseola* (Figure 60) when dried after starvation (Jacobs 1909). It is possible that the reason for the reduced survivorship of well-fed *M. quadricornifera* is that the food interferes with the necessary folding and contraction.

Figure 62. *Macrotrachela quadricornifera*. Photo by Diego Fontaneto and Giulio Melone, with permission.

Figure 63. *Macrotrachela quadricornifera* contracting as it dries. Photo by Claudia Ricci, with permission.

Figure 64. *Macrotrachela quadricornifera* tun. Photo by Diego Fontaneto & Giulio Melone, with permission.

Macrotrachela quadricornifera (Figure 62-Figure 64) shrinks considerably in size during dehydration, with the anhydrobiotic animal having only about 60% of the volume of the hydrated form (Ricci *et al.* 2008; see also Marotta *et al.* 2010). The internal organization changes drastically, with body cavities becoming indistinguishable. Even more extreme is its loss of more than 95% of its weight when anhydrobiotic, mostly as water. This water loss is inconsistent with a 60% volume loss and Ricci and coworkers suggest that it may indicate presence of space-filling molecular species in the dehydrated animal.

Dehydration Conditions: Caprioli and Ricci (2001) found that *Macrotrachela quadricornifera* (Figure 62) was able to survive rapid desiccation, whereas *Philodina roseola* (Figure 60) only survived best when subjected to a slower desiccation rate. Both of these are bdelloid rotifers. Nevertheless, when Caprioli and Ricci (2001) experimented with *Macrotrachela quadricornifera*, *Philodina roseola*, and *Adineta oculata*, they found that these bdelloids are able to somewhat regulate the net water balance during the onset and termination of anhydrobiosis. This would be particularly helpful in a terrestrial environment, even among bryophytes that are in an exposed habitat such as boulders in the sun.

Jacobs (1909) provided an early explanation of the dehydration process that affects the survival rate in *Philodina roseola* (Figure 60). He found that when rotifers were dried slowly, their survival rate was higher (75% survival) than those dried rapidly in a desiccator (12%). At 40°C they actually had a slightly higher survival rate (94%) than those dried at 20°C (82%). However, longevity during dry storage was greater in those dried at 20°C. He supported the importance of **anhydrobiosis** by showing that dry storage produced a higher survival rate than storage at high relative humidity.

Jacobs (1909) found that 82% of *Philodina roseola* (Figure 60) had no survival after he dried starved individuals, but 82% of the well-fed individuals survived the same treatment. This is in contrast to some macroinvertebrates that survive best when the gut is empty (see terrestrial insect chapters), including the rotifer *Macrotrachela quadricornifera* (Figure 62-Figure 64).

The rotifer desiccation process is in some ways similar to that of bryophytes. Both require a lag time between periods of desiccation. Schramm and Becker (1987) found that *Habrotrocha rosa* (Figure 65), a bryophyte dweller, required a recovery period of at least one day before it could survive another period of desiccation.

Biochemical Changes: In nematodes and tardigrades, **trehalose** is produced and stored during desiccation. This molecule helps to stabilize cellular structures and preserve molecular integrity. In more modern studies, researchers have identified the non-reducing disaccharides trehalose and sucrose as playing critical roles in anhydrobiotic survival (Tunnacliffe & Lapinski 2003). One or the other of these sugars is typically present in high concentrations as many types of organisms undergo desiccation, leading to the anhydrobiotic state. These sugars seem to act as water replacement molecules, acting as "thermodynamic and kinetic stabilizers of biomolecules and membranes."

Figure 65. *Habrotrocha rosa*, a bryophyte dweller that requires at least one day of recovery before another desiccation event. Photo by Rkitko at Wikipedia Commons.

But rotifers seem to contradict this wisdom. Protection by trehalose is not the case in the rotifers *Philodina roseola* (Figure 60) or *Adineta vaga* (Figure 12) (Tunnacliffe & Lapinski 2003). No simple sugars seem to increase at all. Contrary to the high non-reducing disaccharide concentrations found during dehydration in nematodes, brine shrimp cysts, bakers' yeast, resurrection plants, and plant seeds, the rotifers lack these high intracellular sugar concentrations in preparation for desiccation, yet have excellent desiccation tolerance (Tunnacliffe & Lapinski 2003).

Among the **Bdelloidea**, species are either desiccation tolerant or not; the difference is not a matter of degree (Örstan 1998; Ricci 1998). Lacking trehalose, they must have something that permits them to survive. That "something" continued to be elusive. Next, Tunnacliffe *et al.* (2005) found a hydrophilic protein in *Philodina roseola* (Figure 60) upon dehydration. This is an LEA protein that also is associated with desiccation tolerance in plants. Furthermore, this protein appears in desiccation-tolerant nematodes and micro-organisms and appears to have a role in desiccation tolerance (Denekamp *et al.* 2010; Hand *et al.* 2011). Hand and coworkers found that these LEA protein genes are expressed in the resting eggs of rotifers such as *Brachionus plicatilis* (Figure 66) and the female adults that formed these resting eggs.

Longevity during Anhydrobiosis

The record for survival after the longest period of anhydrobiosis is that of *Macrotrachela quadricornifera* (Figure 62). It survived 59 years on a moss on a herbarium sheet, becoming active when it was rewet (Rahm 1923). But even Rahm questioned his own record, suggesting it may have been the result of more recent contamination from windborne dust carrying dormant rotifers. Furthermore, even in this species the success of recovery decreases with time (Caprioli & Ricci 2001).

Pennak (1953) cites one bdelloid rotifer that was revived from moss after 27 years of dry storage. Unfortunately, no reference is cited and we cannot evaluate whether the moss might have had rotifers introduced from dust or nearby more recently dried mosses.

To determine survival time, Guidetti & Jönsson (2002) examined rotifers that had been kept dry for 9-138 years. The adult stage may have a limited cryptobiotic lifespan in the presence of oxygen, but the rotifer *Mniobia* (Figure 67) survived live as eggs for nine years on bryophytes, suggesting that the egg stage (see Figure 68) might have greater longevity than the cryptobiotic adult stage. This appears to be the longest record for **rotifer** survival in anhydrobiosis other than the possible 59 years for an adult *Macrotrachela quadricornifera* (Figure 62-Figure 64) reported by Rahm (1923) from a herbarium moss or the undocumented record from Pennak (1953).

Age Differences

Age affects recovery rate from desiccation but has no effect on the subsequent longevity of *Macrotrachela quadricornifera* (Figure 62) that do recover (Ricci *et al.* 1987). In experiments, fertility of 5-day-old stressed rotifers had significantly decreased, whereas 14-day-old stressed individuals had decreased life spans. Age also affected ability to survive drying. The highest recovery rate occurred for 8-day-old rotifers stressed for 4 days, whereas no rotifers aged 5 days survived 30 days of drying.

Size Differences – Aquatic vs Terrestrial

The moss-dwelling rotifer strains differ slightly in size, with terrestrial moss dwellers being smaller than the aquatic strains of the same species (Ricci 1991). This smaller size may permit them to take advantage of adhering moss water for a longer period of time. Among the *Macrotrachela quadricornifera* (Figure 62), eggs and juveniles are less able to recover from desiccation than are mature animals. This species is a good **bet-hedger**, encompassing multiple strategies for survival in a variety of habitats. The moss habitat undoubtedly offers the advantage of slow drying, which increases survivorship upon rewetting (Ricci *et al.* 2003a).

Reproductive Effects

In a study of nine species of **bdelloid rotifers**, Ricci (1983) found that those moss-dwelling terrestrial rotifers living in unpredictable environments had less likelihood of reproducing than aquatic species with a more predictable environment. Thus, it is not surprising that they reproduced less, but lived longer. Moss-dwelling species tend to reproduce throughout their mature lives and never senesce, whereas the aquatic species have a greater reproductive output and are more likely to die after reproduction, having a senescent period at the end of their lives. The strategy of the aquatic species would not serve the terrestrial moss-dwelling taxa well due to the unpredictable nature of the habitat. The terrestrial moss-dwellers, on the other hand, can enter the state of **anhydrobiosis** when the conditions become unfavorable. During this state they can tolerate extremes of temperature and desiccation and do not need food. Frequent reproduction could be detrimental to these animals if they do not have sufficient resources to sustain them during the anhydrobiotic state. Success is further supported by a delay in maturity that reduces reproductive cost. On the other hand, in the water, large adults may be easy prey, favoring a shorter time to maturity.

Furthermore, the aquatic (non-moss) strains of *Macrotrachela quadricornifera* (Figure 62-Figure 64) invested maximum resources in reproduction (**r strategists**), consequently reducing their survival, whereas the moss-dwelling strains were long-lived and invested fewer resources in their reproduction (**K strategists**) (Ricci 1991). Ricci points out that the moss habitat experiences a much greater temperature fluctuation in a shorter period of time than would occur in the aquatic non-moss habitats. Ricci suggests that the terrestrial moss habitat has much more important limiting factors – availability of food and moisture, whereas a wide temperature range with sudden changes must be tolerated.

Temperature Protection

Despite all the preparation for anhydrobiosis, these dormant beings are not as well protected as we once thought. On the other hand, Rahm (1923) found that once dry, at least some rotifers can survive 151°C for 35 minutes. Broca (1860) revived rotifers with water after they remained dry in a vacuum for 82 days, then were immediately heated to 100°C for 30 minutes.

The temperature relationships of the moss-dwelling rotifers are interesting. Compared to the non-moss populations, those of *Macrotrachela quadricornifera* (Figure 62) living among mosses exhibit an irregular response to increasing temperature in the range of 16-24°C (Ricci 1991).

Recovery Rate

As one might expect, terrestrial rotifers have the greatest desiccation recovery rates compared to aquatic rotifers. When fifteen bdelloid species (6 genera) were collected from water and terrestrial moss environments, the highest recovery rates following anhydrobiosis for seven days were for the adults from terrestrial mosses (Ricci 1998). Activity generally resumed in about one hour after rehydration. Ricci suggests that evolutionarily all bdelloid rotifers originally had the ability to enter anhydrobiosis, but that some species have subsequently lost it. Aquatic species had only 20-50% recovery among young, pre-reproductive individuals, whereas moss-dwelling species had 50-100% recovery among these juveniles. This improved in adults of both groups. Could it be that this group evolved originally in a moss habitat? On the other hand, *Otostephanos macrantennus*, a moss and soil dweller (Ricci 1998), did not survive desiccation at any life stage, except for one individual older adult. Furthermore, its eggs collapsed and were unable to survive desiccation, whereas the overall viability among these fifteen species was 40-60%. Ricci considered *Otostephanos macrantennus* to have "an anomalously low desiccation survival rate."

The Bryophyte Connection

The data for *Macrotrachela quadricornifera* (Figure 62) and other species raise the question of how these animals survive on bryophytes. To partially answer this question, Ricci *et al.* (1987) collected mosses from a spring-fed pond in Italy. Hence, it is likely that the humidity remained higher than that of the laboratory. Furthermore, the mosses themselves provide capillary spaces that can lock in water for a longer period of time than that of the surroundings. Unlike the rotifers that depend on eggs for reproduction, bdelloid rotifers in this study had a much lower hatching rate (19%) compared to 40-100% (Pourriot & Snell 1983) reported for those species that depend on resting eggs to colonize new environments. *Macrotrachela quadricornifera* (Figure 62-Figure 64) is a parthenogenetic rotifer, requiring no partner to reproduce. Therefore, its life on a moss leaf is not dependent on finding a partner in what can be an isolated habitat. The ability of the moss leaf to disperse in the wind provides a means for the rotifer likewise to disperse.

Certainly one of the most important adaptations of bryophyte dwellers is this ability to withstand drying.

Bdelloid rotifers in particular are common among bryophytes and humus-containing soil (Sládeček 1983). Many of these are able to desiccate for long periods of time and become active again. Pennak (1953) reports that one bdelloid rotifer revived after 27 years of desiccation.

Other Protections during Anhydrobiosis

Once in the state of anhydrobiosis, the rotifer gains protections not available to it in the active state. Among these is the ability to survive strong ultraviolet light (Rahm 1923, 1926, 1937). In its normal hydrated state, strong UV light kills the rotifers "almost instantly." This dehydrated state also confers a high tolerance to low temperatures (-190°C) (Rahm 1923), and Becquerel (1950) showed survival of *Habrotrocha constricta* (Figure 69) and *Philodina roseola* (Figure 60) at 0.05K (-273.1°C, or close to absolute zero)! Anhydrobiosis also stops the internal clock of the rotifers so that they do not age unless they are in the active state (Ricci *et al.* 1987). This is an advantage for those living among bryophytes that dry periodically.

Figure 69. *Habrotrocha constricta*, a species of both aquatic and epiphytic mosses that is able to survive at 0.05K. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Gladyshev and Meselson (2008) demonstrated that bdelloid rotifers have extreme resistance to ionizing radiation. Using bryophyte dwellers *Adineta vaga* (Figure 12) and *Philodina roseola* (Figure 60), they were able to show that the reproduction is much more resistant to ionizing radiation than that of the monogonont *Euchlanis dilatata* (Figure 70). They suggest that this resistance is due to the same evolutionary adaptation that permits these rotifers to survive desiccation in their natural habitats. They consider the mechanism to involve DNA breakage that is repaired following rehydration. This breakage/repair sequence may be the mechanism that kept their load of transposable genetic elements low, thus contributing to the success of the asexual species for such a long time rather than suffering from the early extinction suffered by so many other asexual taxa. This connection should be explored in bryophytes that also have survived for a very long time as asexual organisms. Kamisugi *et al.* (2016) found indications of the possibility in *Physcomitrella patens*, a moss that demonstrates repair genes for damaged chromosomes.

Figure 70. *Euchlanis dilatata*, a monogonont moss dweller that has poor resistance to ionizing radiation. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Surviving Fungi

Wilson (2011) found yet another advantage to having anhydrobiosis in the life cycle. He pointed out that organisms that lack sexual reproduction usually do not survive evolutionary time. The **Red Queen hypothesis** is that the limited capacity to create new genetic makeup leads to extermination due to rapidly evolving parasites and pathogens. But the asexual **Bdelloidea** have indeed survived under these conditions. Wilson explains this survival of bdelloid rotifers as a result of their ability to disperse while in a desiccated state, arriving in a new location parasite free.

In experiments, wind dispersal during seven days of desiccation successfully removed a fungal parasite from populations of one species and permitted them to disperse independent of their fungal parasite (Wilson 2011). Wilson desiccated a "heavily infected" population of *Habrotrocha elusa* on a moss, placed it in a wind chamber, and collected those that landed on target dishes. These were rehydrated after 7 days. In 70% of the dishes, new populations became established and two-thirds of these were free of parasites. However, if the rotifers were "dispersed" while wet, all the new populations were infected and were killed by the fungus.

Wilson (2011) made an additional observation on *Adineta vaga* (Figure 12) collected from an **epiphytic** moss. In bryological literature, **epiphytic** moss refers to those mosses living on trees or shrubs; these are often referred to as "tree mosses" in the rotifer literature. Following anhydrobiosis this species had enhanced **fecundity** (reproductive rate) compared to those that had not been dehydrated, even when they were infected with fungal parasites. This suggests that the desiccation-rehydration cycle may serve as a cue to invest heavily in reproduction.

Food

Rotifers obtain their food by rotating **cilia** in the **corona** (Figure 71) that directs the food into the mouth. This enables them to eat small particles of organic matter, bacteria, algae, protozoa, and even other rotifers (Wikipedia 2012b). [These same cilia can be used for

swimming (Fontaneto & Ricci 2004)]. The food is directed to the mouth and the modified pharynx called a **mastax** (Figure 72-Figure 73), the latter consisting of the **trophus** and its musculature. Their menu usually consists of food items that are up to 10 μm in size (Wikipedia 2012b). This ability to filter such small particles from their environment makes them useful in maintaining clean water in aquaria. Clément *et al.* (1980) described the muscle structure and method of controlling the cilia to obtain food for the moss dweller *Philodina roseola* (Figure 60, Figure 71) and planktonic *Brachionus calyciflorus* (Figure 74) and their ability to reject some foods.

Figure 74. *Brachionus calyciflorus*, a species that can reject some foods. Photo from Academy of Natural Sciences in Philadelphia, through Creative Commons.

Food choices differ with habitat, even within the same species. The bdelloid rotifer *Macrotrachela quadricornifera* (Figure 62-Figure 64) is a filter feeder whose food preference and survivorship both differ among the habitat strains (Ricci 1991). Moss dwellers were unable to survive on yeast (*Saccharomyces cerevisiae*) alone, whereas the two aquatic strains survived and grew. One of the moss-dwelling strains was unable to eat the one-celled green alga *Chlorella pyrenoidosa* (see Figure 75). The other moss strain did best on the bacterium *Escherichia coli*, which resulted in poor growth of all the other strains. It appears that the habitat may influence the types of enzymes available for digestion of food. We cannot, however, say if this is an environmental response during development or a genetic one that has persisted through a number of moss-dwelling generations.

Figure 75. *Chlorella vulgaris*; *C. pyrenoidosa* a rejected food for moss-dwelling *Macrotrachela quadricornifera*. Photo by Sarah Duff, through Creative Commons.

Most of the **rotifer** inhabitants of *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112) feed on small particles of food directed to them by their wheel cilia (Figure 76) (Hingley 1993). They mash their food with their **mastax** (Figure 72-Figure 73, Figure 3), thus modifying these in the ecosystem.

Figure 76. The two "wheels" of cilia on this moss-dwelling rotifer are in full motion. Photo courtesy of Andi Cairns.

A few rotifers actually bite their food. For example, among the moss dwellers, this method is used by *Lindia torulosa* (Figure 77-Figure 78) and *Notommata*

groenlandica (Figure 79), but there are many others as well (Plewka 2016).

Role in the Food Web

Tiny animals usually have bigger animals that eat them. The rotifers fall prey to copepods, fish, and Bryozoa, but small rotifers are also eaten by bigger rotifers (Wallace *et al.* 2006). For example, members of the rotifer genus *Lecane* (Figure 122, Figure 128) are eaten by the rotifer *Dicranophorus robustus* (Figure 80) (Jersabek *et al.* 2003), both known from bryophytes. On the other hand, when the *Asplanchna* ate too much *Keratella* (Figure 81), the *Asplanchna* died, possibly due to the spines and hard lorica of the *Keratella* (Figure 57).

Figure 80. *Dicranophorus robustus*, a bryophyte dweller that eats smaller rotifers on bryophytes. Photo from Jersabek *et al.* 2003, through Creative Commons.

Figure 81. *Asplanchna* sp. overfed on *Keratella* sp. This large rotifer died after eating a large quantity of the smaller *Keratella* (van Egmond 2003). Photo by Wim van Egmond, with permission.

Some rotifers, especially **sessile** (attached) rotifers, are easy prey for larger invertebrates. For example, Antarctic tardigrades appear to be important predators on rotifers (Sohlenius & Boström 2006). Some rotifers make tubes in which to hide. *Ptygura velata* (Figure 82-Figure 83) solves the problem of becoming someone else's dinner by making a tube from its own fecal pellets (Figure 82-Figure 83), where it withdraws from danger (Edmondson 1940).

Figure 82. *Ptygura* sp. with its case made of its own fecal pellets, attached to a *Sphagnum* leaf. Photo by Wim van Egmond, with permission.

Figure 83. Close view of *Ptygura* sp. showing fecal pellets in the case. Photo by Wim van Egmond, with permission.

Rotifers participate in a food web within the moss habitat. Therefore, things that hurt their food items indirectly impact the rotifers. For example, rotifer biomass on *Sphagnum fallax* (Figure 25) decreased in response to experimentally added lead (Nguyen-Viet *et al.* 2007). The mechanism, however, appeared to be indirect due to the loss of microbial biomass and not due to the direct effects of lead on the rotifers. The biomass of bacteria, microalgae, testate amoebae, and ciliates decreased significantly and "dramatically." The linkage appears to be that bacteria provided food for the ciliate and testate protozoa, and these in turn provided food for the rotifers. Rotifers do have preferences, and these preferences affect the species composition of algae in their ecosystems (Wikipedia 2012b). They also affect the species composition through competition for food with Cladocera and Copepoda.

Specific Habitats

We would probably make some very interesting discoveries if bryologists and rotifer biologists would join forces. But rotifer folks rarely name the bryophytes where their rotifers dwell, and most bryologists can't name the rotifers they find and are likely to miss the dormant ones. Some rotifers may have very specific habitats, particularly among bryophytes that offer unusual conditions.

Lobule Dwellers

Claudine Ah-Peng expressed surprise to find invertebrates in the lobules of some species of *Lejeuneaceae*, notably in the lobules of the leafy liverwort *Acrolejeunea emergens* (Figure 84-Figure 85). These occurred on plants at the Piton de la Fournaise volcano (Réunion in the Indian Ocean) collected on a 1986 lava flow.

Figure 84. *Acrolejeunea emergens* with several orange invertebrates in the lobules. These appear to be resting stages of rotifers. Photo courtesy of Claudine Ah-Peng.

Figure 85. *Acrolejeunea emergens* with an emerging invertebrate, apparently a **rotifer**, in a lobule. Photo courtesy of Claudine Ah-Peng.

Bdelloid rotifers seem to be common in lobules, even in the tiny leafy liverwort *Microlejeunea* (Figure 86). Blanka Shaw has provided me with pictures of the tiny leafy liverwort *Microlejeunea ulicina* (Figure 87) from Whitewater Falls in Transylvania County, North Carolina, USA, with rotifer inhabitants, again in lobules. These initially motionless animals began moving their "wheels" when the warmth of the microscope light activated them.

Figure 87. *Microlejeunea ulicina* with a rotifer emergent from a lobule. Scale is 50 μm . Photo courtesy of Blanka Shaw.

In North America, Puterbaugh *et al.* (2004) found that rotifers were common in the lobules of the leafy liverwort *Frullania eboracensis* (Figure 88-Figure 92). The younger outer portions of the plants had more rotifers in the lobules than did the interior lobules. Sterile plants had a mean ratio of 0.83 ± 0.15 rotifers per lobule. Male and female plants had a mean ratio of 0.38 ± 0.04 rotifers per lobule. Sterile plants likewise tend to be younger. Since we would expect older lobules to have more rotifers due their greater time available for colonization, these findings suggest that older portions may have something, perhaps a chemical exudate, that discourages the colonization by rotifers, or it could be due to lobule size difference, microhabitat differences, or accessibility.

Figure 92. Lobules of *Frullania eboracensis* with dormant rotifers. These dormant stages could be resting eggs or cysts. Photo courtesy of Mark Pokorski.

Hess *et al.* (2005) found rotifers in lobules of *Colura* sp. (Figure 93-Figure 95) and *Pleurozia purpurea* (Figure 96-Figure 100). These liverworts have a trap lid on the lobules, and it appears that the inhabitants might not be able to escape, dying in the lobule (trap) and contributing organic matter that could break down and provide nutrients to the liverworts. However, there does not seem to be any evidence that *Microlejeunea* (Figure 86-Figure 87) or *Frullania* (Figure 88-Figure 92) species have this trapping action.

Figure 100. Lobule of *Pleurozia purpurea* showing lid. Photo courtesy of Sebastian Hess.

Lobules are not necessary for rotifer habitation of the leafy liverworts. *Jungermannia cordifolia* (Figure 101), with only a flat leaf surface to offer, likewise has its fauna of these interesting invertebrates (Javier Martínez Abaigar, pers. comm. 2008), as do mosses that lack similar structures.

Figure 101. This *Lepadella* species, with its "wheels" hidden and its toes showing, is feeding on detrital material associated with the liverwort *Jungermannia cordifolia*. Photo courtesy of Javier Martínez Abaigar.

Des Callaghan (Bryonet 10 November 2012) kindly provided us with a YouTube video <http://youtu.be/kHhBBppqh_Y> of rotifers feeding from the lobules of the tiny *Lejeunea patens* (Figure 102-Figure 103) in Wales and another of rotifers in lobules of *Harpalejeunea molleri* (Figure 104). I knew that the ciliated "wheels" directed food into the mouth, but I never realized the speed or the distance of that effect. The particles started outside the field of view and travelled farther than the extended length of the rotifer. Some particles came from near the foot and others shot in like a meteor from the height of the cilia or a little above, but from some distance.

Retort Cells

Curiously, two species of *Habrotrocha* (Figure 105) (*Habrotrocha roeperi*, Figure 106; *Habrotrocha reclusa*, Figure 107) choose to live in the **retort** cells (Figure 106, Figure 108) of the stems of some species of *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112), entering through the subterminal pore. **Retort** cells differ from other *Sphagnum* outer stem (Figure 110) and branch cells by having a terminal neck that terminates in a pore, somewhat like the neck of a leather wine flask. Hingley (1993) found it interesting that these rotifer species seemed to avoid the stem cells of *Sphagnum palustre* (Figure 109), *S. papillosum* (Figure 27, Figure 110), and *S. magellanicum* (Figure 111-Figure 112), all species of the subgenus *Sphagnum* that has spiral thickenings in the **cortical** (outer stem) cell walls (Figure 110).

Figure 112. *Sphagnum magellanicum*, a species whose stem cells lack retort cells and are avoided by retort-cell species of *Habrotrocha*. Photo by Michael Lüth, with permission.

In addition to living in *Sphagnum* retort cells, *Habrotrocha roeperi* (Figure 106) and *Habrotrocha reclusa* (Figure 107) live inside the outer cells of *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112) branches (May 1989). May states that these rotifers could be considered as parasites. I have to question what nutrition they get from the *Sphagnum* by living in those outer cells. It is more likely that they feed on associated micro-organisms.

Roofs

Colonization of mosses on roofs permitted Hirschfelder *et al.* (1993) to compare species of rotifers on an upright acrocarpous moss (*Ceratodon purpureus*; Figure 31) and a mat-forming pleurocarpous moss (*Brachythecium glareosum*; Figure 113). They collected mosses every two weeks from roofs aged 3-92 years, dried them at 20°C, and cut them into small pieces. The pieces were re-wet in deionized water and examined for awakening rotifers. The mat-forming moss had significantly more species and greater numbers of rotifers than did the upright moss, but species on *C. purpureus* differed little from those that could be found on *B. glareosum*. They found that rotifer colonization of the

mosses continued for decades and that the colonization of the mosses was rapid. Nevertheless, the numbers of rotifer species increased with time (Figure 114).

Figure 113. *Brachythecium glareosum*, a rotifer habitat on roofs. Photo by Des Callaghan, with permission.

Figure 114. Succession of rotifer species that increase in number with age of roof. Redrawn from Hirschfelder *et al.* 1993.

Arctic and High Altitude

De Smet and Beyens (1995) considered rotifers to be one of the dominant bryophyte dwellers on Devon Island. In the Arctic Spitsbergen, the bdelloid rotifers among mosses had an unexpectedly high species richness – 52 taxa (Kaya *et al.* 2010). Kaya and coworkers concluded that the moisture regime and geographic localization of the mosses were the most important ecological factors in affecting the differences in species composition between samples. (See also De Smet 1988).

Fontaneto and Ricci (2006) examined elevational effects on the rotifer fauna of lichens and mosses across the Italian, French, and Swiss Alps. Distances among the 47 sample sites ranged from 1 m to 420 km. Low elevation sites ranged 850-1810 m asl; high elevation sites were 2984-4527 m asl. They found significant differences in both species richness and species composition between the mosses and lichens at high elevations. Nevertheless, there

was no significant difference in the heterogeneity of the species assemblages. High-elevation **alpha diversity** (diversity of each site, *i.e.* local species diversity) was significantly lower than that at lower elevations. On the other hand, when comparing only species richness, there was no difference between higher and lower elevations.

Alpha diversity in these Alp rotifers was significantly lower at high-elevation than at low-elevation sites, but the estimated number of species was not reduced when compared with sites at low elevations (Fontaneto & Ricci 2006). Geographical distance between sites had no effect on species composition of rotifers in either mosses or lichens. The high elevation sites did not simply represent a reduction in number of species represented at lower elevations. Rather, they indicated that low density of favorable habitat patches, coupled with the low number of available propagules (moss riders), accounts for the heterogeneity of rotifers among the moss patches and the lower richness in individual patches at higher elevations.

Antarctic

In the Antarctic, rotifers share the mosses with tardigrades and nematodes among the microinvertebrates. Early explorations of de Beauchamp (1913) in the Antarctic revealed the bdelloid *Mniobia* (Figure 67) among mosses. Most of the bdelloids he located were contracted and could not be identified. In addition, he found the monogononts *Lindia torulosa* (Figure 115), *Colurella adriatica* (Figure 3), and *C. colurus*.

Figure 115. *Lindia torulosa* head, a species that lives among mosses in the Antarctic. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Petz (1997) found that 95% of the samples from Wilkes Land, East Antarctica, had rotifers, with the highest numbers in mosses (1,311/g), although it was tardigrades that dominated. Water and organic matter seemed to be the most important controlling factors for these invertebrate numbers.

The Antarctic mosses sport an active community of invertebrates that move among the stems and branches. Priddle and Dartnall (1978) showed experimentally that wind caused mixing in summer, resulting in the transport of larval rotifers from shallow portions of the lake. Priddle

and Dartnall found six rotifer species along the stems of aquatic mosses [*Warnstorfia sarmentosa* (Figure 116), *Drepanocladus* sp. (probably *Sanionia uncinata*; Figure 117)]. Two of these rotifers were bdelloids and four were sessile monogonont species. These rotifers preferred the middle stem zones of mosses where the highest growths of epiphytic algae and other epiphytic organisms occurred. Of these, four species chose leaf axils, whereas the other two settled on the bare underside of the leaf.

Figure 117. *Sanionia uncinatus*, a suitable substrate for Antarctic rotifers. Photo by Michael Lüth, with permission.

These studies were followed by those of Dartnall and Hollowday (1985), Hansson *et al.* (1996), Dartnall (1980, 1995, 1997, 2000, 2005a,b (flooded moss carpets), all providing records of Antarctic bryophytes.

Dartnall and Hollowday (1985) found that *Macrotrachela concinna* was most often encountered in terrestrial mosses. An unidentified species of *Philodina* (Figure 60) occurred on growing tips of mosses in the lake. *Notholca salina* and *Reticula gelida* (Figure 118) were most common in the flooded moss carpet. *Adineta barbata* (Figure 119) was collected from drying mosses.

Hansson *et al.* (1996) found that rotifers in the Antarctic (South Georgia) were rare in the open water and were restricted mostly to mosses in shallow areas, as well as sediment surfaces. These taxa were varied, including *Cephalodella auriculata* [Figure 120; a cold-water species (Segers 2001)], *C. gibba* [Figure 121; (see also De Smet 2001)], a cold-water species (Segers 2001) known from habitats with pH <3.0 in Germany (Deneke 2000), *Lecane closterocerca* (Figure 122; see also Hingley 1993), *L. lunaris* (Figure 123), *Lepadella patella* (Figure 124; see also Hingley 1993), *Resticula* sp. (Figure 125), *Testudinella* sp. [perhaps *Testudinella patina* (Figure 126) found by Hingley (1993)], *Tricocerca brachyura* (Figure 127), and several bdelloid rotifers among the more common ones.

One of the common habitats for Antarctic rotifers is the moss *Sanionia uncinata* (Figure 129). In this habitat, the rotifers (Figure 130) are subject to predation by nematodes (Newsham 2004).

Fontaneto *et al.* (2015) determined that the number of monogonont rotifer species decreases toward the poles. The number of bdelloid species, on the other hand, increases toward the poles. Bryophytes play an important role in providing habitats for them farther north and south. The **Bdelloidea** are most common in limnoterrestrial environments – mosses, lichens, and soils (Wallace *et al.* 2006; Fontaneto & De Smet 2015). The **Monogononta**, although sometimes present in limnoterrestrial habitats, including mosses, are mostly aquatic. Hansson *et al.* (1996) found that rotifers were rare in the open water of the Antarctic region, being restricted to the vegetation (mainly mosses) in shallow areas as well as the sediment surface.

Sudzuki (1964) enumerated the moss-water community at Langhovde in the Antarctic region and found that it was "not so unusual." He identified 13 rotifer species in the Antarctic region. These included *Adineta gracilis* (Figure 131), *Adineta* sp., *Encentrum antarcticum* (invalid species), *Habrotrocha* (Figure 105-Figure 107), *Lepadella patella matsuda* (invalid subspecies), *Macrotrachela* sp. from Langhovde. However, some of these species are now invalid. Sudzuki (1979) also sampled mosses using polyurethane foam in a variety of Antarctic sites. These added *Habrotrocha cf. gulosa* and *Macrotrachela nixa* to the moss rotifer fauna.

Figure 131. *Adineta gracilis*, a moss dweller that lives among Antarctic moss carpets. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Freshwater plankton and submerged mosses supported 13 species of monogonont rotifers in the South Shetland Islands (Janiec 1993, 1996a, b; Janiec & Salwicka 1996).

In their studies of southern Victoria Land, Schwarz *et al.* (1993) found that the protozoa, rotifers, nematodes, and tardigrades dominate the invertebrate fauna of the moss-dominated flushes. These invertebrates, including rotifers, were concentrated at 5-10.83 mm depth in the moss carpets. In post-melt cores, the upper 5 mm of the moss mats had more rotifers (and other invertebrates) than in pre-melt samples.

Nevertheless, whereas the rotifers are common on terrestrial mosses, few studies have gone farther than identifying them as rotifers. It is likely that new species, or at least cryptic species, remain to be described there.

Nunataks

Sohlenius and Boström (1996, 2005) examined samples from **nunataks** (Figure 132; exposed, often rocky portions of ridges, mountains, or peaks that escape snow and glaciation, typically vegetated by algae, mosses, and lichens). Among these samples, 67% contained rotifers, with the most frequent and diverse microfauna group being bdelloid rotifers (19 species).

Figure 132. **Nunatak** in Antarctica. Photo by Stephen Bannister, through Creative Commons.

In moss cushions alone from Antarctic nunataks, Sohlenius and Boström (2006) found that 82% of their 91 samples had rotifers, the highest, above the nematodes (64%) and tardigrades (32%). Jennings (1976) studied the ecology of bdelloid rotifers in moss carpets on Signy Island. He found bdelloid and two monogonont rotifer species. These included *Adineta gracilis* (Figure 131), *A. steineri* (Figure 133), *A. vaga* (Figure 12), *Habrotrocha constricta* (Figure 69), *H. crenata* (Figure 134, *H. pulchra*, *Macrotrachela concinna*, *M. kallosoma*, *Mniobia burgeri*, and *Philodina plena* (Figure 135-Figure 136; see also Donner 1980).

Bog and Fen Habitats

The terminology of bog and fen has differed between North America and Europe, with North Americans tending to refer to any habit with dominant *Sphagnum* as a bog, whereas the Europeans have considered bogs to be defined by their water sources as only precipitation (*i.e.*, raised bogs or other peatland with no source of mineral-rich water) (Rydin & Jeglum 2013). Those low-nutrient sites with groundwater sources are considered by the Europeans to be poor fens. Other differences in nomenclature exist, making the habitat discussion in this chapter a little fuzzy since I had no way to know which definition the researcher might be using. Fortunately, the rotifers seem to care more about the species of bryophytes than the source of the water, most likely liking the same habitat types as their bryophyte substrates.

The diversity of habitats in bogs and fens results in a number of species preferring these ecosystems. Halsey *et al.* (2000) considered *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112) to be a suitable habitat for rotifers due to its large water-holding capacity. Unique communities characterize the various stages in the peatland ecosystem (Francez & Dévaux 1985).

Sayre and Brunson (1971) considered rotifers to be excellent tools for research on the periphyton/epiphyte organisms on mosses in peatlands. Although *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112) seems to be important for many species of rotifers, many rotifers are missed during casual observance because their size is less than 200 µm (Gilbert & Mitchell 2006). Some are missed because they hide inside hyaline cells of *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112) leaves and stems, entering through the pores (Hingley 1999), or in outer branch cells (May 1989).

Nevertheless, an important deterrent for many rotifers is that *Sphagnum* acidifies its surroundings (Clymo 1963, 1964; Williams *et al.* 1998) and may account for a higher species diversity in rich fens than in *Sphagnum* peatlands. Since many rotifer species are intolerant of a low pH, especially loricate species, the low pH limits the rotifer diversity (Nogrady *et al.* 1993) (see Acidity below.) On the other hand, *Sphagnum* is important in the phosphorus and nitrogen cycling in bog ecosystems, with the help of

Figure 134. *Habrotrocha crenata*, a beech litter species that is also known from Antarctic moss carpets. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 135. *Philodina plena*, a *Sphagnum* dweller that lives in Antarctic moss carpets. Photo by Michael Plewka <www.plingfactory.de>, with permission

the rotifers that process the detritus (Błędzki & Ellison 1998, 2002).

Some rare species can be common among *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112). For example, the *Tetrasiphon hydrocora* (Figure 137) was not uncommon in association with *Sphagnum* in Lac des Femmes, Quebec, Canada, yet seemed to be rare on a more general scale (Nogrady 1980). It likewise was one of the rotifers reported in the peatland study by Hingley (1993). One reason for the occurrence of rare species among *Sphagnum* may be its ability to serve as a safe site/refugium against predators (Kuczyńska-Kippen 2008). *Sphagnum* also provides a source of food such as the desmids seen in the gut of *Tetrasiphon hydrocora* (Figure 137). Desmids are common in *Sphagnum* peatland pools and among the *Sphagnum* plants (personal observation), providing food for many kinds of rotifers. Others may require the alternating wet and dry cycles.

Figure 137. *Tetrasiphon hydrocora* with the desmid *Micrasterias rotata* in its gut. Photo by Wim von Egmond, with permission.

Species Richness

The abundant peatlands of the Scandinavian countries has resulted in most of our basic knowledge of peatlands arising there.

Pejler and Bērziņš (1993a) found that species richness of rotifers associated with the *Sphagnum* (Figure 157) in Swedish peatlands ranged from 33 to 59, including both **Bdelloidea** and **Monogononta**. In an extensive study of peatlands in Poland, Bielańska-Grajner *et al.* (2011) examined the rotifers in eight sampling locations in peatlands, including 2 raised bogs, 2 poor fens, 1 intermediate fen, and 1 rich fen. They found 42 taxa of **Monogononta** and 26 of **Bdelloidea**. **Monogononta** comprised only 4-18% of the numbers among the eight sites sampled. On the other hand, bdelloids were dominant and contributed 80% overall to the number of individuals, ranging 56-85%. Among the **Bdelloidea**, the most abundant rotifers were *Habrotrocha angusticollis* (Figure 4), *H. lata* (Figure 138), *H. roeperi* (Figure 106), *Macrotrachela quadricornifera* (Figure 62-Figure 64), *Rotaria rotatoria* (Figure 17), *Lecane elasma* (Figure 139), *L. lunaris* (Figure 123), *L. scutata* (Figure 140).

Figure 138. *Habrotrocha lata* from *Sphagnum* pond. Photo by Michael Plewka <www.plingfactory.de>, with permission.

The large genus *Lecane* (Figure 139-Figure 140) enjoys widespread distribution, including the Antarctic. Nevertheless, there are species in this genus restricted to *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112) bogs (Pejler & Bērziņš 1994). *Lecane elasma* (Figure 139) is considered characteristic of *Sphagnum* (Francez & Dévaux 1985).

Figure 139. *Lecane elasma*, a peatland species. Photo by Jersabek *et al.* 2003, with permission.

Figure 140. *Lecane scutata*, one of the abundant bdelloid rotifers in Polish peatlands. Photo by Jersabek *et al.* 2003, with permission.

Bielańska-Grajner *et al.* (2011) selected *Habrotrocha angusticollis* (Figure 4), *Dicranophorus capucinus* (Figure 141), *Keratella serrulata* (Figure 142), and *Lepadella elliptica* for further analysis and found that abiotic factors were important determinants of distribution. Nevertheless, the researchers found that the highest density of rotifers occurred in a raised bog dominated by *Sphagnum angustifolium* (Figure 157), but this might suggest that a number of rotifer species may prefer the same abiotic conditions as this moss. Francez and Dévaux (1985) similarly found the highest proportion of characteristic rotifer species in a low moor where *Sphagnum angustifolium* was dominant.

As noted, the **Bdelloidea** are the dominant group, in peatlands mostly represented by the genera *Philodina* (Figure 143-Figure 144) and *Habrotrocha* (Figure 145) (Gilbert & Mitchell 2006). Among the **Monogononta**, peatlands are occupied mostly by *Colurella* (Figure 3), *Euchlanis* (Figure 146-Figure 148), *Lecane* (Figure 139-Figure 140), and *Trichocerca* (Figure 149) (Gilbert & Mitchell 2006). Francez (1981), who identified 142 species in peatlands, found that in France both abundance and average size were greater in fens than in bogs. Many kinds of rotifers are unable to live among peat mosses because of the high degree of acidity (Hingley 1993).

In Australia, Koste and Shiel (1989) identified members of the **Euchlanidae**, **Mytilinidae**, **Trichotriidae**, all members of **Monogononta**. In *Sphagnum* pools

(Figure 150) they found *Diplois daviesiae* and *Euchlanis meneta* (Figure 151) in acid water and on submerged *Sphagnum* (Figure 150). *Trichotria truncata* (Figure 152), an acidophile, occurred among *Sphagnum*.

Rotifer studies in North American bogs have been somewhat limited compared to the number of bogs present in the northern part of the continent. We can safely say that the **Bdelloidea** are the most abundant rotifers among the mosses in peatland habitats (Sayre & Brunson 1971). Some species of rotifers are **tyrphobionts**, restricted to peatlands, but many are also known from other types of habitats (Warner & Asada 2006). Few species seem to be restricted to peatlands, conforming to the typical widespread nature of rotifers.

Most Canadian peatland studies concentrated on the plants and vertebrates. Warner and Asada (2006) were among the first to include invertebrates in an extensive survey. In a **poor fen** (similar to a bog in bryophyte species composition) in Newfoundland, Canada, Bateman and Davis (2007) found 25 **bdelloid** and 39 **monogonont** rotifers. Among these, 27 were new records for Canada and 13 new for North America. They found an average of 354 rotifers per cm² and 17 species per formation. These were seasonal, with the **monogononts** almost vanishing in winter. The **bdelloids** decreased, but not so dramatically.

The first extensive study of New England, USA, included 31 bogs from Vermont, Massachusetts, and northwestern Connecticut (Błedzki & Ellison 2003). Błedzki and Ellison collected from **interstitial spaces** (pore water), bog pools, and pitcher plants (see below). These three habitats yielded 38 rotifer species among more than 50,000 individuals. These bogs had a rotifer density that ranged 150-51,250 individuals dm⁻³ (Błedzki & Ellison 2002).

The bog ponds had 16 species; the interstitial spaces had 14 (Błedzki & Ellison 2003). The rotifer species richness increased significantly with bog elevation. On the other hand, latitude, longitude, and bog area made no significant difference in richness. The most frequent species was *Habrotrocha rosa* (Figure 65), present in pore water of 30 out of 31 bogs, but never in the bog pools. This species comprised 31% of the collected rotifers (Błedzki & Ellison 2002). The other abundant species were *Lecane pyriformis* (Figure 153), *L. lunaris* (Figure 123), *Cephalodella gibba* (Figure 121), and *Polyarthra vulgaris* (Figure 154). The sampling methods involved 50 ml plastic centrifuge tubes pressed into the *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112) mat (Błedzki & Ellison 2003). These tubes readily filled with water. While this method may have been effective for those rotifers that swam in the pore water, their methodology most likely missed attached species that rarely enter open water, such as *Collotheca* (Figure 48) and *Lecane* (Sakuma *et al.* 2002).

Edmondson (1940) explored the rotifers in bogs in Wisconsin, USA. Although he found no species to be restricted to *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112), the rotifer *Collotheca heptabrachiata* was known only from *Sphagnum* in Wisconsin. In his studies, both *Ptygura pilula* (Figure 155) and *P. velata* (Figure 156) occurred in "enormous numbers" in one *Sphagnum* peatland during the latter part of July and all through August.

For more species associated with *Sphagnum* or peatlands, see individual families in the following subchapters.

Abiotic Factors

The hummocks and hollows of bogs and fens present very different moisture and temperature regimes, and this is represented by differences in rotifer species (Bateman & Davis 2007). The summits of the hummocks in a poor (**mesotrophic**) fen (a habitat similar to a bog) in Newfoundland, Canada, house predominately bdelloid rotifers, although these never become desiccated. They found that position on the hummock was important in determining species composition. The **Bdelloidea** were the main rotifers on the tops of the hummocks. The **Monogononta**, on the other hand, increased in number of species and individuals from top to bottom, reaching their greatest number of species in the hollows. Nevertheless, the total numbers of rotifers was greatest at the tops of the hummocks. They determined that desiccation did not occur and that predation was not an important factor in determining distribution.

As the peatland water content decreases, the fauna become less like that of open water. Among peat mosses, the species with the highest percentage of characteristic rotifer species is the **oligotrophic** (low nutrient) *Sphagnum angustifolium* (Figure 157) of low moors (Francez & Dévaux 1985). Pejler and Bērziņš (1993a) found most bdelloids need lots of oxygen, commensurate with their limnoterrestrial environment, but some survive in soft bottom sediments.

Figure 157. *Sphagnum angustifolium*, a commonly dominant peat moss that provides a home for species of *Habrotrocha*, *Macrotrachela*, *Rotaria rotatoria*, and *Lecane*. Photo by Michael Lüth, with permission.

Acidity

The acidity of the water may play a role in distribution, but it is difficult to determine if it is a direct or indirect effect. Bērziņš and Pejler (1987) found that **oligotrophic** (low nutrient) species occur at a *pH* optimum at or below 7.0, whereas **eutrophic** (rich in nutrients and so supporting a dense population) species are generally at or above this level. The rotifers may be there because of a suitable *pH* and absent elsewhere because the *pH* is too high or too low, or they may be there because they are limited to a particular substrate such as *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112), which is itself limited to that same *pH* range (Edmondson 1940). Edmondson considers the rotifers *Lecane satyrus* (Figure 158), *Notommata falcinella* (Figure 159), *Lindia pallida* (Figure 160), among others, to be limited to *Sphagnum*. Jersabek *et al.* (2003) also reported *Notommata falcinella* from submerged *Sphagnum* in Maryland, USA. In these cases, it appears to be the substrate that is important, as these species are not found on other substrates at the same *pH*.

Figure 158. *Lecane satyrus*, a species that seems to be limited to *Sphagnum*. Photo by Jersabek *et al.* 2003 from Rotifer World Catalog, through Creative Commons.

Figure 160. *Lindia pallida*, a species that seems to be limited to *Sphagnum*. Photo by Christian Jersabek, through Creative Commons.

Lecane lunaris (Figure 123) is tolerant of a broad pH range (Pejler & Bērziņš 1993b). This widespread species furthermore occurs in peatlands in both New England, USA (Błedzki & Ellison 2003), and Poland (Bielańska-Grajner *et al.* 2011). *Habrotrocha angusticollis* (Figure 4), a characteristic species for peatlands, particularly *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112), generally occurs in a pH range of 3.8-6.4 (Warner & Asada 2006). **Bdelloidea** dominate in peatlands. This group is typically dominant in acidified water (Bateman & Davis 1980; Bielańska-Grajner *et al.* 2011), but it has a broad pH tolerance range (Bērziņš & Pejler 1987; Bateman & Davis 1980). Their reliance on parthenogenesis makes colonization easier, often evoking the **founder principle** (loss of genetic variation in new population established elsewhere by very small number of individuals from larger population), and may account for this wider range of pH tolerance among populations (Bērziņš & Pejler 1987; Ricci 1987).

In the Wisconsin study of Edmondson (1940), *Ptygura mucicola socialis* (Figure 161-Figure 162) was found amid a colony of the **Cyanobacterium** *Gloeotrichia* sp. (Figure 163) at the low pH of 3.5 in a *Sphagnum* peatland. It is interesting that these rotifers are often associated with algae on the mosses, presumably using them as a food source, although it might be other organisms associated with the algae that provide the food.

Surface Configuration

Flat, broad surfaces do not seem to be suitable for most sessile rotifers, something to consider when using an artificial substrate. Edmondson (1940) suggested this may relate to their method of feeding. But it could also relate to capillary water.

Sphagnum (Figure 25-Figure 27, Figure 109-Figure 112, Figure 150) leaf morphology seems to play a role in the location of the rotifers. The rotifer *Collotheca gracilipes* lived on the concave side of a submerged moss leaf along with the green algae *Bulbochaete* (Figure 164) and *Oedogonium* (Figure 165) (Edmondson 1940). And *Collotheca cucullata* occurred on the concave side of a *Sphagnum* leaf (Figure 166) in a different peatland at pH 5.6. *Ptygura velata* (Figure 156) likewise is found on the concave side of the leaf, suggesting the importance of water held there by capillarity in the interstitial spaces. On *Sphagnum perichaetiale* (syn. *Sphagnum erythrocalyx*; Figure 167-Figure 168), the rolled tip of the leaf provides a similar protection, and Edmondson found more than 200 rotifers residing there!

Rotifer and other invertebrate species assemblages change as the peatland develops so that specific associations can be described for each stage (Francez & Dévaux 1985). Likewise, communities differ with position in the hummock-hollow complex (Bateman & Davis 1980). The oligotrophic *Sphagnum angustifolium* (Figure 157), a species typical of mineral-rich sites (Hale 2012), seems to have one of the most unique and consistent assemblages of rotifer taxa (Francez & Dévaux 1985). Water content of the moss environment is the major factor determining the fauna, with the wettest mosses having communities most similar to those of the water. This is further supported by changes in protozoa species arising as a result of drainage (Warner & Chmielewski 1992).

Like the **Protozoa (Rhizopoda)**, rotifers have both horizontal and vertical distribution patterns among the *Sphagnum* (Figure 25-Figure 27, Figure 109-Figure 112) (Meisterfeld 1977) and this may account for some variation in the distribution patterns of animals that prey upon them. But this vertical zonation also reflects the food available to the microfauna (Strüder-Kypke 1999). Differences in light and nutrients result in a denser colonization in the upper part where photosynthetic cryptomonads can provide food and mobile ciliate protozoa can take advantage of these food sources. Lower in the mat, but within the upper 30 cm, sessile ciliates and heterotrophic flagellates predominate. Moisture seems to be the dominant

determiner of species assemblages, with pH being secondary (Charman & Warner 1992). As Bērziņš and Pejler (1987) indicated, pH may not in itself be a strong determinant of rotifer assemblages in peatlands, but rather may create an environment that supports oligotrophy or eutrophy as determining factors.

Pitcher Plants

The pitcher plants, especially *Sarracenia purpurea* (Figure 169), are interesting habitats for rotifers. These plants require the moist habitat of peatlands to become established and grow, growing upward as the moss grows upward. Hence, rotifers that live in the water of their pitcher-like leaves are indirectly dependent on the peat mosses (*Sphagnum*).

Figure 169. *Sarracenia purpurea* with water in leaves, home for several rotifer species. Photo by David Midgley, through Creative Commons.

Rotifers in the pitcher plant leaves are important in the cycling of nitrogen and phosphorus (Błedzki & Ellison 1998, 2002). By eating the detritus, they convert these two nutrients into forms usable by the pitcher plants. In their study of Massachusetts, USA, pitcher plants (*Sarracenia purpurea*; Figure 169), Błedzki and Ellison (1998) found that *Habrotrocha rosa* (Figure 65) could provide a pitcher plant leaf with 8.8-43 mg of N and 18.2-88 mg of P in a single growing season, far exceeding that supplied by insects and rainfall. The rotifers accomplish this by having populations of ca. 400 individuals per leaf pitcher. These rotifers can excrete $\sim 5.2 \mu\text{g NO}_3\text{-N}$, $\sim 3.91 \mu\text{g NH}_4\text{-N}$, and $\sim 18.4 \mu\text{g PO}_4\text{-P}$ per day into a single leaf.

Błedzki and Ellison (2003) compared the rotifers in the pitcher plant leaves [*Sarracenia purpurea* (Figure 169)] to those of pore water and bog ponds. These three habitats had low species similarity (Jaccard indices of similarity < 0.25). The most common species was *Habrotrocha rosa* (Figure 65). This species had its highest production at pH 4 in culture (Błedzki & Ellison 1998). The pitcher plant water had a pH range of 3.5-6.3, dropping from the higher pH as the dying trapped insects decompose (Fish & Hall 1978). The *H. rosa* is subject to severe predation by the *Diptera* larvae that also live in the pitchers, including several mosquito species (Błedzki & Ellison 1998). Numbers of *H. rosa* are inversely related to numbers of these larvae.

Lecane lunaris (Figure 123) and *Notholca acuminata* (Figure 170) occurred in water-filled leaves in a Vermont bog. In that same bog *Cephalodella anebodica* occurred in a water-filled leaf (Błedzki & Ellison 2003).

Aquatic Bryophytes

Most of the studies on rotifers of **lentic** bryophytes are in peatlands. Several studies on littoral species have also been described above because they involved peat mosses. However, there have been a number of studies on the rotifers of stream bryophytes.

Drazina *et al.* (2011) studied both lakes and streams and found that rotifers were the dominant group of meiofauna among aquatic bryophytes, with 52 species among bryophytes in Europe (National Park Plitvice Lakes). In fast water, they averaged 219 individuals per cm^3 . Several researchers have found the **Bdelloidea** to be dominant among rotifers associated with submerged mosses (Badcock 1949; Madaliński 1961; Donner 1972).

Streams

In his study of rotifers in German streams, Donner (1964) found that the rotifers were the most numerous as inhabitants of mosses. Fontaneto *et al.* (2005) analyzed an 80-m stretch of a stream in NW Italy to describe the **meta-community** (set of interacting communities linked by dispersal of multiple, potentially interacting species) structure of rotifers that colonized mosses. Mosses were absent in the riffles, but the shoreline was almost continuously covered with submerged mosses (*Brachythecium* sp. – Figure 171). The same species of moss also occurred in the pools. The researchers concluded that rotifers in pools most likely arrived from other pools by travelling with their moss substrate, whereas within the pool they could move about by themselves. Different movement capabilities of the species within pools could account for small scale differences in communities. The species occupying these habitats in this stream segment were *Adineta vaga minor* (Figure 12), *Embata hamata*, *Habrotrocha bidens* (Figure 172), *H. constricta* (Figure 69), *H. gracilis*, *H. pulchra*, *Macrotrachela quadricornifera* (Figure 62-Figure 64), *Philodina acuticomis odiosa*, *P. flaviceps* (Figure 173), *P. plena* (Figure 135-Figure 136), *P. rugosa* (Figure 174), *P. vorax* (Figure 175), *Pleuretra brycei* (Figure 61, Figure 176), and *Rotaria rotatoria* (Figure 17). There was only a slight trend of differences in species composition from upstream to downstream (Figure 177).

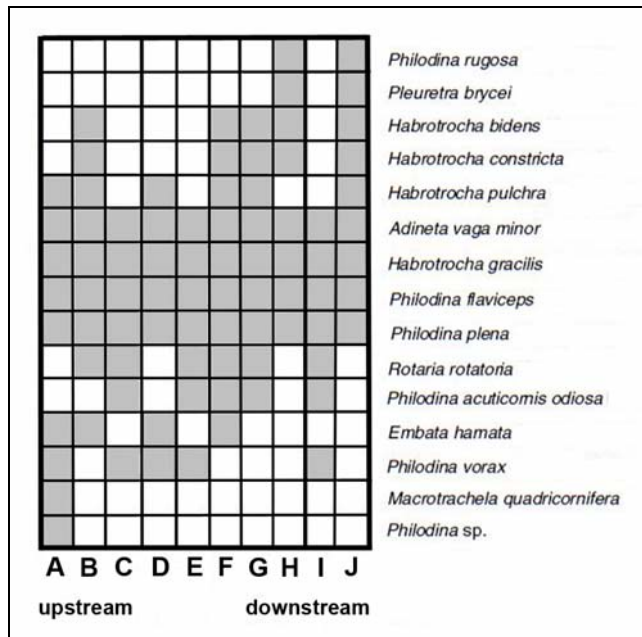

Figure 177. Distribution of moss-dwelling rotifers in a stretch of an Italian stream, arranged from upstream to downstream. Based on Fontaneto *et al.* 2005.

Suren (1992) suggested that the high densities of meiofaunal communities, including rotifers, associated with the bryophytes in New Zealand alpine streams may result from the food value of the large periphyton component and the shelter from fast water currents. In the stream bed, these organisms move into interstitial spaces in the substrate to avoid fast flow. Among the bryophytes, where they occur in high densities, they live among the stems and leaf axils where they are less exposed.

Bryophytes in streams provide a safe harbor within a tumultuous habitat and a substrate for food organisms (Suren 1992). Although the stream has an ameliorated temperature compared to terrestrial systems, its constantly changing water levels and flow rates make it a challenging environment for small organisms, especially attached species. Bryophytes offer a place where flow rate reaches virtually zero at the base, providing a range of flow rates. Furthermore, current can affect where rotifers occur within the moss mat, with some species remaining in lower layers where the current is reduced to zero. Hence, it appears that flow rate has little effect on bryophyte fauna in different parts of mountain streams (Madaliński 1961). However, this ignores the fact that bryophytes themselves may be limited by current.

Linhart *et al.* (2002b) considered the stream bryophyte-rotifer association to result from the exposure of the stream bryophytes to water current (Wulforst 1994). Historically, the bryophytes have been considered to be refuge sites from flow (Madaliński 1961; Elliot 1967; Gurtz & Wallace 1984; Suren 1992) due to the reduction of flow within the moss mat (Gregg & Rose 1982; Madsen & Warncke 1983; Sand-Jensen & Mebus 1996). But for

small invertebrates, this argument is questionable because the flow rates at the surface layer of gravel or bedrock sediments are similar to those within the moss mats (Williams & Hynes 1974; Gregg & Rose 1982; Angradi & Hood 1998). On the other hand, the **Monogononta** do seem to be affected by the flow within the mats of *Fontinalis antipyretica* (Figure 34). Could it be ease of food capture rather than protection from flow that determines where they are able to live? Or refuge from predators?

Some rotifers are able to withstand the flow of a stream, whereas others in streams hide among the bryophytes or other protected areas. Linhart *et al.* (2002b) collected data to compare the **Bdelloidea** and **Monogononta** relative to flow velocity amid the moss *Fontinalis antipyretica* (Figure 34) and on the surrounding mineral substrate. The **Monogononta** were unable to withstand the high flow velocities, whereas the **Bdelloidea** did not seem to have a preference. Therefore, the ratio of **Bdelloidea** to **Monogononta** had a strong positive relationship to the flow velocity within the moss with the ratio of **Bdelloidea** to **Monogononta** reaching as high as 13:1 in high flow areas in these streams. A similar relationship did not exist on the mineral substrate. Linhart and coworkers concluded that this does not support the concept of the mosses serving as a refugium from flow.

Bryophytes also serve as traps for drifting rotifers. Madaliński (1961) found that bryophytes in streams that flow out of lakes have a richer fauna than those in torrents arising from springs. Hence, numbers can vary widely between streams, perhaps due to available food and flow rate, as well as differences in sources for new or replacement fauna. Rotifers on the moss *Fontinalis antipyretica* (Figure 34) reached over 100,000 per mL in one stream in the Czech Republic and over 400,000 per mL in another (Vlčková *et al.* 2002).

Suren (1992) investigated the role of shade in determining the meiofaunal communities of bryophytes in New Zealand alpine streams. He found that the unshaded site had higher meiofaunal densities than did the shaded site and that bryophytes had higher faunal densities than did gravel habitats. Furthermore, the meiofaunal communities differed between bryophytes and gravel. He suggested that food value within the bryophyte habitat may account for the higher densities of rotifers and other meiofauna there.

In a Wisconsin, USA, study, *Ptygura linguata* occurred only on the bladderwort (*Utricularia* sp.; Figure 38) and the brook moss *Fontinalis* sp. (Figure 34) (Edmondson 1940). *Ptygura cristata* (Figure 178), a species known previously only from Australia, likewise was found on *Fontinalis* in the inlet to a Wisconsin lake! Molecular studies may tell us that these long-distance variants are actually different species, or at least microspecies. Or did some limnologist wear the same boots in both places?

Figure 178. *Ptygura cristata*, a species known from *Fontinalis*. Drawing by Murray (1913) from Rotifer World Catalog, through Creative Commons.

Waterfalls

Savatenalinton and Segers (2008) examined the rotifers among the wet mosses of a waterfall in Thailand. Among these, they found the new species *Lecane martensi* (Figure 179). They located twelve species in their single day of collection, December 2004. *Lepadella minuta* and *Lecane agilis* (Figure 180-Figure 181) were new to Thailand. The other species were *Brachionus angularis* (Figure 182-Figure 183), *B. forficula* (Figure 184), *Colurella adriatica* (Figure 3), *Keratella cochlearis* (Figure 185), *K. tropica* (Figure 186), *Lecane arcuata*, *L. lunaris* (Figure 123), *L. paxiana*, and *Trichocerca pusilla* (Figure 187) among the waterfall mosses.

Krakatau

Krakatau is a volcanic island west of Java and south of Sumatra. Heinis (1928) examined the moss fauna of the island. Rotifers were identified on the moss *Philonotis* sp. (Figure 30). Heinis found *Rotaria montana*, *Habrotrocha angusticollis* (Figure 188), *Macrotrachela ehrenbergi* (Figure 189), *Macrotrachela papillosa* (Figure 190), and *Adineta gracilis* (Figure 191).

Seasons

In Oregon, USA, densities of rotifers did not vary by season in the moss *Eurhynchium oregonum* (Figure 36), a tree trunk and log dweller, whereas those of nematodes, tardigrades, mites, and some annelids did (Merrifield & Ingham 1998). They suggested that the low numbers of rotifers in moss samples may be due to the use of the Baermann funnel for sampling. This technique is not suitable for immobile organisms like rotifers, as indicated by their comparison with subsequent squeezings and agitation of the moss.

Periphytic rotifers living on non-bryophytic macrophytes must find a way to survive the winter season in parts of the world where these macrophytes disappear as winter approaches. On the other hand, life is possible on bryophytes because they are present year-round. There are insufficient detailed studies to make any generalizations about differences in life cycles of bryophyte dwellers vs periphyton on other macrophytes and algae.

Bielańska-Grajner *et al.* (2011) assessed the numbers (density) of rotifers in spring, summer, and autumn in peatland types in eastern Poland. They found considerable differences among sites. For example, in one raised bog (DB1) the greatest density of rotifer individuals was in summer, whereas in another (DB2), the greatest density was in autumn (Figure 192).

Figure 192. Seasonal changes in moss-dwelling rotifers from eight peatlands in eastern Poland. DB1, DB2, & M1 = raised bogs; M1 & J = poor fens; L1 & L2 = intermediate fen; BB = rich fen. Modified from Bielańska-Grajner *et al.* 2011.

Bateman and Davis (1980) examined the seasonal differences among rotifers in a hummock-hollow complex in a poor fen in Newfoundland, Canada. The *Monogononta* all but disappeared in winter. *Bdelloidea* decreased but still maintained relatively good numbers.

Ricci *et al.* (1989) found no seasonal replacement of clones of *Macrotrachela quadricornifera* (Figure 62-Figure 64) from a terrestrial moss in northern Italy. Likewise, the isozyme variant composition was unaffected by temperature changes. Instead, relative humidity seemed to regulate the number of isozyme morphs.

Danger amidst the Bryophytes

The fungi *Lecophagus longispora* (Figure 194-Figure 195) and *L. musicola* (Figure 196-Figure 199) use adhesive pegs that attract rotifers (George Barron, pers. comm. 25 January 2010). But the rotifers are lured to the fungus, only to be attacked themselves. Once the rotifers are attached, the pegs adhere, using lectin/carbohydrate bonding, and the fungus penetrates the rotifer, ultimately parasitizing it.

Figure 193. *Lecophagus longispora* infecting four rotifers. Photo by George Barron, with permission.

Figure 196. *Lecophagus muscicola* that has captured two rotifers and two adhesive pegs. Photo by George Barron, with permission.

Figure 199. Conidia (X600) of *Lecophagus muscicola*. Photo by George Barron, with permission.

Another fungus dangerous to some bryophyte-dwelling species is *Zoophagus insidians* (Figure 200). Aquatic rotifers attempt to feed on its branch tips, but the adhesive tips bond (possibly lectin/carbohydrate bonding) to the rotifer mouth and inside the oral cavity (Barron 2012). The tip grows there and assimilative hyphae penetrate the body cavity of the rotifer, releasing digestive enzymes that ultimately digest the rotifer from the inside. This attack on the rotifer mouth permits this fungal species to select loricated rotifers (Prowse 1954).

Figure 200. *Philodina roseola*, sometimes a bryophyte dweller, caught by the fungus *Zoophagus insidians*. Photo by Wim van Egmond, with permission.

Whisler and Travland (1974) refer to the fungus as "wily" because of its sneak attack on the rotifers. When the **adhesive peg** of the fungus contacts the rotifer (Figure 201), the fungus is stimulated to release a glue from its trap. The traps are branches that are packed with vesicles containing an electron-dense glue, and upon contact the two layers of the fungal wall separate and the vesicles fuse with the cell membrane. The cilia of the rotifer are stuck to the fungal trap by this glue. Growth of the fungal **haustorium** [slender projection from fungal thread (hypha) of parasitic fungus that enables it to penetrate host] proceeds rapidly, digesting the rotifer within a few hours.

Zoophagus (Figure 200-Figure 201) apparently does not produce zoospores, with those few zoospores reported apparently belonging to contaminants (Dick 1990; Powell *et al.* 1990). Instead it reproduces by **fusiform conidiospores** (asexual fungal spores; see Figure 199), and it has been placed in the *Zygomycetes* (Powell *et al.* 1990)

due to its reproductive differences. These conidiospores are sometimes referred to as gemmae.

Ozone Hole and Pollution Dangers?

A number of researchers have chosen the microfauna of terrestrial bryophytes as indicators of air pollution effects (Steiner 1994a, b). Meyer *et al.* (2010) compared the microfauna on transplanted mosses (*Pseudoscleropodium purum* – Figure 202) in rural, urban, and industrial areas of France. The mosses were placed in jars in open shelters that prevented contamination carried by rain. They found that the biomasses for microalgae, bacteria, rotifers, and testate amoebae were greatest in the rural area. However, at the end of the study there were no significant differences for nematodes or rotifers. Although the mosses absorbed Al, Cr, Cu, Fe, Pb, Sr, and Zn, only Cu and Pb had a significant effect on the biomass of rotifers.

Figure 202. *Pseudoscleropodium purum*, the moss used in transplant experiments to assess effects of pollution on microfauna, including rotifers. Photo by Hermann Schachner, through Creative Commons.

Responses of functional groups to air pollution is often ignored in favor of simpler studies on single species. Nguyen-Viet *et al.* (2007) examined the effects of

simulated lead pollution by experimenting in controlled laboratory conditions on the microbial communities associated with *Sphagnum fallax* (Figure 203). But in this case, the biomass of rotifers was not significantly affected by lead addition. However, the biomass decreased in all treatments (including controls) during the experiment (20 weeks). On the other hand, biomasses of bacteria, microalgae, testate amoebae, and ciliates were dramatically and significantly decreased in both Pb addition treatments (625 & $2,500 \mu\text{g L}^{-1}$ of Pb^{2+}) compared to the controls. This decrease in microbial food source unbalanced the microcosms, causing significant differences in microfaunal community structure. Trophic links were changed because the testate amoebae and ciliates had strongly reduced biomass, whereas the bacteria had a relatively stable contribution to the microbial biomass. These changes affected the rotifer biomass through the food web.

Figure 203. *Sphagnum fallax*, a species that absorbs lead but houses rotifers that are not harmed directly by lead additions. Photo by Christian Fischer, through Creative Commons.

Although there seemed to be no differences in growth of *Sphagnum magellanicum* (Figure 111-Figure 112) under the ambient UV-B radiation in the ozone hole and reduced UV-B under filters in Tierra del Fuego, southern Argentina, the rotifer fauna of this moss seems to prefer the greater UV-B under ambient conditions (Searles *et al.* 1999). The rotifers were actually more numerous under the ambient conditions of UV-B in the ozone hole than under the reduced UV-B created by the filters.

Summary

Rotifers (Rotifera) can enter a state of **cryptobiosis** (dormant state) and survive desiccation right along with bryophytes, also getting dispersed with the fragments of mosses. The **bdelloid rotifers** are the most common among bryophytes and are **parthenogenetic**, hence are all female. In the **Monogononta**, unfertilized eggs develop into a male. In unfavorable conditions, monogononts form thick-walled resting "eggs" (really zygotes and embryos). They depend on water not only for hydration, but for locomotion and directing food to the mouth using cilia in the corona.

The dehydrated state (**anhydrobiosis**) helps to protect them from UV light, high temperatures, cold temperatures, and fungal infection. When confronted with drying conditions, bdelloid rotifers form a compact structure known as a **tun**. Slow drying produces the greatest survival and production of the disaccharide sugar **trehalose** maintains membrane integrity. Activity generally resumes within one hour of rehydration, but they need about a day of active state before they go into another dehydrated state. The record survival for an egg appears to be nine years, whereas an adult of *Macrotrachela quadricornifera* mya have survived dry on a moss on a herbarium sheet for 59 years. Mucus appears to deter predation, but it could also protect against or slow dehydration.

Bryophyte-dwelling rotifers tend to be smaller than those in open water. Terrestrial bryophytes provide slow but unpredictable and frequent drying. Adaptations to bryophyte living include small size, ability to attach or crawl in small spaces, parthenogenesis, dormancy by egg and tun, detritus as a food source, and structures such as tubes, mucus, and loricas for protection. Bryophytes contribute cover, water film, slow drying, and periphytic and detrital food sources.

Tardigrades may be significant predators, but rotifers such as *Ptygura velata* construct a tube from their own feces for protection. Some rotifers in epiphytic sites live in lobules of leafy liverwort leaves (*Frullania*, *Microlejeunea*, *Colura*, *Pleurozia purpurea*, *Acrolejeunea*) where desiccation is less frequent and there is a modicum of protection.

Rotifers are common on bryophytes. In the Antarctic the terrestrial species are largely restricted to mosses. Peatland habitats have the highest diversity among the bryophyte habitats, with the **Bdelloidea** predominating. *Habrotrocha roeperi* and *Habrotrocha reclusa* seem to be restricted to the **retort** cells of some *Sphagnum* species. Bog and fen rotifers are mostly widespread species with wide habitat tolerances. A few are restricted to bryophytes in bogs. In *Sphagnum* peatlands, acidity seems to discourage many species, with more species and greater abundance in fens. Rotifers in pitcher plants contribute to decomposition and nutrient cycling in the leaves, especially for nitrogen and phosphorus. In aquatic habitats, those occupying *Fontinalis antipyretica* can reach densities 151 times that of adjacent mineral substrate. Hundreds of thousands of rotifers can exist in 100 mL of this moss. Unique species can occur among bryophytes in waterfalls. Fine particulate matter trapped by mosses can serve as food. In the Antarctic, many **rotifers** prefer the middle stem zone where epiphytic algae are most abundant.

Acknowledgments

Bryonettors have been wonderful in sharing their observations, making their photographs available to me, and seeking photographs from others. Robert Wallace helped me to understand the life cycle and structures of the rotifers. Paul Davison has been helpful in providing

suggestions and offering images. Tom Thekathyil alerted me to the image of a rotifer on a *Sphagnum* cell and Des Callaghan helped me find the email address of the photographer. Tom Powers, Jean-Marie Cavanilhac, and Walter Dioni helped me obtain images and permission from others. My special thanks go to Michael Plewka for his generous permission to use so many of his beautiful images from Plingfactory and his help in the identification of other images. Aydin Orstan helped me find email addresses and pointed out errors in an earlier version of the chapter. Many other photographers have also been generous with permission for the use of their images. I appreciate Claudia Ricci for her help in tracking down current names and in providing images. Caspar Chater helped me find a reference on moss repair genes. Christian Jersabek was helpful with an earlier version of this chapter and provided permission for use of his images. Diego Fontaneto taught me the difference between mucous and mucus. Willem De Smet provided an extensive review of technical information in this sub-chapter.

CHAPTER 4-6

INVERTEBRATES: ROTIFER TAXA – BDELLOIDEA

Figure 1. Rotifer on a *Sphagnum* leaf. Photo by Marek Miś at <<http://www.mismicrophoto.com/>>, with permission.

Taxa on Bryophytes

With about 2200 species, rotifers are a group with a wide range of aquatic, marine, and **limnoterrestrial** (requiring watery matrix in terrestrial habitats, but also subject to desiccation) species, permitting us to analyze habitat relations. This analysis is limited with respect to bryophytes because few studies describe those in the bryophyte habitat, and those that do typically simply indicate "moss." This is demonstrated by the delineation of rotifer habitats in the comprehensive study on the relationship of rotifers to habitat, using only **macrophytes** (housing periphytic rotifers), open water (with planktonic forms), **minerogenous** sediments (with **psammon** and **hyporheos**), **organogenous** sediments, and other organisms (*i.e.* parasites and epizoans) (Pejler 1995). Bryophytes are not given separate attention. Pejler (1995) pointed out that rotifers are mostly cosmopolitan, hence

suggesting that ecological barriers are more important in determining their distribution. Nevertheless, Pejler considers rotifers to lack strong restrictions of habitat. Extreme environments do support few species, but can support large numbers of individuals, typically primary consumers. On the other hand, when rotifer species are numerous the differences in their morphology are so great that patterns of adaptations are difficult to define.

Pejler (1995) considered that adaptations to chemical and physical environments may develop rapidly in geologic time, whereas those changes that are more fundamental occur over a longer time period. Differences in structure of **troph**i (tiny, calcified, jaw-like structures in the pharynx) seem to facilitate differences in food type and these differences are most apparent among **Bdelloidea**, but even in extreme environments, differences don't seem to

correlate with habitat and closest relatives seem to occur in "normal" habitats.

Although many taxa can be found on bryophytes, few have been studied relative to the role of the bryophytes, and finding the existing studies among published literature can be a bit hit or miss. I am unable to summarize adaptations except to suggest that being small (which applies to the entire phylum) and being able to attach may be advantages. Movement among bryophytes is mostly inchworm style rather than being accomplished by the cilia. The trophi need to be adapted to the available food, with detritus being abundant among the bryophytes. The species included here most likely provide a very incomplete list, and the ecological information included with the images is likewise very incomplete. Furthermore, the distribution of species is poorly known, although many are considered cosmopolitan. Due to these limitations, these chapters are organized first by classification rather than ecology.

CLASS BDELLOIDEA

The name **Bdelloidea** (the "B" is silent) refers to the method of movement and means "leech-like." The **Bdelloidea** have a **corona** that is split into two, creating two "wheels" to direct food to the mouth (Figure 1). It is the smaller in number of species of the two classes and has only four families (Melone & Ricci 1995), all of which are represented on bryophytes. In fact, Donner (1956, 1975) reported that 95% of the rotifers living on terrestrial mosses, soil, and lichens are in the **Bdelloidea**. The most species on soil and moss are in the genus *Habrotrocha*, (Figure 14-Figure 25) whereas 30% of the overall species in **Bdelloidea** are in *Macrotrachela*.

This group is comprised of ~460 species, only one of which Segers (2008) considered to be marine, but Fontaneto (2006) reported several strictly marine species. They are distinguished from the **Monogononta** by the presence of two ovaries (**Monogononta** have only one). This class of rotifers is comprised entirely of females and is exclusively **parthenogenetic** (having offspring from unfertilized eggs), negating the need for males to complete the life cycle.

The bdelloid rotifers are characterized by an elongated body with a telescopically retractable foot, single dorsal antenna, and apical rostrum (Melone & Ricci 1995). The ciliary apparatus is used for both locomotion and collecting food, making it adaptive based on the animal's life style. The moss dwellers typically have a narrower wheel apparatus, a more rigid cuticle that has cuticular spines or knobs, and smaller toes (Donner 1953, 1956).

The **bdelloids** are known from freshwater and soil, and are common on **bryophytes**. They have a retractable head with a well-developed **corona** that is divided into two parts. Movement includes both swimming and crawling, but they seldom venture into the plankton (Fontaneto & Ricci 2004). Crawling is similar to the movement of inchworms, or some leeches, using the toes and head while arching the mid body, then elongating again forward.

Burger (1948) suggested three regulatory mechanisms to determine the suitability of mosses for the **Bdelloidea**:

1. The age of the moss at the site affects the time during which colonization has been possible, and that in turn affects the number of species present.
2. Water presence and resultant osmotic potential affect activity of the rotifers.
3. Availability of suitable food is important. This includes both size of potential food and food quality (Ricci 1984).

Kutikova (2003) considered their morphological structures, obligate parthenogenesis, and **anhydrobiosis** to be important adaptations to living among mosses and other terrestrial substrata that have sharp environmental fluctuations. Most of the **bdelloids** survive unfavorable periods, particularly drought, by entering a type of dormancy known as **anhydrobiosis**, *i.e.* dry dormancy (Gilbert 1974; Ricci 1987, 1998, 2001). All the bdelloids that live among bryophytes are able to secrete mucus as they dry (Figure 2) and create a case-like structure with adhering particles. It is their ability to withstand drying, along with their parthenogenetic reproduction (Ricci 1992), that fosters their cosmopolitan distribution (Fontaneto *et al.* 2006, 2007, 2008). And this ability of anhydrobiosis may also be the reason that Horkan (1981), in his report on Irish rotifers, found only this group on mosses other than those in bogs. Furthermore, no **Bdelloidea** were present in the Irish bogs, on bog moss, or in bog pools, suggesting they may require those dry periods. On the other hand, Diego Fontaneto (pers. comm. 2 November 2016) finds **Bdelloidea** to be common among mosses in bogs. It could be that hydrology plays an important role, but Fontaneto also finds **Bdelloidea** in habitats that never dry.

Figure 2. *Habrotrocha pusilla textris* in mucilaginous nest with 2 eggs, a condition that permits them to survive drought. Photo by Michael Plewka <www.plingfactory.de>, with permission.

In addition to the ability of anhydrobiosis and the addition of mucus, those **Bdelloidea** living in habitats that dry frequently may have thicker integuments that include distinct outgrowths, granules, and spines (*Macrotrachela multispinosa*, *Dissotrocha aculeata*) (Kutikova 2003). However, the value of these thick integuments is unknown (Diego Fontaneto, pers. comm. 2 November 2016).

Richters (1907) described six bdelloid rotifers from mosses in the Kerguelen Islands in the Antarctic. On the other hand, **Bdelloidea** were conspicuously absent from the littoral mosses on Svalbard (De Smet 1988).

Only one carnivorous **bdelloid** is known, and it is not known from **bryophytes**. Rather, the **bdelloids** filter or scrape or browse their diet of bacteria, one-celled algae, yeast, or particulate organic matter (Ricci 1984).

Adinetidae

Ricci and Covino (2005) demonstrated various aspects of anhydrobiosis in the **Adinetidae**, using *Adineta ricciae*. Rotifers that recovered from anhydrobiosis had similar longevity and significantly higher **fecundity** (reproductive rate of an organism or population) than did the hydrated controls. Lines of offspring produced after the anhydrobiosis dormancy likewise had significantly higher fecundity and longevity than controls from mothers of the same age. The name *A. ricciae* led me on a search to find its connection to the thallose liverwort genus *Riccia*, one that has several members that are dormant in muds and revive when the area is flooded. But of course, the genus is not named for the liverwort, but for the rotifer biologist, Claudia Ricci.

Adineta

The genus *Adineta* has many **cryptic species** (species that look alike but can't interbreed), as demonstrated by DNA and a diversity of narrow ecological niches (Fontaneto *et al.* 2011). This diversity has led to superfluous names in many of the rotifer genera. This text follows the nomenclature of Segers (2007).

Several species of *Adineta* are known from bryophytes. *Adineta barbata* (Figure 3), *A. gracilis* (Figure 4), and *A. vaga* (Figure 5) occur in bogs on or among *Sphagnum* (Figure 6) (Myers 1942; Hingley 1993; Bielańska-Grajner *et al.* 2011). *Adineta barbata*, in particular, is associated with *Sphagnum subsecundum* (Figure 7) (Horkan 1981; Hingley 1993; Jersabek *et al.* 2003). *Adineta vaga* is more widespread, occurring on sandstone, roof, and **epiphytic** (in this case growing on trees) mosses as well. *Adineta vaga rhomboidea* occurs on the terrestrial weedy moss *Ceratodon purpureus* (Figure 8) (Yakovenko 2000).

Figure 3. *Adineta barbata*, a species known to live on *Sphagnum subsecundum* (Figure 7) and other mosses. Photo by Jersabek *et al.* 2003, with permission.

Figure 8. *Ceratodon purpureus*, home for *Adineta vaga* var. *rhomboidea*. Photo by Jiří Kameníček, with permission.

Other species occur on bryophytes in various habitats. In most cases, the habitat is simply listed as moss, or some other non-bryophyte habitat and moss. These include *Adineta cuneata* (Figure 9) on moss (Plewka 2016), *A. steineri* (Figure 10) on epiphytic mosses (Hirschfelder *et al.* 1993; Plewka 2016), and *A. tuberculosa* (Figure 11) on moss (Horkan 1981; Plewka 2016).

Figure 11. *Adineta tuberculosa*, a moss inhabitant. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Bradyscela

In addition to the *Adineta* species, *Bradyscela clauda* (Figure 12) occurs on the terrestrial moss *Brachythecium rutabulum* (Figure 13) (Madaliński 1961; Plewka 2016).

Figure 13. *Brachythecium rutabulum*, home for *Bradyscela clauda* in Europe. Photo by Michael Lüth, with permission.

Habrotrochidae

The **Habrotrochidae** is a family with three genera, all of which occur among mosses.

Habrotrocha

Habrotrocha species are common inhabitants among *Sphagnum* (Figure 6) (Bateman 1987; Peterson *et al.* 1997; Błedzki & Ellison 1998) as well as other mosses. *Habrotrocha* is able to survive decreasing moisture with the protection of a mucous matrix (Kutikova 2003). This is particularly helpful when mosses are drying. The members of *Habrotrocha* accumulate various small adhering particles, thus further providing them a shelter to protect them while they are dry.

Habrotrocha ampulla (Figure 14), *H. angusticollis* (Figure 15-Figure 16), *H. collaris* (Figure 37-Figure 38), *H. constricta* (Figure 28-Figure 29), and *H. lata* (Figure 17-Figure 18) live among or on *Sphagnum* in *Sphagnum* ponds (Myers 1942; Horkan 1981; Hingley 1993; Jersabek *et al.* 2003; Bielańska-Grajner *et al.* 2011; Plewka 2016).

Figure 18. *Habrotrocha lata* from *Sphagnum* pond. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Some species of *Habrotrocha* use the protection of *Sphagnum* retort cells (Figure 19-Figure 21) for their homes (Plewka 2016). These are special cells that have a pore in a flask-like neck at the end of the stem epidermal

cell. The rotifers that live there extend outward from the pore to feed. This is particularly true for *Habrotrocha reclusa* (Figure 22), known from *Sphagnum subsecundum* (Figure 7) (Myers 1942) and *H. roeperi* (Figure 23; Bielańska-Grajner *et al.* 2011; Plewka 2016).

Figure 23. *Habrotrocha roeperi*, a retort cell dweller. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Bog habitats for *Habrotrocha* (Figure 24), in particular *H. rosa* (Figure 25), include pitcher plants (*Sarracenia purpurea*, Figure 26), where the rotifers are a major food source for co-habiting members of the *Culicidae* (mosquitoes) (Bateman 1987), causing the mosquito population numbers to rise (Błędzki & Ellison 1998). The pitcher plants are common plants among the *Sphagnum* (Figure 6) in bogs and provide a pool of water in their leaves. The rotifers are an important source of N and P in the bog/fen-dwelling pitcher plants.

There are many species in *Habrotrocha* that live among bryophytes. These include *H. bidens* (Figure 27) on mosses on the ground (Hingley 1993; Plewka 2016), *H. constricta* (Figure 28-Figure 29) on *Sphagnum*, water mosses, and **epiphytic** bryophytes (those growing on trees) (Myers 1942; Horkan 1981; Hingley 1993; Plewka 2016), *H. novemdens* (Figure 30) on mosses (Plewka 2016), *Habrotrocha pavid*a on the mosses *Ceratodon purpureus* (Figure 8) and *Bryum argenteum* (Figure 31) (Yakovenko 2000), *H. pusilla* (Figure 32) in mucilage on moss (Horkan 1981; Plewka 2016), and *H. quinquedens* (Figure 33) on both wet and dry mosses (Plewka 2016). Some species also occur in the lobules of the leafy liverwort *Frullania* (Figure 34-Figure 35; Michel Verolet).

Hirschfelder *et al.* (1993) examined the rotifers among epiphytic bryophytes and added *Habrotrocha flava*, *H. fusca*, and *H. insignis*.

A number of additional species are known from bryophytes, but with no additional details. Madaliński (1961) reported *H. microcephala* and *H. tridens* (see also Bielańska-Grajner *et al.* 2011) from the environs of Tatra streams. Horkan (1981) reported *Habrotrocha aspera* (Figure 36; see also Plewka 2016); see also Hingley 1993 for bog mosses), and *H. pulchra*. Hingley (1993) added *H. longula*, and *H. minuta*; Peters *et al.* (1993) added *H. eremita*. It appears that 1993 was a good year for bryophyte rotifer studies.

Otostephanos

The genus *Otostephanos* has species on *Sphagnum* (Figure 6), but others occur on terrestrial mosses. *Otostephanos auriculatus* (Figure 39-Figure 40) occurs on *Sphagnum* and *O. jolantae* (Figure 41) occurs in *Sphagnum* ponds (Plewka 2016). *Otostephanos monteti*

(Figure 42) lives on the emergent moss *Drepanocladus aduncus* (Figure 43) (Yakovenko 2000). *Otostephanos cuspidilabris* is known from "soggy" plants of the moss *Atrichum* sp. (Figure 44-Figure 45) (Yakovenko 2000). *Otostephanos macrantennus* is a bryophyte dweller (Ricci 1998). Two species live among dry mosses, *O. regalis* (Figure 46) on roof mosses (Hirschfelder *et al.* 1993; Plewka 2016) and *O. torquatus* (Figure 47) on mosses on concrete (Peters *et al.* 1993; Plewka 2016).

Figure 47. *Otostephanos torquatus* from dry moss on concrete. Michael Plewka <www.plingfactory.de>, with permission.

Scepanotrocha

Some members of a second genus seem also to find the retort cells of *Sphagnum* to be a suitable home. *Scepanotrocha rubra* (Figure 48-Figure 49) lives in these cells, extending out of them to feed (Figure 48) (Myers 1942; Plewka 2012).

Figure 48. *Scepanotrocha rubra* in a retort cell of a *Sphagnum* stem. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 49. *Scepanotrocha rubra*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

In addition to the retort dwellers, *Scepanotrocha corniculata* (Figure 50) lives on mosses, *S. semitecta* (Figure 51) is a *Sphagnum* (Figure 6) dweller, and *S. simplex* (Figure 52) lives on epiphytic mosses as well as *Sphagnum*, once again demonstrating the seemingly wide range of microhabitats used by a single rotifer species (Plewka 2016).

Figure 52. *Scepanotrocha simplex*, a species that lives on both epiphytic mosses and *Sphagnum*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Philodinavidae

Only two species from this family seem to be moss dwellers. *Philodinavus paradoxus* (Figure 53) lives in

lakes, rivers, and streams (Madaliński 1961; Ricci & Melone 1998; Plewka 2016) and is preyed upon by flatworms, larger moss-dwelling rotifers, and nematodes (Schmid-Araya & Schmid 1995). It is tiny (200 μm long) and creeps with leech-like movements, being unable to swim (Ricci & Melone 1998). Instead, its strong foot anchors it to its substrate, a feature of importance in streams and rivers. Its corona is poorly developed and it obtains its food by browsing, facilitated by the ciliated buccal field and trophi protruding throughout the mouth. Its disjunct distribution in Europe and New Zealand may indicate a lack of collecting and lack of experts on this group.

Figure 54. *Henoceros falcatus*, a stream moss dweller. Photo by Michel Verolet, with permission.

Figure 53. *Philodinavus paradoxus*, a species from stream mosses. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Within its short lifetime of only 20 days, *Philodinavus paradoxus* can produce 6-7 eggs (Ricci & Melone 1998). These seem to have about the same resistance to desiccation damage as adults, with only 10% of each surviving 7 days of desiccation, a desiccation intolerance that is typical of aquatic rotifer taxa.

Henoceros falcatus is commonly found in the same mosses in running waters with *Philodinavus paradoxus* (Diego Fontaneto, pers. comm. 2 November 2016). Ricci and Melone (1998) reported this species from mosses. They noted that *H. falcatus* was first found in mosses submerged in streams in South Africa (Milne 1916). Later *H. falcatus* was found in similar habitats in Europe, South America, Asia, and Hawaii (Schmid-Araya 1995; Turner 1996). The two species co-occur in Austria (Schmid-Araya 1995) and in Valle Argentina, Italy. It seems to be common for these two species to co-occur, suggesting similar ecological requirements. In fact, rather than being rare (Schmid-Araya 1995; Ricci & Melone 1998), Fontaneto *et al.* (2007) consider them to be fairly common in their specialized habitat of stream mosses.

Philodinidae

The philodinids use their cilia or foot and rostrum (Figure 55) to facilitate swimming (Hickernell 1917). At high temperatures these rotifers engage in active swimming, but in cold water they creep like a leech with the cilia retracted. During feeding, they attach themselves by the foot and use the cilia to direct food to the pharynx. When drying occurs, the animal forms a ball and dries up. The ball is formed by retracting both the head and the foot into the trunk of the rotifer and losing all the water, pulling the organs together and eliminating spaces. When they get water again, they resume their normal shape in ten minutes or less.

Ceratotrocha and Didymodactylos

This family has many bryophyte-dwelling species. *Ceratotrocha cornigera* is the only member of its genus documented from bryophytes, including bogs (Horkan 1981; Hingley 1993). *Didymodactylos carnosus* (Figure 55) likewise is known from mosses (Ricci & Melone 2000; Plewka 2016).

Figure 55. *Didymodactylos carnosus*, common in moss. Note the two rings of cilia. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Dissotrocha

Dissotrocha has several known bryophyte-dwelling species. *Dissotrocha aculeata* (Figure 56), *D. macrostyla* (Figure 57), and *D. spinosa* occur on or among *Sphagnum* (Figure 6) (Horkan 1981; Hingley 1993; Bielańska-Grzajner

et al. 2011; Plewka 2016). *Dissotrocha scutellata* (Figure 58-Figure 59) is known from the moss *Andreaea rupestris* (Figure 60-Figure 61), a rock dweller that dries out frequently (Plewka 2016).

Figure 56. *Dissotrocha aculeata*, a species known from *Sphagnum* and other mosses. Photo by Jersabek *et al.* 2003, with permission.

Macrotrachela

A number of species of the large genus *Macrotrachela* occur on mosses. Some of these are from *Sphagnum* (Figure 6), including *Macrotrachela concinna* (Myers 1942; Hingley 1993), *M. crucicornis* (Myers 1942), *M. decora* (Figure 62) (Plewka 2016), and *M. papillosa* (Figure 63) (Horkan 1981; Hingley 1993).

Figure 62. *Macrotrachela* cf. *decora* from *Sphagnum*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 63. *Macrotrachela papillosa*, a *Sphagnum* dweller. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Other species occur in contrasting habitats of both *Sphagnum* (Figure 6) and mosses growing on trees. These include *M. multispinosa* (Figure 64-Figure 65; Myers 1942; Horkan 1981; Hingley 1993; Jersabek *et al.* 2003), *M. nana* in stream environs (Figure 67; Madaliński 1961; Bielańska-Grajner *et al.* 2011; Plewka 2016), *M. plicata* (Figure 66; Myers 1942; Horkan 1981; Hingley 1993; Jersabek *et al.* 2003; Bielańska-Grajner *et al.* 2011; Plewka 2016), and *M. quadricornifera* (Figure 68; Myers 1942; Horkan 1981; Hingley 1993; Jersabek *et al.* 2003; Bielańska-Grajner *et al.* 2011; Plewka 2016).

Figure 68. *Macrotrachela quadricornifera*, a species from *Sphagnum* and epiphytes. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Others are known only as epiphytes, including *M. aculeata* (Figure 69; Plewka 2016), *M. magna* (Figure 70; Plewka 2016), and *M. tuberculabris* (Figure 71; Plewka 2016).

Figure 69. *Macrotrachela aculeata* from mosses on trees. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 71. *Macrotrachela tuberculabris* from moss on tree. Michael Plewka <www.plingfactory.de>, with permission.

Additional members of the genus occurred on various mossy substrates, including *Macrotrachela ehrenbergii* (Figure 72) on *Sphagnum* (Figure 6), mosses on walls, and epiphytes (Peters *et al.* 1993; Jersabek *et al.* 2003; Plewka 2016), *M. habita* (Figure 74) on *Sphagnum*, moss on trees, rocks, and ground (Myers 1942; Horkan 1981; Hirschfelder *et al.* 1993; Jersabek *et al.* 2003; Plewka 2016), *M. insolita* (Figure 75) on mosses submerged in pond (Hirschfelder *et al.* 1993; Plewka 2016) and in peatlands (Bielańska-Grajner *et al.* 2011), *M. musculosa* (Figure 76) on *Sphagnum*, ground mosses, and epiphytic mosses (Myers 1942; Hirschfelder *et al.* 1993; Plewka 2016), *M. punctata* (Figure 77-Figure 78) on dry mosses on rocks (Hirschfelder *et al.* 1993; Plewka 2016); *M. zickendrahti* (Figure 79) on *Sphagnum* and other mosses (Jersabek *et al.* 2003; Plewka 2016). For *M. muricata*, I have found little information except it occurs on mosses (Horkan 1981).

The absence of records for moss dwellers may be common. For example, Ricci (1980) found *Macrotrachela plicatula* (Figure 80) among mosses in Uganda. This was the first time it had been found since its 1911 description as a new species.

Figure 80. *Macrotrachela plicatula* from *Sphagnum*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Mniobia

Mniobia likewise has its *Sphagnum* (Figure 6) dwellers, including those found by Hingley (1993): *M. incrassata* (Figure 81-Figure 82), *M. magna* (Figure 84), *M. obtusicornis* (Figure 85), *M. symbiotica* (see also Hudson 1889; Horkan 1981). Among these, *M. incrassata* is known from other mosses as well (Plewka 2016). *Mniobia scarlatina* (Figure 83; Jersabek *et al.* 2003) and *M. tetradon* (Myers 1942; Horkan 1981) occur on epiphytic mosses. *Mniobia symbiotica* also occurs in the lobules of the leafy liverwort *Frullania eborensis* (Figure 86-Figure 88), an epiphyte in eastern USA (Biechele 2014).

Figure 88. *Frullania eboracensis* from Ohio, USA, with a rotifer in a lobule – possibly *Mniobia symbiotica*. Photo by Bob Klips, with permission.

Mniobia orta (Peters *et al.* 1993) and *M. russeola* (Horkan 1981; Hirschfelder *et al.* 1993) are also bryophyte dwellers.

Pleuretra

The genus *Pleuretra* seems to prefer habitats that dry out. *Pleuretra humerosa* (Figure 89-Figure 90) occurs on dry mosses on granite (Plewka 2016). *Pleuretra lineata* (Figure 91-Figure 93) occurs on the mosses *Andreaea rupestris* (Figure 60-Figure 61) and *Grimmia pulvinata* (Figure 94) (Hirschfelder *et al.* 1993; Plewka 2016), both species of exposed rocks. *Pleuretra brycei* (Figure 95-Figure 96) is also a bryophyte dweller, but among *Sphagnum* (Figure 6-Figure 7) and demonstrates the spines that help to protect it among the bryophytes (Madaliński 1961).

Philodina

Philodina acuticornis (Figure 97), *P. nemoralis* (Figure 98), and *P. brevipes* live on *Sphagnum* (Figure 6) (Hingley 1993). *Philodina citrina* (Figure 99-Figure 100), *P. plena* (Figure 101), *P. proterva*, and *P. vorax* (Figure 102) all occur on *Sphagnum* (Figure 6) (Hirschfelder *et al.* 1993; Jersabek *et al.* 2003; Bielańska-Grajner *et al.* 2011; Plewka 2016). But *P. plena* also occurs on epiphytes (Myers 1942) and *P. citrina* and *P. vorax* live on epiphytic mosses and mosses on rock or concrete. *Philodina nemoralis* (Figure 103; Plewka 2016) and *P. rugosa* (Figure 105; Horkan 1981; Hingley 1993; Fontaneto *et al.* 2007; Plewka 2016) live in contrasting submersed and dry habitats, including on epiphytic mosses. Other rotifers on epiphytic mosses include *Philodina childi* (Figure 104; Horkan 1981; Hingley 1993; Plewka 2016). Other members of the genus that are associated with bryophytes include *P. erythrophthalma*, *P. flaviceps* (Figure 106), and *P. roseola* (Figure 107-Figure 111) (Horkan 1981; Hirschfelder *et al.* 1993; Madaliński 1961; Plewka 2016).

Rotaria

Rotaria (Figure 110) is a genus that moves like a leech, permitting it to move among bryophytes. The genus *Rotaria* is able to move among mosses and other substrata by creeping with its head and foot (van Egmond 1999). The foot is sticky, enabling it to attach to a surface while it feeds (Dickson & Mercer 1966; Schmid-Araya 1998). The anterior cilia (Figure 111) make a current that directs the food toward the pharynx for ingestion.

Figure 110. *Rotaria*, fully extended as it would be for its leech-like movement. This is a genus with several bryophyte-dwelling species that can move about the bryophytes in this manner. Photo by Wim van Egmond, with permission.

Figure 111. *Rotaria*, showing the two wheels that direct the food into the gullet. Photo by Yuuji Tsukii, with permission.

Several species of *Rotaria* live in association with *Sphagnum* (Figure 6). These include *R. citrina* (Figure 112-Figure 113), *R. haptica*, *R. macroceros* (Figure 114), *R. macrura* (Figure 115-Figure 116; see also Horkan 1981; Bielańska-Grajner *et al.* 2011), *R. magnacalcarata*, *R. neptunia* (Figure 117-Figure 118), *R. neptunoida* (Figure 119), *R. quadrioculata*, *R. socialis* (Figure 120), *R. spicata*, and *R. tardigrada* (Figure 121; see also Bielańska-Grajner *et al.* 2011) (Hingley 1993; Plewka 2016). In addition to the *Sphagnum* dwellers, *R. rotatoria* (Figure 122) and *R. macrura* live on mosses (Madaliński 1961; Horkan 1981; Plewka 2016) as well as living in peatlands (Bielańska-Grajner *et al.* 2011). *Rotaria sordida* (Figure 123) is unusual in living not only on mosses on limestone, but also in living on the thallose liverwort *Marchantia polymorpha* (Figure 124; Horkan 1981; Hirschfelder *et al.* 1993; Plewka 2016) and in peatlands (Bielańska-Grajner *et al.* 2011).

Desiccation Tolerance

Ricci (1998) compared the desiccation survival percentage of rotifers in the **Philodinidae** from water vs those from terrestrial mosses. The rotifers from terrestrial mosses survived seven days of desiccation better than did those from the water (Figure 125). The 2-day-old rotifers (juveniles) had poor resistance to desiccation. *Rotaria rotatoria*, *R. neptunia*, and *Otostephanos macrantennus*, all from bodies of water that do not dry out, did not recover from desiccation at any life stage. On the other hand, *Philodina acuticornis* and *R. neptunoida* likewise live in permanent bodies of water (including among mosses) and do withstand desiccation. Ricci also summarized indications of desiccation tolerance of **Bdelloidea** reported in the literature and from her own studies (Table 1).

Figure 125. Recovery rates of rotifers collected from terrestrial mosses (M) and from water bodies (W). Life stages are e = newly laid eggs or embryos; 2-d = 2-day-old juveniles; 8-d = 8-day-old adults. Numbers above bars = sample size; (number) = number of replicates. Bars represent mean recovery rates among replicates; vertical lines = standard error. *Percentage viability adjusted to control. Redrawn from Ricci (1998).

Table 1. Genera of **Bdelloidea** that inhabit mosses compared to those from water, among genera for which desiccation tolerance is known. Adapted from Ricci (1998). Habitats are based on Donner (1965).

Adinetidae		
<i>Adineta</i>	moss, water	+ Dobers 1915; Örstan 1995
<i>Bradyscela</i>	moss	(+) Donner 1976
Habrotrichidae		
<i>Habrotricha</i>	mainly moss & soil	+ Schramm & Becker 1987
<i>Otostephanos</i>	moss, <i>Sphagnum</i>	(+) Murray 1911
<i>Scepanotrocha</i>	moss, soil	(+) Donner 1976
Philodinavidae		
<i>Abrochtha</i>	water	+ Ricci 1998
<i>Henoceros</i>	water	+ Ricci 1998
<i>Philodnavus</i>	water	+ Ricci 1998
Philodinidae		
<i>Didymodactylos</i>	moss	(+) Donner 1976
<i>Macrotrachela</i>	moss, water	+ Dobers 1915; Ricci <i>et al.</i> 1987
<i>Mniobia</i>	moss, soil	+ Dobers 1915
<i>Pleuretra</i>	moss	(+) Murray 1911
<i>Philodina</i>	moss, water	+ Jacobs 1909; Ricci 1998
<i>Rotaria</i>	mainly water, soil	+ Ricci 1998

Summary

The rotifers in **Bdelloidea** are the most frequently represented rotifers on bryophytes. The bryophyte dwellers are usually not also planktonic and typically attach to the bryophytes by their toes. They move like an inchworm or use their cilia. They obtain their food from the microscopic organisms and detritus among the mosses. Only females exist and the eggs can typically survive desiccation. Mucus helps these rotifers to survive desiccating conditions.

Bryophyte-dwelling **Bdelloidea** include four families known from bryophytes: **Adinetidae**, **Habrotrichidae**, **Philodinavidae**, **Philodinidae**. The **Adinetidae** are known from bogs and other bryophytes. The **Habrotrichidae** have a number of species from bogs and from other bryophytes. Many of the species live in such small niches as *Sphagnum* retort cells and liverwort lobules. The **Philodinavidae** has two moss dwelling species that often occur together in streams. The **Philodinidae** creep in cold water and live attached on plants; a number of species occur on bryophytes. The **Philodinidae** terrestrial moss dwellers tested have greater desiccation tolerance than do the aquatic species. Adults are more desiccation tolerant than juveniles.

Acknowledgments

Claudia Ricci has generously answered my questions. Bryonettors have been wonderful in making their photographs available to me and seeking photographs from others. Tom Powers and Walter Dioni helped me obtain images and permission from others. Christian D. Jersabek very generously gave me permission to use the wealth of images from the Online Catalog of Rotifers. Tom Thekathyil and Des Callaghan helped me in finding and gaining permission from Marek Miś for the beautiful image in the frontispiece and others. Aydin Orstan helped me find email addresses and reviewed an earlier version of the chapter. Diego Fontaneto reviewed this sub-chapter and offered many suggestions and corrections. Many photographers have been generous with permission for the use of their images and others have provided them online through Creative Commons and other public domain sources. Antonio Guillén provided me with credit information on images from Proyecto Agua. My special thanks go to Michael Plewka for his generous permission to use so many of his beautiful online images.

CHAPTER 4-7a

INVERTEBRATES: ROTIFER TAXA –

MONOGONONTA

Figure 1. *Keratella* sp. among *Sphagnum* leaves. Photo by Marek Mis <www.mismicrophoto.com>, with permission.

CLASS MONOGONONTA

This is the largest of the two classes of rotifers, comprised of ~1570 species, ~1488 of which are free-living in fresh water of limnoterrestrial habitats (Segers 2008). It differs from the **Bdelloidea** in having two sexes and having only one ovary. Nevertheless, asexual reproduction occurs over and over until environmental conditions, often related to crowding, trigger the reproduction to become sexual (Welch 2008). At this time, the eggs of the **amictic** (non-sexual) females hatch into **mictic** females that produce their eggs by meiosis. The **haploid** eggs that are not fertilized develop into much smaller males and fertilization of a female by these males produces **diploid** eggs that become resting eggs.

The monogonont rotifers mostly eat small particles and organisms by filtering them, some actually seize them, and some are parasitic.

ORDER COLLOTHECACEA

Many members of this order are **sessile** (attached) and some are colonial. These rotifers have a foot that lacks toes, but they possess many foot glands that are used for adhesion. The females are predominantly sessile, but males and immature rotifers are free-living. The rotary apparatus surrounds a funnel-like **invagination**. Many are surrounded with a jelly sheath.

Collothecidae

Many members of the Collothecidae are plant and algal inhabitants. The **Collothecidae** provide us with evidence of adaptive strategies embodied in reproduction. An examination of 65 species of rotifers, including this family, revealed that egg volume of rotifers increased as body volume increased, but the relative size of eggs actually decreased as body size increased (Wallace *et al.*

1998). This means that smaller species, typical among planktonic species and bryophytes, invest the most in egg production. The **Flosculariidae (Flosculariaceae)** species are of intermediate size and their relative investment in egg mass is likewise intermediate. The **Collothecidae** family has the largest species and the lowest relative biomass of egg production among those examined by Wallace *et al.*

Collotheca

Collotheca (Figure 2-Figure 8) is a common genus in peatlands, living in *Sphagnum* pools (Figure 5) and on *Sphagnum* (Figure 2, Figure 21, Figure 61-Figure 62).

Figure 2. *Collotheca* on *Sphagnum*. Photo by Marek Mis <www.mismicrophoto.com>, with permission.

Figure 5. *Sphagnum* pond, home for rotifers. Photo by Michael Luth.

Collotheca campanulata occurs on wet mosses as well as in the plankton on Svalbard (De Smet 1993). The relationships of this species to aquatic flowering plants can instruct us on relationships to look for among bryophytes. *Collotheca campanulata (gracilipes)* (Figure 6) is selective in its location on its aquatic plant substrate (Wallace & Edmondson 1986). On plants such as *Elodea canadensis*, it selected (98%) the lower (**abaxial**) surfaces of the leaves. When given equal opportunities for four plant species, it selected *Lemna minor* over *Elodea canadensis*, but in the field more were found on *Elodea canadensis*, with densities reaching more than six individuals per mm². Light made a difference, with 91% of the rotifers selecting the **adaxial** (upper) surface in continuous light, but showing no preference in continuous darkness. **Alpha amylase** appears to be the chemical that helps them to identify a plant substrate. Those rotifers that were induced to settle on the abaxial surface produced more eggs than those that were induced to settle on the adaxial surface. It would be interesting to see if these relationships persist on liverworts like *Riccia fluitans* (Figure 9) and *Ricciocarpos natans* (Figure 10). But what would they do on mosses like *Fontinalis* (Figure 11)? They are also known from bog

pools where they attach to *Sphagnum* (Figure 2, Figure 21, Figure 61-Figure 62) and algae (Figure 8).

Sphagnum peatlands (Figure 61) are home to several species of *Collotheca*. *Collotheca coronetta* (Figure 12-Figure 13) and *Collotheca ornata* (Figure 14) live sessile on *Sphagnum* (Figure 21, Figure 62) (Jersabek *et al.* 2003). *Collotheca ornata* also occurs on wet mosses and in plankton on Svalbard. *Collotheca crateriformis* (Figure 15-Figure 16) and *C. trilobata* (Figure 17) live among *Sphagnum* (Figure 21). Bielańska-Grajner *et al.* (2011) reported *C. wiszniewski* from bogs and fens in Poland.

Figure 12. *Collotheca coronetta*, a species that occurs sessile on *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Figure 17. *Collotheca trilobata* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Stephanoceros

So far I have found few reports on *Stephanoceros* from bryophytes, but then, it is a genus with only two species (Meksuwan *et al.* 2013), both of which occur on bryophytes. And even the taxonomy is questionable, with the genus arguably belonging to *Collotheca*. *Stephanoceros fimbriatus* (Figure 18-Figure 20) is a sessile species that lives on *Sphagnum* (Figure 21) as one of its substrates (Jersabek *et al.* 2003). *Stephanoceros millsii* (Figure 22) is known from bryophytes.

Figure 22. *Stephanoceros millsii*, a species known from bryophytes. Note the eggs. Photo by Jersabek *et al.* 2003.

ORDER FLOSCULARIACEA

Not only do the members of this order lack toes; some of the planktonic species lack feet as well. Nevertheless, they have multiple **foot glands** to secrete glue. The rotary organ has a double ring of cilia that surrounds the anterior of its lobe-like appendages. Species may be either free-living or sessile and are suspension feeders.

Conochilidae

The species *Conochilus hippocrepis* (Figure 23-Figure 24) is typically planktonic in both ponds and large bodies of water, but among these habitats you can find it associated with *Sphagnum* (Figure 21) (Jersabek *et al.* 2003). It generally lives in a habitat with a pH of 6.3-8.3 and temperature range of 6.4-15.4°C (de Manuel Barrabin 2000). Its colonies can reach 30-60 members that are joined in a gelatinous case (Figure 25). Detritus and bacteria, generally abundant in the habitat, serve as food (Pourriot 1977).

Figure 23. *Conochilus hippocrepis* female, member of a genus known on *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Figure 24. *Conochilus unicornis* female, member of a genus known to associate with *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Figure 25. *Conochilus* sp. colony. This genus has species that are sessile on *Sphagnum*. Photo by Wim van Egmond, with permission.

Conochilus hippocrepis (Figure 23-Figure 24) is sensitive to increasing predator pressure from the copepod *Parabroteas sarsi* (Figure 26) (Diéguez & Balseiro 1998). As the predator increases in size and begins to prey on the *C. hippocrepis*, this rotifer responds by increasing its colony size (Figure 25). This seems to be the only member of this family known to associate with bryophytes, in particular *Sphagnum* (Figure 21).

Figure 26. *Parabroteas sarsi* male, predator on *Conochilus hippocrepis*. Photo by Cristián Correa Guzmán, with permission.

Flosculariidae

In this family the male is small and free-swimming, whereas the female lives in a tube and usually attaches by its modified foot. Some of these females (e.g. *Ptygura linguata*) live on the bladders of species of the bladderwort *Utricularia*. But, sadly for the rotifers, they also constitute part of the diet of these same bladderworts (Mette *et al.* 2000). This habitat affords the rotifers a special aid in getting food as it is sucked into the bladder. Bryophytes can offer no such aid, and although the genera on bryophytes are often the same because they are sessile, species differ.

Floscularia

The genus *Floscularia* (Figure 27-Figure 29) is a tube builder and is known to live on *Sphagnum* (Figure 66) (Hingley 1993). Jabez Hogg described this tube-building behavior in 1883 (*In Rotifers* 2012). The case is composed of tiny pellets. Gosse, in 1851 (*In Rotifers* 2012), reported a specimen attached to a submerged moss in a pond and observed its case-building behavior. I cannot improve upon the text provided by Hogg (1854, *In Rotifers* 2012): "In November, 1850, Mr. Gosse found a fine specimen of a *Floscularia* (Figure 27-Figure 29) attached to a submerged moss from a pond at Hackney; this he watched as it engaged in building its case, and at the same time discovered the use of the curious little rotatory organ on the neck. When fully expanded, the head is bent back at nearly a right angle to the body, so that the [rotary] disc (Figure 29) is placed nearly perpendicularly, instead of horizontally; the larger petals, which are the frontal ones, being above the smaller pair." The terminology has changed, but the observations still provide us with a clear picture of this rotifer on a moss. He discovered the role of these wheels of cilia by adding carmine to the water and observing its pathway.

Figure 27. *Floscularia confiera* female, a species that occurs sessile on *Sphagnum* and in bog pools. Photo by Jersabek *et al.* 2003, with permission.

Figure 29. Tip of case of *Floscularia ringens*, showing the geometric arrangement of pellets and the rotary apparatus. Photo by Martin Mach, with permission.

Gosse (1851 *In Rotifers* 2012) provided a charming description of the feeding as well: "If the atoms be few, we see them swiftly glide along the facial surface, following the irregularities of outline with beautiful precision, dash round the projecting chin like a fleet of boats doubling a bold headland, and lodge themselves, one after another, in the little cup-like receptacle beneath." But these were not used as food. Rather, they were eventually emptied from the cup, which was bent down to the margin of the case and the pellet, mixed with "salivary secretion," added to the margin of the case (Figure 29). Each pellet required 2-3 minutes to be gathered and deposited.

Fontaneto *et al.* (2003) added detail to tube building in *Floscularia*. They observed that each pellet in the tube has a hole in the middle. The pellets are cemented together with "glue bundles" and the tube is lined with mucus.

Ptygura

As I read through account after account of rotifer sampling, I can't help but wonder if more attention should be given to the bryophyte habitat for locating new rotifer species, especially for sessile groups like this one. A number of these species are sessile on *Sphagnum* (Figure 66) and feed on associated algae. De Smet (1990) reported an unidentified species from wet mosses on Svalbard.

Ptygura rotifer (Figure 30) is a free-swimming rotifer (Michael Plewka, pers. comm. 6 August 2016), but Hingley (1993) collected them among *Sphagnum* (Figure 66) as well and reported them as sessile there.

Ptygura brachiata (Figure 31-Figure 32) and *P. velata* (Figure 33) likewise are species that live on *Sphagnum* (Figure 66) (Jersabek *et al.* 2003; Opitz 2016). In addition, a number of species live on other bryophytes as well as living in bogs. For example, *Ptygura crystallina* (Figure 34) lives on bryophytes and in bogs in the Pocono Mountains, Pennsylvania, USA. *Ptygura melicerta* (Figure 35-Figure 38) forms colonies (Figure 35) in a lake in Wisconsin, USA, but it is also present on bryophytes and in bog pools. It is common among colonies of the *Cyanobacterium Gloeotrichia* (Figure 38) (Plewka 2016).

Figure 38. *Ptygura melicerta* with *Gloeotrichia*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Ptygura pilula (Figure 39) seems to be more commonly a moss dweller, including *Sphagnum* (Figure 40), where it passes dry periods with a gelatinous covering (Plewka 2016). It incorporates feces (Figure 39-Figure 41) into this tubular housing, further adding to its protection. It also produces resting eggs (Figure 42) that help it to survive dry periods. *Ptygura stygis* is also known from submerged mosses (Ptygura 2016).

Figure 39. *Ptygura pilula* with feces in gelatinous housing. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 42. *Ptygura pilula* resting egg. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Hexarthridae

In a study of a Turkish lake, Gülle *et al.* (2010) found that rotifers were most abundant from June through August and disappeared from November through April. It was a member of the **Hexarthridae**, *Hexarthra fennica*, that was one of the dominant taxa – 51% of the zooplankton. The rotifers were most dense at a depth of 5 m. But it seems that bryophyte dwellers are few. I found only *Hexarthra mira* (Figure 43-Figure 44) reported as a bog and occasional bryophyte dweller, but this species is likewise planktonic. It most likely occurred among mosses accidentally from open water. Its amictic eggs become resting eggs (Figure 45-Figure 46), helping to permit its survival as its habitat dries.

Figure 43. *Hexarthra mira*, a typically planktonic species known from bryophytes and bogs. Photo by Jersabek *et al.* 2003, with permission.

Figure 46. *Hexarthra mira* resting egg. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Testudinellidae

The family **Testudinellidae** includes both saltwater and freshwater species. It is characterized by having dorsal and ventral plates of the lorica that are completely fused laterally. The body is greatly flattened dorso-ventrally (top-bottom). The foot is long and retractile (see Figure 49 and Figure 50) with a tuft of cilia at its tip. These rotifers are free swimming, typically in the littoral zone, but members of *Testudinella* (Figure 48-Figure 59) may also occur on bryophytes and in *Sphagnum* pools (Figure 5) as well as on other macrophytes. There are three genera, but only *Testudinella* seems to be represented on bryophytes.

Myers (1942) provided one of the more detailed texts on rotifer habitats. Among these are a number of species that live on or among *Sphagnum* (Figure 21) or in pools (Figure 5) among the peatlands. One such species is *Testudinella armiger* (Figure 47), a species that lives on the emergent species *Sphagnum cuspidatum* (Figure 21).

Figure 47. *Testudinella armiger*, an inhabitant of *Sphagnum cuspidatum*. Photo by Jersabek *et al.* 2003, with permission.

The records for *Sphagnum* (Figure 21) associates include *Testudinella aspis*, *T. emarginula* (Figure 48), *T. epicopta* (Figure 49), *T. tridentata* (Figure 50-Figure 51), and *T. truncata* (Figure 52) (Myers 1942; Jersabek *et al.* 2003). *Testudinella emarginula* occurs in *Sphagnum* bogs (Figure 66) (Jersabek *et al.* 2003). This cosmopolitan species lives on plant surfaces, although it occasionally occurs in the plankton (de Manuel Barrabin 2000). It is a cold-water species (7.7-7.8°C) with a circumneutral pH preference (pH 6.8-7.5) and wide alkalinity range.

Figure 52. *Testudinella truncata*, a *Sphagnum* dweller. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Testudinella incisa (Figure 53) is typically a plankton species (Plewka 2016), but it also occurs in association with *Sphagnum* (Figure 54) (Jersabek *et al.* 2003). The former subspecies, *T. incisa emarginula*, is now considered a separate species, *T. emarginula*, so it is possible that the reference to the planktonic *T. incisa* really belongs to *T. emarginula*.

Figure 53. *Testudinella incisa*, a species sometimes associated with *Sphagnum*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 54. *Testudinella emarginula* from a *Sphagnum* bog. Photo by Jersabek *et al.* 2003, with permission.

Some members of *Testudinella* (Figure 55) are known from bryophytes outside of bogs. Others, such as *Testudinella elliptica* (Figure 56-Figure 57), live among both bog bryophytes and non-bog bryophytes.

Figure 55. *Testudinella patina*, a genus that occurs on bryophytes. Note the complete retraction of the foot. Photo by Wim van Egmond, with permission.

Figure 56. *Testudinella elliptica*, a species that lives on both *Sphagnum* and other bryophytes. Photo by Michael Plewka <www.plingfactory.de>.

Figure 57. *Testudinella elliptica*, a species that lives on both *Sphagnum* and other bryophytes. Photo by Michael Plewka <www.plingfactory.de>.

Testudinella patina (Figure 58-Figure 59) is a planktonic species that likes small bodies of water where aquatic plants are abundant (de Manuel Barrabin 2000), but it is also known from peatlands (bogs or fens) in Poland (Bieleńska-Grzajner *et al.* 2011). Bryophytes are among the aquatic plants in some associations where it has been found. The aquatic plant area provides it with its preferred foods of the green alga *Chlorella* (Figure 64) and diatoms (Figure 60). It tolerates high salinity and lives in a pH range of 6.3-8.89. It enjoys a wide temperature range of 9.5-24.3°C. Some occur on mosses in Antarctica (Figure 59).

Figure 58. *Testudinella patina* female, a species that sometimes is associated with aquatic bryophytes. Here its cilia are withdrawn. Photo by Jersabek *et al.* 2003, with permission.

ORDER PLOIMIDA

This order has the most families. But are these species ones likely to be on bryophytes? Myers (1942) reported 52 species of ploimate rotifers among *Sphagnum subsecundum* (Figure 61-Figure 62) from collections in 1941.

Figure 61. *Sphagnum subsecundum* in its habitat, home of *Pedipartia gracilis*. Photo by Michael Lüth, with permission.

Figure 62. *Sphagnum subsecundum*, home of *Pedipartia gracilis*. Photo by Michael Lüth, with permission.

Wallace *et al.* (2008) asked if "everything is everywhere?" They answered this question in the Chihuahuan Desert pools in Mexico. They found that indeed the specialized, warm-water habitat of the desert did not support "everything." The microinvertebrate fauna was dominated by rotifer families that are also common on bryophytes: **Brachionidae**, **Lecanidae**, **Lepadellidae**, and **Notommatidae**. Both habitats dry up. The full statement for "everything is everywhere" includes "but the environment selects." The desert pools are actually a similar environment to that of bryophytes that dry out between rain events.

Trochosphaeridae

Cryptic species, morphologically indistinguishable biological groups incapable of interbreeding, are not uncommon in many rotifer families. *Filinia* species of **Trochosphaeridae** are highly variable and likely comprise a number of cryptic species (Ruttner-Kolisko 1989). This is at least in part due to the parthenogenetic reproduction that can quickly lead to a clone of genetically identical individuals in a **founder population** in a lake or other habitat. This is furthermore complicated by the absence of many good morphological characters by which to distinguish species. In the *Filinia terminalis-longiseta* group, ecological properties differ and suggest the existence of these microspecies, or perhaps sister species. Only two members of the **Trochosphaeridae** seem to be known from bryophytes: *Filinia longiseta* (Figure 63) and *F. terminalis* (Figure 65).

Filinia longiseta (Figure 63) is known from bryophytes in England and Ireland. This is typically a cosmopolitan planktonic species of lakes, ponds, moorland waters, and even brackish water (de Manuel Barrabin 2000). It lives in a wide range of warm temperatures (7.7-26.2°C) and pH (6.3-9.9). It is a filter feeder on detritus, bacteria, and small algae like *Chlorella* (Figure 64) in a size range of 10-12 µm (Pourriot 1965) and most likely competes for its food with members of the rotifer genus *Conochilus* (Figure 23-Figure 25).

Figure 63. *Filinia longiseta*, a bryophyte dweller in lakes, ponds, and moorland waters. Photo by Jersabek *et al.* 2003, with permission.

Figure 64. *Chlorella vulgaris*, a green alga that is often associated with *Sphagnum* and that provides food for *Testudinella patina*. Photo by Sarah Duff, through Creative Commons.

Filinia terminalis (Figure 65) is morphologically variable but seems to occupy a narrow and well-defined niche (Ruttner-Kolisko 1980). At an oxygen content of less than 2 mg L⁻¹, it can reach as many as 1000 individuals per liter. Not surprisingly, it is facultatively anaerobic. Its food sources include bacteria that are chemosynthetic or that decompose plankton.

Figure 65. *Filinia terminalis* female, Photo by Jersabek *et al.* 2003, with permission.

Although *Filinia terminalis* (Figure 65) is a cosmopolitan, planktonic species, it is known from bryophytes and *Sphagnum* bogs (Figure 66) (de Manuel Barrabin 2000). Its preferred conditions are mesotrophic to eutrophic in a pH range of 6.64-8.22. Its temperature range is relatively wide: 7.3-22.8°C, although de Manuel Barrabin considers it to be a species of the cool **hypolimnion** (bottom layer of deep lake or ocean; temperature never goes below 4°C). Ruttner-Kolisko (1980) found that it prefers temperatures below 12-15°C.

Figure 66. *Sphagnum papillosum*, a bog moss. Photo by James K. Lindsey, with permission.

Brachionidae

This is a family dominated by planktonic species and was the family with the most species represented in Spanish reservoirs (de Manuel Barrabin 2000), but a few seem to spend time among bryophytes, perhaps as a place to avoid predation, or just dropped there by moving water. An interesting study by Stenson (1982) demonstrated, however, that an experimental reduction of the fish population led to an increase in larger rotifers and a decrease in the smaller filter-feeding species such as *Keratella cochlearis* (Figure 79), a member of the **Brachionidae**. Stenson attributed this to a change in competition for food from rotifers such as *Polyarthra* (**Synchaetidae**; Figure 67).

Figure 67. *Polyarthra major*, a large rotifer that eats smaller rotifers. Note the feather-like blades that are used like paddles in swimming. Photo by Wim van Egmond, with permission.

Anuraeopsis

Anuraeopsis fissa (Figure 68-Figure 71) has been reported from a pond in Pennsylvania, USA (Jersabek *et al.* 2003). This is a planktonic rotifer that has been found among bryophytes and in bog pools. It prefers warm water and a **eutrophic** (nutrient-rich) habitat (Margalef 1955). It frequents small water bodies (de Manuel Barrabin 2000). Its food includes bacteria and detritus (Pourriot 1977) and it may become food for the rotifer *Asplanchna* (Figure 72) (Guiset 1977).

Figure 68. *Anuraeopsis fissa* with an emerging juvenile from a pond in Pennsylvania, USA. Photo by Jersabek *et al.* 2003, with permission.

Figure 72. *Asplanchna*, in this case with a gut of *Keratella*. It is also a predator on *Anuraeopsis fissa*. Photo by Wim van Egmond, with permission.

Brachionus

Brachionus urceolaris (Figure 73) is planktonic, common in small, alkaline bodies of water (pH 7.25-9) (de Manuel Barrabin 2000). It can occur in moving water and is relatively tolerant of high salinity. It is a cosmopolitan species with a wide temperature tolerance (7.35-24.3°C). Despite its alkaline preference, Hingley (1993) found it closely associated with *Sphagnum* (Figure 21) in a bog.

Figure 73. *Brachionus urceolaris*, a species that is closely associated with bog *Sphagnum*. Photo from Proyecto Agua, with permission.

Brachionus urceolaris (Figure 74), and probably others, has a survival trick against predation. The eggs survive consumption by predators such as the cladoceran *Leptodora kindtii* (Figure 75) without harm (Nagata *et al.* 2011). Often the cladocerans would eject the eggs, and they typically ejected the lorica while digesting the living contents. There was a negative correlation between the portion of unconsumed (ejected) eggs and the length of the predator. That is, longer predators ejected fewer eggs. Nevertheless, hatching success seemed to be independent of the predator's body length. As many as 75% of the undigested eggs hatched successfully.

Figure 75. *Leptodora kindtii*, a large cladoceran that is a predator on *Brachionus urceolaris*. Drawing by A. Milnes Marshall, through Public Domain.

Kellicottia

Kellicottia is a genus with only two species (Segers 2007). *Kellicottia longispina* (Figure 76-Figure 77) is a central European species known from bryophytes, but it is actually typically a planktonic species (Plewka 2016). Its long spines no doubt help to protect it from predation (see Barnhisel 1991), but Madaliński (1961) suggested they

may help attach it to bryophytes. It is active year-round as an inhabitant of oligotrophic lakes with a rather narrow pH range of 8.2-8.5, but as expected its temperature range is broad (10.6-21.8°C) and it does not occur in small bodies of water (de Manuel Barrabin 2000). Its food is primarily chrysomonads and centric diatoms (Pourriot 1977).

Keratella

Feeding rates are inversely related to the density of food organisms in *Keratella cochlearis* (Figure 79), as well as in the planktonic, but occasional bryophyte-dweller, *Polyarthra vulgaris* (Synchaetidae), and *Polyarthra dolichoptera* (Bogdan & Gilbert 1982). *Keratella cochlearis* preferred the alga *Chlamydomonas* (Figure 80) to all other foods offered, perhaps explaining the rarity of this rotifer among mosses, where *Chlamydomonas* also is

uncommon (pers. obs.). Nevertheless, *K. cochlearis* lives in bog/fen habitats (Bielańska-Grajner *et al.* 2011) where some species of *Chlamydomonas* occur (Struder-Kypke & Schonborn 1999).

Figure 79. *Keratella cochlearis* showing lorica, a species that is mostly planktonic but also occurs in bog/fen peatlands. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 80. *Chlamydomonas globosa*, a genus that is food for *Keratella cochlearis*. Photo by Picturepest, through Creative Commons.

Nevertheless, a number of species of *Keratella* live among bryophytes. *Keratella mixta* (Figure 81) lives among *Sphagnum* (Figure 62) (Jersabek *et al.* 2003). Others live in peatlands (bogs or fens), including *K. paludosa* (Figure 82) (Bielańska-Grajner *et al.* 2011).

Figure 81. *Keratella mixta* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Figure 82. *Keratella paludosa* from *Sphagnum*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Keratella quadrata (Figure 83-Figure 85) is a species known from bryophytes. This is also a cosmopolitan species that is active all year round (de Manuel Barrabin 2000). It is tolerant of mineralization and survives a wide pH range of 6.64-10.19. Its temperature range is likewise wide (6.4-26.1°C), as expected for a perennial species. It has broad food preferences, including detritus, bacteria, and algae in the Chlorococcales, Volvocales, Euglenales, Chrysophyceae, and diatoms (Pourriot 1977). As is typical among rotifers, females are larger than males (Figure 84). Resting eggs (Figure 85) help it to survive in this changeable habitat.

Figure 83. *Keratella quadrata* showing lorica and cilia. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 85. *Keratella quadrata* resting eggs. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Keratella serrulata (Figure 86-Figure 88) is the only planktonic brachionid that is a specialist of acid water, particularly water from bogs with *Sphagnum* (Figure 21) (Bērziņš & Pejler 1987; Bielańska-Grójner *et al.* 2011). Its known pH is around 6.6 and temperature around 18.6°C (de Manuel Barrabin 2000). It feeds on algae in the Chrysophyceae and Volvocales (Pourriot 1977). *Sphagnum* is important in creating its acid habitat – it lives especially in the outflow of *Sphagnum* bogs and poor fens (Jersabek *et al.* 2003).

Figure 86. *Keratella serrulata*, an inhabitant of acid bog outflow water. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 89. *Keratella serrulata* showing rotary cilia. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Keratella also can occur among wet mosses in waterfalls. Savatzenalinton and Segers (2008) found *Keratella cochlearis* (Figure 79) and *Keratella tropica* (Figure 90) in a waterfall in Thailand, but it is likely that these planktonic species were carried there from open water (De Smet, per. comm. 3 November 2016).

Figure 90. *Keratella tropica*, a waterfall moss dweller. Photo by Jersabek *et al.* 2003, with permission.

Notholca

Although *Notholca* is a relatively large genus, only three species seem to be bryophyte dwellers. *Notholca foliaceae* (Figure 91) occurs on mosses (Plewka 2016). *Notholca latistyla* is restricted to the Arctic and occurs on submerged mosses (De Smet 1990). *Notholca squamula* likewise occurs on submerged mosses on Svalbard.

Figure 91. *Notholca foliaceae* from moss. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Dicranophoridae

The **Dicranophoridae** are predators and are agile in pursuing and capturing their prey (Pejler & Bērziņš 1993a). Unlike many rotifers, the **Dicranophoridae** are not planktonic – other predatory rotifers exist among the plankton – and they avoid the sediments where their prey organisms are not sufficiently abundant. Unlike many rotifers, these have been documented on two species of bryophytes through a study of their substrata. *Albertia naidis* (Figure 92), *Aspelta angusta* (Figure 97), *A. aper* (Figure 95), *A. circinator* (Figure 96), *Dicranophorus forcipatus* (Figure 117-Figure 118), *D. haueri*, *D. robustus* (Figure 113-Figure 114), *Encentrum eurycephalum*, *E. fluvatile*, *E. lupus*, and *E. mustela* (Figure 134), and *E. uncinatum* (Figure 131), were all present on 1-10% of the 122 collections of *Fontinalis* (Figure 11). *Aspelta aper*, *A. circinator*, *Dicranophorus epicharis* (Figure 107), *D. luetkeni* (Figure 110-Figure 112), *Encentrum arvicola*, *E. elongatum*, *E. incisum* (Figure 127), *E. lupus*, *E. sutor*, *E. sutoroides*, *E. tyrphos*, and *Wierzejskella velox* (Figure

139-Figure 140) were all present on 1-10% of the 194 collections of *Sphagnum* (Figure 21). The species differ, but only the genus *Albertia* is present exclusively on *Fontinalis*, and only *Wierzejskella* is present exclusively on *Sphagnum* in this comparison. Both sets of bryophyte dwellers occur on a wide variety of other plant substrata – none was specific to bryophytes.

Albertia

Only one species of this relatively small genus is associated with bryophytes. *Albertia naidis* (Figure 92) not only occurs among *Sphagnum* (Figure 5) and *Fontinalis* (Figure 11), but it also is parasitic on *Stylaria lacustris* (Figure 93), an oligochaete (segmented worm) (Jersabek 2003).

Figure 92. *Albertia naidis* subsp. *intrusor* from among *Sphagnum* and parasitic on *Stylaria lacustris*. This species is also known from the aquatic moss *Fontinalis*. Photo by Jersabek *et al.* 2003, with permission.

Figure 93. *Stylaria lacustris*, an annelid that is parasitized by *Albertia naidis*. Photo by Niels Sloth, with permission.

Aspelta

Several species of *Aspelta* live among *Sphagnum* (Figure 5) (e.g. *A. beltista*, Figure 94) (Jersabek *et al.* 2003). Others occur not only with *Sphagnum*, but also occur with the aquatic moss *Fontinalis* (Figure 11). These are *Aspelta aper* (Figure 95) (Pejler & Bērziņš 1993a) and *A. circinator* (Figure 96) (Plewka 2016). *Aspelta angustus* (Figure 97) occurs among mosses on rock and also among the periphyton on *Sphagnum* (Figure 21) (Plewka 2016).

Figure 94. *Aspelta beltista* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Dicranophorus

Sphagnum (Figure 21) seems to be a common habitat for a number of species of *Dicranophorus*. These include *Dicranophorus alcimus* (Figure 101; Jersabek *et al.* 2003), *D. artamus* (Figure 102; Jersabek *et al.* 2003), *D. biastis* (Figure 103; Jersabek *et al.* 2003), *D. capucinus* (Figure 104-Figure 105; Jersabek *et al.* 2003; Bielańska-Grajner *et al.* 2011), *D. colastes* (Figure 106; Jersabek *et al.* 2003), *D. epicharis* (Figure 107; Pejler & Bērziņš 1993a), *D. facinus* (Figure 108; Myers 1942), *D. hercules* (Bielańska-Grajner *et al.* 2011), *D. isotheres* (Figure 109; Jersabek *et al.* 2003), *D. luetkeni* (Figure 110-Figure 112; Jersabek *et al.* 2003; Bielańska-Grajner *et al.* 2011), and *D. proclastes* (Myers 1942).

Figure 112. *Dicranophorus luetkeni* female with egg. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Dicranophorus robustus (Figure 113-Figure 114), like several other members of the **Dicranophoridae**, occurs on both the bog moss *Sphagnum* (Figure 21) and the brook moss *Fontinalis* (Figure 11) (Hingley 1993; Pejler & Bērziņš 1993a). It commonly ingests members of the rotifer genus *Lecane* (Figure 115), a very large genus that is abundant on bryophytes (Jersabek *et al.* 2003). This dual habitat of *Sphagnum* and *Fontinalis* also works for *D. rostratus* (Figure 116; Hingley 1993; Jersabek *et al.* 2003).

Figure 113. *Dicranophorus robustus* from *Aufwuchs*, a species found with bryophytes, including *Sphagnum* and *Fontinalis*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 116. *Dicranophorus rostratus* female, a species known from *Sphagnum* (Myers 1942) and *Fontinalis*. Photo by Jersabek *et al.* 2003, with permission.

Some species are known thus far only from *Fontinalis* (Figure 11). Among these is *Dicranophorus forcipatus* (Figure 117-Figure 118) (Pejler & Bērziņš 1993a; Plewka 2016), including its occurrence on Svalbard exclusively on submerged mosses (De Smet 1993).

Figure 117. *Dicranophorus forcipatus*, a rotifer found among bryophytes in several studies, including *Fontinalis*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 118. *Dicranophorus forcipatus*, a rotifer found among bryophytes in several studies, shown here feeding on the surface of *Spirogyra* sp. Photo by Michael Plewka <www.plingfactory.de>, with permission.

The aquatic *Dicranophorus hercules* (Figure 119) is known from bryophytes (Jersabek *et al.* 2003), but its typical habitat is in the **psammon** (interstitial community among sand grains in fresh water) (Ruttner-Kolisko 1954; Pejler & Bērziņš 1993b). In fact, Wizsniewski (1934, 1937) considered this species to be exclusive to the psammon. Nevertheless, Bielańska-Grajner *et al.* (2011) found it among the peatland bryophytes in Poland.

Figure 119. *Dicranophorus hercules*, a species known from bryophytes. Photo by Jersabek *et al.* 2003, with permission.

Dorria

Dorria dalecarlica (Figure 121) is the only species in the genus (Segers 2007) and is a moss dweller in aquatic habitats, where it lives on dripping and submersed *Fontinalis dalecarlica* (Figure 11) (Myers 1942).

Figure 120. *Dorria dalecarlica*, a species that can occur on submerged mosses in streams. Photos by Jersabek *et al.* 2003, with permission.

Figure 121. *Dorria dalecarlica*, a species that can occur on submerged mosses in streams. Photos by Jersabek *et al.* 2003, with permission.

Encentrum

The genus *Encentrum* is a large genus with a number of species that live on bryophytes. *Sphagnum* (Figure 21, Figure 66) dwellers include *E. aquilus* (Figure 122; Jersabek *et al.* 2003), *E. arvicola* (Pejler & Bērziņš 1993a), *E. carlini* (Figure 123; Jersabek *et al.* 2003), *E. elongatum* (Pejler & Bērziņš 1993a), *E. felis* (Figure 124-Figure 125; Hingley 1993; Jersabek *et al.* 2003), *E. glaucum* (Figure 126; Hingley 1993), *E. incisum* (Figure 127; Pejler & Bērziņš 1993a), *E. saundersiae* (Figure 128; Myers 1942), *E. sutor* (Pejler & Bērziņš 1993a), *E. sutoroides* (Pejler & Bērziņš 1993a), *E. tobyhannaense* (Figure 129; Jersabek *et al.* 2003), and *E. tyrphos* (Pejler & Bērziņš 1993a).

Figure 129. Trophus of *Encentrum tobyhannaensis* from among *Sphagnum*. Often this is the only structure that can be recognized in old collections. Photo by Jersabek *et al.* 2003, with permission.

As seems to be a common feature of this family, several species live on both *Sphagnum* (Figure 21, Figure 66) and *Fontinalis* (Figure 11). These are *Encentrum lupus* (Pejler & Bērziņš 1993a), *E. mustela* (Figure 130) (Hingley 1993; Pejler & Bērziņš 1993a), and *E. uncinatum* (Figure 131; Horkan 1981; Hingley 1993; Pejler & Bērziņš 1993a; Plewka 2016). *Encentrum eurycephalum* and *E. fluviale*, on the other hand, are only known from *Fontinalis* (Pejler & Bērziņš 1993a). *Encentrum mucronatum* and *E. uncinatum* live on submerged mosses on Svalbard, where the former is one of the most frequent species (De Smet 1990); *E. cf. marinum* (Figure 132) lives exclusively among submerged mosses on Svalbard, whereas *E. mustela* occurs on submerged mosses and in the plankton (De Smet 1993).

Figure 132. *Encentrum marinum*, a species that occurs exclusively among submerged mosses on Svalbard. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Encentrum lutra (Figure 133) also lives in the unpredictable habitat of epiphytic mosses (Plewka 2016). The habitat of *E. permolle* (Figure 134) is on moss (Plewka 2016) in Antarctic islands (Fontaneto *et al.* 2015).

Figure 134. *Encentrum permolle*, a moss dweller in the Antarctic. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Pedipartia

Pedipartia is a genus with only one species, *P. gracilis* (Figure 135) (Segers 2007). This rotifer species is known from just one species of *Sphagnum*, *S. subsecundum* (Figure 61-Figure 62) (Myers 1942; Jersabek *et al.* 2003).

Figure 135. *Pedipartia gracilis* from among *Sphagnum subsecundum*. Photo by Jersabek *et al.* 2003, with permission.

Streptognatha

Streptognatha is another genus known by only one species (Segers 2007). *Streptognatha leptota* (Figure 136-Figure 137), a species reported in Great Britain and elsewhere, occurs on *Sphagnum* (Figure 21, Figure 66) (Jersabek *et al.* 2003).

Figure 136. *Streptognatha lepta* female, lateral view, a species known from *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Figure 137. *Streptognatha lepta* female, a rotifer known to associate with *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Wierzejskiella

Of the eight species (Segers 2007) of *Wierzejskiella*, three are known bryophyte dwellers. And all three live on *Sphagnum* (Figure 21, Figure 66). *Wierzejskiella elongata* (Figure 138) lives among *Sphagnum* (Myers 1942). *Wierzejskiella velox* (Figure 139-Figure 140) occurs both among *Sphagnum* and in *Sphagnum* pools (Myers 1942).

Figure 140. *Wierzejskiella velox* from *Sphagnum*, shown here with its forcipate trophi extruded as it approaches the desmid food item.. Photo by Mark Plewka <www.plingfactory.de>, with permission.

Epiphanidae

This family has rotifers that are usually planktonic, so like most of the rotifers on bryophytes, it is likely that the bryophyte is a temporary refuge. Many of the members of this family are marine (Koste 1978; Fontaneto *et al.* 2006, 2008), where no bryophytes are known.

Cyrtonia

Cyrtonia is another genus with only one species (Segers 2007), and that species is a moss dweller – *C. tuba* (Figure 141-Figure 142). It is known from ponds, but it has also been collected from mosses (Jersabek *et al.* 2003).

Figure 141. *Cyrtonia tuba*, a pond and moss dweller. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 142. *Cyrtonia tuba* from a pond in Ohio, USA. This species has been collected from mosses. Photo by Jersabek *et al.* 2003, with permission.

Epiphanes

This genus of nine species seems to have only one that lives with bryophytes. *Epiphanes brachionus* (Figure 143)

lives in *Sphagnum* (Figure 21, Figure 66) bogs (Plewka 2016).

Figure 143. *Epiphanes brachionus* from a *Sphagnum* bog. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Mikrocodides

Mikrocodides, a genus of three species (Segers 2007), typically occurs in the plankton and among the periphyton. One species, *Mikrocodides chlaena* (Figure 144-Figure 146), however, lives among mosses and in bog pools (Plewka 2016).

Figure 144. *Mikrocodides chlaena*, a species that occurs among mosses and in bog pools. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 146. *Mikrocodides chlaena* female from New Jersey, USA. This species has been collected from mosses and from bog pools. Photos by Jersabek *et al.* 2003, with permission.

Euchlanidae

This family is characterized by a lorica consisting of connected plates (Koste & Shiel 1989). The toes are elongated. Of the five genera in the family, only *Euchlanis* is known from mosses.

Sphagnum (Figure 21, Figure 66), as usual, is a common substrate, with a number of species of *Euchlanis* associated with it. These include *E. callysta* (Figure 147), *E. calpidia* (Figure 148-Figure 149), *E. dilatata* (Figure 156-Figure 157), *E. incisa* (Figure 150) and *E. triquetra* (Figure 151-Figure 155) (Błędzki & Ellison 2003; Jersabek *et al.* 2003).

Figure 147. *Euchlanis callysta* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

There seems to be a paucity of studies on rotifers beyond listing the taxa present in various water bodies. But in the **Euchlanidae**, at least one species that is known from *Sphagnum* (Figure 21, Figure 66) seems to have been the subject of several kinds of biological studies. For example, *Euchlanis dilatata* (Figure 156-Figure 157) has proven its ability to serve as a sensitive biomonitor (Sarma *et al.*

2001). In an experiment on herbicides, this species experienced a significant reduction in population density and rate of population increase in the presence of methyl parathion. These responses were exacerbated as the concentration of methyl parathion increased, regardless of food (*Chlorella vulgaris* – Figure 64) concentration. However, higher food concentrations served to mediate the effect on the rate of population increase.

Figure 157. *Euchlanis dilatata*, a species that has been collected from bryophytes. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Euchlanis dilatata (Figure 156-Figure 157) is a benthic-periphytic species known from littoral zones of small bodies of eutrophic waters (de Manuel Barrabin 2000), but can occur on bryophytes (Jersabek 2016) and other macrophytes (Plewka 2016). On Svalbard, it occurs exclusively on submerged mosses, along with *E. deflexa* (Figure 159) and *E. meneta* (Figure 158) (De Smet 1988, 1993). *Euchlanis dilatata* occurs in both fresh water and brackish water, preferring water rich in nutrients, especially those favoring *Cyanobacteria* (de Manuel Barrabin 2000). These waters generally have a pH range of 6.3-9.6 and a temperature range of 6.4-24°C. Although only 200 µm long, this species is consumed by damselfly naiads

(Ejsmont-Karabin *et al.* 1993). In the lab, it is able to survive on *Cyanobacteria* [*Limnothrix redekei* (Figure 160), *Oscillatoria. limnetica* (Figure 161), *Aphanizomenon flos-aquae* (Figure 162), *Anabaena* sp. (Figure 163)], all genera that can be found with *Sphagnum*, and a prochlorophyte (*Prochlorothrix hollandica*) (Gulati *et al.* 1993). In the field *E. dilatata* consumes detritus, bacteria, *Cyanobacteria*, and the diatom *Cyclotella* (Figure 164) (Carlin 1943), all likewise present among *Sphagnum*. It often benefits from the convenience of attaching to planktonic algae colonies (Pejler 1962).

Figure 164. *Cyclotella caspia*, food for *Euchlanis dilatata*. Photo by Janina Kownacka, Nordic Microalgae <www.nordicmicroalgae.org>, with online permission.

Euchlanis incisa (Figure 165-Figure 167) is likewise a *Sphagnum* (Figure 21-Figure 66) dweller, in the northeastern USA (Błedzki & Ellison 2003), but it is also known from the non-bog aquatic moss *Fontinalis* (Figure 11) (Plewka 2016).

Figure 165. *Euchlanis incisa* female, a species known from bryophytes. Photo by Jersabek *et al.* 2003, with permission.

Figure 166. *Euchlanis incisa*, a species known from bryophytes, including *Fontinalis*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 167. *Euchlanis incisa*, a species known from bryophytes. Photo by Jersabek *et al.* 2003, with permission.

In addition to *Sphagnum*, other bryophytes may be substrates for members of *Euchlanis*. *Euchlanis meneta* (Figure 158-Figure 168) is among the dominant rotifers on mosses on Devon Island, Baffin Bay, Canada (De Smet & Beyens 1995). This species is also known from the other end of the Earth, from New Zealand (Shiel & Green 1996).

Figure 168. *Euchlanis meneta* female, a species known from bryophytes. Photo by Jersabek *et al.* 2003, with permission.

Euchlanis oropha (Figure 169) is a widespread **rheophilic** (loving flowing water) species that can occur on mosses, among other substrates.

Figure 169. *Euchlanis oropha* female, a species known from bryophytes. Photo by Jersabek *et al.* 2003, with permission.

Gastropodidae

This family is distinguished by its oval shape and sac-like or compressed body plan. It has a thin shell that surrounds the entire body with only a small opening for the head and ventrally located foot (Figure 170-Figure 173) that is sometimes absent. The family occurs primarily in fresh water, with few marine species. There are two genera, but only members of *Gastropus* seem to have been collected from bryophytes. Of the three species in this genus, two are known bryophyte dwellers: *G. hyptopus* (Figure 170-Figure 171) and *G. minor* (Figure 172) (Plewka 2016). *Gastropus stylifer* lives on submerged mosses in trenches of Alaskan polygons (Segers *et al.* 1996).

Summary

The rotifers in **Monogononta** are often represented on bryophytes, especially in peatlands. The Class **Monogononta** has three orders and is the largest class of rotifers. Many members of order **Collothecacea** are sessile. Some members of family **Collothecidae** are known from *Riccia fluitans*, *Sphagnum*, and other bryophytes. Members of the order **Flosculariacea** are suspension feeders, and known bryophyte dwellers include members of **Conochilidae**, **Filiniidae**, **Flosculariidae**, **Hexarthriidae**, and **Testudinellidae**. The order **Ploimida** includes both planktonic and non-planktonic families that are known from bryophytes. Those included in this subchapter are **Brachionidae**, **Dicranophoridae**, **Epiphanidae**, **Euchlanidae**, and **Gastropodidae**. Additional families are in the next sub-chapters.

Acknowledgments

Bryonettors have been wonderful in making their photographs available to me and seeking photographs from others. Tom Powers and Walter Dioni helped me obtain images and permission from others. Christian D. Jersabek very generously gave me permission to use the wealth of images from the Online Catalog of Rotifers. Tom Thekathyl and Des Callaghan helped me in finding and gaining permission from Marek Mís for the beautiful image in the frontispiece and others. Many photographers have been generous with permission for the use of their images and others have provided them online through Creative Commons and other public domain sources. Antonio Guillén provided me with credit information on images from Proyecto Agua. My special thanks go to Michael Plewka for his generous permission to use so many of his beautiful online images and for providing some of the identifications on images from others. Michael Lüth has generously given me permission to use any of his

bryophyte images. Claudia Ricci has generously answered my questions. Aydin Orstan provided me with email addresses and pointed out errors in an earlier version of the chapter. Willem De Smet was invaluable in finding errors and making nomenclatural updates on the near-final version of this sub-chapter.

CHAPTER 4-7b

INVERTEBRATES: ROTIFER TAXA – MONOGONONTA

Figure 1. *Lecane stokesii*, a monogonont rotifer that can be found among bryophytes. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Taxa on Bryophytes, Ploimida continued

Lecanidae

The **Lecanidae** were represented by the second highest number of species among rotifers in the reservoirs in Spain (de Manuel Barrabin 2000) and their species are well represented among those rotifers collected with bryophytes as well (e.g. Jersabek et al. 2003). One reason for this is that the family has only one, but a very large, genus – *Lecane*. The genus *Lecane* is the second largest genus of rotifers, with at least 160 species (Segers 1995).

Not surprisingly, there are a number of *Lecane* species living in *Sphagnum* (Figure 1, Figure 2). One of the early reports including *Sphagnum* dwellers was that of Haring (1915) in Panama. These included *L. bifurca* (Figure 3; see also Myers 1942), *L. flexilis* (Figure 4-Figure 5; see

also Bielańska-Grajner et al. 2011), *L. inermis* (Figure 7-Figure 8), *L. monostyla* (Figure 9; see also Bielańska-Grajner et al. 2011), and *L. tenuiseta* (Figure 10; see also Bielańska-Grajner et al. 2011). The *Sphagnum* associates include those in bogs and fens. Błedzki and Ellison (2002) found *Lecane pyriformis* (Figure 11) and *L. lunaris* (Figure 44-Figure 45) to be among the abundant *Sphagnum* dwellers in their study. To these, Bielańska-Grajner et al. (2011) added *L. bulla* (Figure 12-Figure 13), *L. intrasinuata* (Figure 14), *L. luna* (Figure 15), and *L. perpusilla* as bog dwellers. But *Sphagnum* fauna records must be viewed with caution. Methods using pore water often miss the relatively immobile rotifers that live on mosses (Sakuma et al. 2002).

Figure 2. *Sphagnum* and *Potentilla tridentata*, home for many kinds of rotifers. Photo by Nancy Leonard, with permission.

Figure 3. *Lecane bifurca* lives among mosses, including *Sphagnum*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Hingley likewise found *Lecane flexilis* (Figure 4-Figure 5; see also Bielańska-Grajner *et al.* 2011) among *Sphagnum* (Figure 2), but Jersabek *et al.* (2003) further reported it from the floating thallose liverwort, *Riccia fluitans* (Figure 6). This rotifer species occurs infrequently in the plankton, preferring instead the littoral (near shore) zone (de Manuel Barrabin 2000). It occurs more frequently in alkaline habitats (Pejler 1962; Koste 1978) in a pH range of 6.64-7.87, although Koste and Shiel (1990) found it in slightly acidic water. Its wide temperature range (9.50-21.13°C) permits it to be cosmopolitan (de Manuel Barrabin 2000).

Figure 6. *Riccia fluitans*, a floating liverwort that is home to *Lecane flexilis*. Photo by Jan-Peter Frahm, with permission.

In *Lecane inermis* (Figure 7-Figure 8), a *Sphagnum* (Figure 2) dweller, **mictic** (producing eggs that without fertilization develop into males but with fertilization form resting eggs that later develop into amictic females) females have the longest lives of 11.1 ± 0.28 days, followed by amictic females with a lifespan of 8.9 ± 0.11 days, and the shortest lifespan in males at 5.7 ± 0.07 days (Miller 1931). In males, death of 83% of the population occurs in the four to six days. Sexual females lay one egg every 8.6 hours, whereas the **amictic** (producing eggs that

develop without fertilization) female lays one every 7.5 hours. Amictic females usually die within 24-36 hours after laying the last egg, but among the mictic females, 19% live six more days after depositing eggs. Typically, *Lecane inermis* is a littoral species that also occurs in warm water such as thermal springs and geysers (de Manuel Barrabin 2000). Its typical temperature is around 19.4°C, but it can be found near geysers at temperatures up to 62.5°C. Its environmental pH is usually around 7.3.

Figure 7. *Lecane inermis*, a *Sphagnum* dweller. The upper image is in the extended state, the lower one in the contracted state. Photo by Jersabek *et al.* 2003, with permission.

Figure 9. *Lecane monostyla*, a *Sphagnum* dweller. Photo by Jersabek *et al.* 2003, with permission.

Lecane tenuiseta (Figure 10) is typically a littoral species, known from a pH around 7.9 and a temperature around 13.5°C (de Manuel Barrabin 2000). Although it is cosmopolitan, its restricted habitat requirements make it relatively rare.

Figure 10. *Lecane tenuiseta*, typically a littoral species, sometimes living among *Sphagnum*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 15. *Lecane luna* from among water plants, also a *Sphagnum* dweller. Photo by Michael Plewka <www.plingfactory.de>, with permission.

One of the most extensive treatments of North American rotifers is that of Myers (1942) for the Poconos in Pennsylvania, USA. He considered *Lecane obtusa*

(Figure 16), *L. opias* (Figure 17; see also Bielańska-Grajner *et al.* 2011), and *L. subulata* (Figure 18-Figure 19) to be small species that are common among *Sphagnum* (Figure 2). In that same publication, he reported *L. depressa* (Figure 20-Figure 21; see also Hingley 1993), *L. formosa*, *L. furcata* (Figure 22), *L. niothis*, *L. pumila* (Figure 23), *L. rhytida*, *L. scutata* (Figure 24; see also Koste & Shiel 1990; Bielańska-Grajner *et al.* 2011), *L. subtilis* (Figure 25; see also Bielańska-Grajner *et al.* 2011), *L. tryphema* (Figure 26), and *L. verecunda* (Figure 27) from *Sphagnum*. He also reported *L. dysoarata* (Figure 28) from the emergent species *Sphagnum cuspidatum* (Figure 29). Horkan (1981) reported *L. quadridentata* (Figure 30-Figure 31) from bog pools.

Lecane scutata (Figure 24) occurs in the littoral zone of lakes where it lives on plant surfaces (de Manuel Barrabin 2000). It is an acidophile, commonly living among *Sphagnum* (Figure 2) (Myers 1942; Koste & Shiel 1990), but it is cosmopolitan and probably not restricted to strongly acid habitats (de Manuel Barrabin 2000).

Hingley (1993) published a manual on the microscopic life in *Sphagnum* (Figure 2), including the rotifer fauna. Her records included *L. agilis* (Figure 32), *L. clara* (Figure 33-Figure 34; see also Bielańska-Grajner *et al.* 2011), *L. closteroerca* (Figure 35-Figure 36; see also Bielańska-Grajner *et al.* 2011), *L. cornuta* (Figure 37-Figure 39), *L. galeata* [Figure 40-Figure 41; see also Jersabek *et al.* 2003 from *Sphagnum subsecundum* (Figure 42) and Bielańska-Grajner *et al.* 2011], *L. hamata* (Figure 43; see also Bielańska-Grajner *et al.* 2011), *L. lunaris* (Figure 44-Figure 45; see also Madaliński 1961; Bielańska-Grajner *et al.* 2011), *L. pyrrha* (Figure 46), *L. signifera* (Figure 47), *L. signifera ploenensis* (Figure 48), and *L. stichaea* (Figure 49-Figure 50).

Figure 34. *Lecane clara*, a species known from bryophytes. Photo by Jersabek *et al.* 2003, with permission.

Lecane closteroerca (Figure 35-Figure 36) is a species known from bryophytes, including *Sphagnum* (Figure 2). This cosmopolitan littoral species is common in the plankton in a pH range of 6.7-9.1 and temperatures of 7.8-24°C (de Manuel Barrabin 2000). Despite its common presence in freshwater, it has a wide tolerance of salinity.

Figure 42. *Sphagnum subsecundum*, home of *Lecane galeata*. Photo by Michael Lüth, with permission.

Lecane hamata (Figure 43) is a cosmopolitan, littoral species living on plant substrata and known from bryophytes (de Manuel Barrabin 2000), including *Sphagnum* (Figure 2; Hingley 1993). It occurs at pH levels around 7.9 with a known from a temperature range of 11.9-13.5°C (de Manuel Barrabin 2000).

Figure 43. *Lecane hamata*, a species known from *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Lecane lunaris (Figure 44-Figure 45) is a cosmopolitan littoral species that is frequent in the plankton (de Manuel Barrabin 2000) and is known to inhabit bryophytes, including *Sphagnum* (Figure 2; Hingley 1993). It is known from water that is rich in nutrients with a pH of 6.3-9.2 and a temperature range of 7.2-26.2°C (de Manuel Barrabin 2000).

Figure 44. *Lecane lunaris*, a *Sphagnum* dweller. Photo by Jersabek *et al.* 2003, with permission.

Figure 50. *Lecane stichaea*, a rotifer associated with *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

To these studies, Jersabek *et al.* (2003) added species from records at the Academy of Natural Sciences of Philadelphia. The *Sphagnum* (Figure 2) associates included *Lecane calcaria* (Figure 51), *L. copeis* (Figure 52), *L. curvicornis* (Figure 53), *L. depressa* (Figure 54), *L. mira* (Figure 55), *L. mitis* (Figure 56), *L. pertica* (Figure 57-Figure 58), *L. psammophila* (Figure 59), *L. satyrus* (Figure 60), and *L. thalera* (Figure 61-Figure 62). Plewka (2016) included *L. acus* (Figure 63) and *L. arcula* (Figure 64), two *Sphagnum* dwellers not included on the other lists here. Jersabek *et al.* (2003) reported *L. lauterborni* (Figure 65) from *Sphagnum wheeleri* in Hawaii (Figure 66).

Figure 51. *Lecane calcaria*, a *Sphagnum* dweller. Photo by Jersabek *et al.* 2003, with permission.

Lecane mira (Figure 55-Figure 56) is a cosmopolitan species that lives on aquatic plants, including *Sphagnum*, and is common in somewhat acid waters, but can also be common at a pH around 7.2 (de Manuel Barrabin 2000). It is known from a temperature around 10.8°C.

Figure 55. *Lecane mira* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Figure 66. *Sphagnum wheeleri*, Home for *Lecane lauterborni* in Hawaii. Photo by Jersabek *et al.* 2003, with permission.

Some researchers include *Sphagnum* (Figure 2) and "moss" (perhaps meaning *Sphagnum*) as the rotifer habitats. Among these are *Lecane elasma* (Figure 67; Jersabek *et al.* 2003; Bielańska-Grajner *et al.* 2011), *L. ligona* (Figure 68; Jersabek *et al.* 2003), and *L. stokesii* (Figure 69) living between mosses (Plewka 2016).

Figure 67. *Lecane elasma* from among mosses and *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Figure 68. *Lecane ligona* from a *Sphagnum* pool. Photo by Jersabek *et al.* 2003, with permission.

A few reports simply list "moss": *L. climacois* (Figure 70; Myers 1942; Jersabek *et al.* 2003), *L. rhopalura* (Figure 71) on submerged moss (Jersabek *et al.* 2003), *L. unguolata* (Figure 72-Figure 74; Madaliński 1961). *Lecane*

arcuata occurs among submerged mosses in trenches of Alaskan polygons (Segers *et al.* 1996) and wet mosses on Svalbard (De Smet 1993).

Figure 69. *Lecane stokesii* from between mosses, including *Sphagnum*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 70. *Lecane climacois* from among mosses. Photo by Jersabek *et al.* 2003, with permission.

Figure 74. *Lecane unguolata* var. *tenuior*, a species known to inhabit bryophytes. Photo by Jersabek *et al.* 2003, with permission.

One of the undersampled habitats seems to be waterfalls. *Lecane martensi* was discovered on wet mosses as a new species in this habitat by Savatnalinton and Segers in 2008. What seems to be most lacking is records of this large genus associated with terrestrial bryophytes.

Figure 75. *Lecane martensi*, a species that was discovered among mosses in a waterfall. Photo by Savatnalinton & Segers 2008, through Creative Commons.

Ituridae

This small family, with only one genus, seems to have little written about it beyond species lists and taxonomic distinctions. Even the map of its distribution showed nothing. I could find only one species, *Itura aurita* (Figure 76-Figure 77), that had been collected from mosses, including from bogs (Horkan 1981). De Smet (1993) reported it from submerged mosses on Svalbard.

Lepadellidae

Many of the **Lepadellidae** are cosmopolitan, often occurring in freshwater habitats (Baribwegure & Segers 2001). In particular, the genera *Colurella* (Figure 78-Figure 86, Figure 88), *Lepadella* (Figure 91-Figure 112), and *Squatinella* (Figure 116-Figure 126) are widespread. These same three genera are well represented among bryophyte collections. A fourth genus, *Paracolurella* (Figure 114-Figure 115), also is known from bryophytes.

Colurella

Colurella adriatica (Figure 78-Figure 79) is an uncommon species that may be cosmopolitan (de Manuel Barrabin 2000). It is a planktonic species in small water bodies that lives among plants in the littoral zone and is known from bryophytes. It seems to prefer basic water around pH 8.4 and is known from temperatures around 23.5°C. It is known from bryophytes (Madaliński 1961)

and occurs among submerged mosses on Svalbard (De Smet 1990, 1993). *Colurella colurus* has similar requirements, but is known from a pH level around 7.1 and temperature of 9.7°C (de Manuel Barrabin 2000). It is known from bryophytes (Madaliński 1961) and occurs among submerged mosses and in plankton on Svalbard (De Smet 1993).

Figure 78. *Colurella adriatica*, a species known from bryophytes and bog pools. Photo by Jersabek *et al.* 2003, with permission.

Figure 79. *Colurella adriatica*, a species that lives among plants in the littoral zone and is known from bryophytes. Photo by Jersabek *et al.* 2003, with permission.

Colurella clausa (Figure 80), *C. denticauda* (Myers 1942) and *C. obtusa* (Figure 81-Figure 83; Horkan 1981; Hingley 1993; Błedzki & Ellison 2003; Plewka 2016), and *Colurella tessellata* (Figure 84-Figure 85; Horkan 1981; Hingley 1993; Jersabek *et al.* 2003) occur with *Sphagnum* (Figure 2). *Colurella obtusa* occurs on Svalbard, where one can find it among submerged mosses and plankton (De Smet 1993). *Colurella hindenburgi* (Figure 86) occurs with *Sphagnum subsecundum* (Figure 87) (Myers 1942; Jersabek *et al.* 2003), but it also occurs among terrestrial bryophytes (Bielańska-Grajner *et al.* 2011) and in submerged mosses and plankton on Svalbard (De Smet 1993). Segers *et al.* (1996) found *Colurella uncinata* among submerged mosses in trenches of Alaskan polygons.

Figure 87. *Sphagnum subsecundum* emerged in a fen. Photo by Michael Lüth, with permission.

The genus *Colurella* has several species associated with terrestrial bryophytes. *Colurella geophila* (Figure 88) lives on epiphytic mosses (Plewka 2016). *Colurella hindenburgi* (Figure 89) lives on mosses on the dry habitat of granite rocks (Colurella 2016) as well as in bogs and fens (in Poland; Bielańska-Grajner *et al.* 2011). Bielańska-Grajner *et al.* (2011) likewise found *C. adriatica* (Figure 78-Figure 79) and *C. colurus* in these bogs and fens. *Colurella paludosa* (Figure 90) lives in *Sphagnum* ponds (Figure 29) (Plewka 2016).

Lepadella

Lepadella species include several that live among bryophytes. Myers (1942), working in the Poconos, Pennsylvania, USA, listed *Lepadella apsicora* (Figure 91), *L. akrobeles* (Figure 92-Figure 93), *L. latusinus* (Figure 94), *L. ovalis* (Figure 95-Figure 96; see also Bielańska-Grajner *et al.* 2011 from Poland), and *L. zigzag* (Figure 97) as *Sphagnum* (Figure 2) associates (Myers 1942).

Figure 91. *Lepadella apsicora*, a *Sphagnum* dweller. Photo by Jersabek *et al.* 2003, with permission.

Figure 94. *Lepadella latusinus*, a species that lives among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Lepadella ovalis (Figure 95-Figure 96) is a cosmopolitan species (de Manuel Barrabin 2000). It is a plankton species that occurs among macrophytes in the littoral zone and it can inhabit bryophytes. It is known at pH levels of 8.58-9.14 and from the temperature range of 23.6-24°C.

Figure 95. *Lepadella ovalis*, a bryophyte dweller. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 96. *Lepadella ovalis* is a plankton species that can inhabit bryophytes. Photo by Jersabek *et al.* 2003, with permission.

Figure 97. *Lepadella zigzag*, from *Sphagnum* in a pool. Photo by Jersabek *et al.* 2003, with permission.

Lepadella patella (Figure 98-Figure 99) is a littoral species known to inhabit bryophytes (de Manuel Barrabin 2000), including submersed mosses on Svalbard (De Smet 1990, 1993) and on submersed mosses in trenches of Alaskan polygons (Segers *et al.* 1996). This cosmopolitan species lives primarily on plant substrata, but occasionally occurs in the plankton of reservoirs, rivers, and ponds. It is uncommon in large bodies of water. It is known from a pH of 6.7-9.3 and temperatures of 9.1-22.3. Bielańska-Grajner *et al.* (2011) and Plewka (2016) reported it from *Sphagnum* (Figure 2) peatlands (bogs or fens).

Figure 98. *Lepadella patella*, a littoral species known to inhabit bryophytes, but also can be found in *Sphagnum* bogs. Photo by Jersabek *et al.* 2003, with permission.

Plewka (2016) and others include several additional species as *Sphagnum* (Figure 2) associates. *Lepadella acuminata* (Figure 100-Figure 101; Hingley 1993; Bielańska-Grajner *et al.* 2011) [also with submersed mosses on Svalbard (De Smet 1993)], *L. elliptica* (Bielańska-Grajner *et al.* 2011); *L. heterostyla* (Figure 102; Plewka 2016), *L. pterygoida* (Figure 103; Hingley 1993; Jersabek *et al.* 2003), *L. triba* (Figure 104; Hingley 1993; Jersabek *et al.* 2003), *L. triptera* (Figure 105-Figure 108; Horkan 1981; Hingley 1993), and *Lepadella whitfordi* (Figure 109; Myers 1942) all are associated with *Sphagnum* or occur in bogs. Both *L. triba* and *L. triptera* occur among submersed mosses on Svalbard (De Smet 1993). *Lepadella beyensi* was described from submersed mosses in a puddle in the high Arctic (De Smet 1994). *Lepadella deridderae* subsp. *alaskae* lives on submersed mosses in trenches of Alaskan polygons (Segers *et al.* 1996). *Lepadella minuta* occurs among submersed mosses on Svalbard (De Smet 1993).

Figure 99. *Lepadella patella*, a rotifer known from a *Sphagnum* bog. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Lepadella acuminata (Figure 100-Figure 101) is a species known to inhabit bryophytes as well as other plant substrata and is only occasionally found among the plankton (de Manuel Barrabin 2000). It occurs with submersed mosses on Svalbard (De Smet 1993). This species does best in water that is slightly acid (Koste 1978) [pH 6.8-8.3 (de Manuel Barrabin 2000)] and has a temperature range of 7.8-19°C (Koste 1978).

Paracolurella

Paracolurella is among the many rotifer genera represented among the *Sphagnum* (Figure 2). It is a genus of only two species, *P. aemula* (Figure 114) and *P. logima* (Figure 115), and both of these occur among *Sphagnum* (Jersabek *et al.* (2003).

Figure 114. *Paracolurella aemula* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Figure 115. *Paracolurella logima* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Squatinella

More rotifers from the genus *Squatinella* occur on or among *Sphagnum* (Figure 2). Myers (1942) reported only *S. bifurca* (Figure 116) as a *Sphagnum* associate. Hingley (1993) reported *S. lamellaris* [Figure 117-Figure 121, typically a periphyton species (Plewka 2016)], *S. longispinata* (Figure 122), *S. microdactyla* [Figure 123; typically a plankton species (Plewka 2016)], and *S. rostrum* (Figure 124-Figure 125; see also Bielańska-Grajner *et al.* 2011). Jersabek *et al.* (2003) added the additional species *S. retrospina* (Figure 126) from a *Sphagnum* bog.

Figure 126. *Squatinella retrospina* from among *Sphagnum* in bog. Photo by Jersabek *et al.* 2003, with permission.

Lindiidae

This is a small family with only one genus and at least fifteen species (De Smet 2005). Three of these occur in salt water. Three species are known from bryophytes. *Lindia annexa* (Figure 127) is a periphytic species that occurs among *Sphagnum* in bogs (de Manuel Barrabin 2000). In reservoirs of Spain it is known at temperatures around 7.9 and a pH of around 6.8. Jersabek *et al.* (2003) also reported a collection of this species from a lake in the Pocono Mountains, Pennsylvania, USA.

Figure 127. *Lindia annexa* is a periphytic species that commonly occurs in *Sphagnum* bogs. Photo from Jersabek *et al.* 2003, with permission.

Lindia pallida (Figure 128) is likewise a *Sphagnum* (Figure 2) dweller, living anywhere that wet or partly submerged *Sphagnum* occurs (Harrington & Myers 1922). To quote Harrington and Myers, "in such locations it may be collected at any time and any place."

Figure 128. *Lindia pallida* from *Sphagnum*. Photo by Christian Jersabek, with permission.

Lindia torulosa (Figure 129-Figure 133) is a large rotifer (>500 μm) that is cosmopolitan, including records from one sub-Antarctic and four Antarctic locations (Dartnall 1995). *Lindia torulosa* is aquatic, but it also inhabits submersed mosses (de Beauchamp 1913) and wet terrestrial mosses (De Smet, pers. comm. 13 November 2016), where it eats the *Cyanobacteria Oscillatoria* (Figure 130-Figure 131) and *Anabaena/Nostoc* (Figure 132) (Koste 1979; Plewka 2016). Its trophi are specialized for eating *Cyanobacteria*.

Figure 133. *Lindia torulosa* showing cilia. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Microcodidae

This family has only one genus, and only a single species, *Microcodon clavus* (Figure 134-Figure 135), a plankton species, is also known from bryophytes (Horkan 1981; Hingley 1993; Jersabek *et al.* 2003). It has no **lorica** (shell) and is shaped like a cone with a long, ventral foot (Naberezhnomu 1984).

Figure 134. *Microcodon clavus* from among *Sphagnum* in bogs. Photo by Jersabek *et al.* 2003, with permission.

Figure 135. *Microcodon clavus*, a plankton dweller that can occur among *Sphagnum*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Mytilinidae

The **Mytilinidae** are **loricate** rotifers (Koste & Shiel 1989). That is, they have a shell. This lorica is triangular to rhombic in cross section and there is often a double keel on the dorsal side. The species are littoral bottom-dwellers, rarely occurring in the plankton. There are only two genera, but only *Mytilina* (Figure 136), a genus with 37 species, is represented among bryophytes, with three species thus far reported here.

Mytilina macrocera (Figure 137) is a *Sphagnum* (Figure 2) dweller (Jersabek *et al.* 2003). *Mytilina mucronata* (Figure 138-Figure 139) occurs on various substrata, including algal filaments (Figure 138; Photo by Jersabek *et al.* 2003), submerged mosses in trench of Alaskan polygons (Segers *et al.* 1996), and among *Sphagnum* in bogs (Horkan 1981; Hingley 1993); on Svalbard, it occurs on wet mosses, but also in the plankton (De Smet 1993). *Mytilina brevispina* (Figure 141-Figure 140) is a bryophyte dweller on *Sphagnum* (Hingley 1993; Plewka 2016).

Figure 136. *Mytilina*, a genus with three species known from bryophytes. Note the triangular (top to bottom) shell and dorsal keel. Photo by Jean-Marie Cavanahac, with permission.

Figure 141. *Mytilina brevispina* from *Sphagnum*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Summary

The monogonont order **Ploimida** is continued here from the previous sub-chapter. The **Lecanidae** is a large family with only one genus, *Lecane*. *Lecane* has many species associated with bryophytes. The **Ituridae** has one species known from bryophytes. The **Lepadellidae** is a cosmopolitan family of freshwater with four genera known from bryophytes. The **Lindiidae** is a small family with only one documented species among bryophytes. The **Microcodidae** has only one species and it occurs with bryophytes. The **Mytilinidae** are littoral species. Three species of *Mytilina* occur among bryophytes.

Acknowledgments

Bryonettors and rotifer photographers have been wonderful in making their photographs available to me and seeking photographs from others. Tom Powers and Walter Dioni helped me obtain images and permission from others. Christian D. Jersabek very generously gave me permission to use the wealth of images from the Online Catalog of Rotifers. My special thanks go to Michael Plewka for his generous permission to use so many of his beautiful online images. Many photographers have been generous with permission for the use of their images and others have provided them online through Creative Commons and public domain sources. Aydin Örstan helped me find email addresses and pointed out errors in an earlier version of the chapter. Claudia Ricci answered my questions and helped me with current nomenclature.

CHAPTER 4-7c

INVERTEBRATES: ROTIFER TAXA – MONOGONONTA

Figure 1. *Cephalodella*, a common genus among *Sphagnum*. Photo by Proyecto Agua Water Project Creative Commons.

Notommatidae

The name **Notommatidae** literally means "eyes on the back." The members of this family have a nearly cylindrical body with a thin foot and two toes. Many of its species are known from bryophytes.

Cephalodella

Cephalodella (Figure 1) is a large genus, with many species that occur among bryophytes. Most of these are associated with *Sphagnum* (Figure 2). These include *Cephalodella abstrusa* (Myers 1942), *C. anebodica* from bogs (Figure 2) (Błedzki & Ellison 2003), *C. apocolea* (Figure 3-Figure 5; Hingley 1993; Jersabek *et al.* 2003), *C. auriculata* (Figure 6-Figure 9; Hingley 1993; Jersabek *et al.* 2003), *C. belone* (Figure 10; Jersabek *et al.* 2003), *C. biungulata* (Figure 11; Jersabek *et al.* 2003), *C. catellina* (Figure 12-Figure 13; Horkan 1981; Hingley 1993), *C.*

compressa (Figure 28; Jersabek *et al.* 2003), *C. derbyi* (Figure 29; Plewka 2016), *C. elegans* (Figure 30; Jersabek *et al.* 2003), *C. forficula* (Figure 26-Figure 25; Horkan 1981; Hingley 1993), *C. gibba* (Figure 15-Figure 17; Horkan 1981; Hingley 1993; De Smet 2001; Jersabek *et al.* 2003; Bielańska-Grajner, *et al.* 2011), *C. gibboides* (Bielańska-Grajner *et al.* 2011), *C. gigantea* (Figure 31; Plewka 2016), *C. intuta* (Figure 21-Figure 22; Hingley 1993), *C. licinia* (Figure 32; Jersabek *et al.* 2003), *C. lipara* (Figure 33-Figure 34; Jersabek *et al.* 2003), *C. mira* (Figure 35-Figure 36; Jersabek *et al.* 2003), *C. mucronata* (Figure 37; Jersabek *et al.* 2003), *C. nana* (Figure 38-Figure 39; plus other bryophytes; Hingley 1993), *C. nelitis* (Figure 40; Jersabek *et al.* 2003), *C. pheloma* (Hingley 1993), *C. plicata* (Myers 1942), *C. rotunda* (Figure 18; Plewka 2016), and *C. tantilloides* (Hingley 1993; Bielańska-Grajner *et al.* 2011).

Figure 5. *Cephalodella apocolea*, a species known from *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Cephalodella auriculata (Figure 6-Figure 9) is a bryophyte dweller in northern climates. In Alaska it occurs among the submerged mosses in the trenches between the polygons (Segers *et al.* 1996).

Figure 6. *Cephalodella auriculata*, a species known from bryophytes. Photo by Jersabek *et al.* 2003, with permission.

Figure 10. *Cephalodella belone* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

On Svalbard *C. biungulata* (Figure 11) lives exclusively on submerged mosses (De Smet 1993).

Figure 11. *Cephalodella biungulata*, a species known from *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Cephalodella catellina (Figure 12-Figure 13), *C. evabroedae*, *C. gibba* (Figure 15-Figure 17), *C. rotunda* (Figure 18), and *C. ventripes* var. *angustior* (Figure 19) occur on submerged mosses, but also in the plankton on Svalbard (De Smet 1988, 1990, 1993). *Cephalodella catellina* comprised up to 20% of the rotifers on the submerged mosses (De Smet 1988). On the other hand, *C. biungulata* (Figure 11), *C. glandulosa*, *C. hoodii* (Figure 20), *C. intuta* (Figure 21-Figure 22), and *C. megalcephala* (Figure 23) occurred exclusively on mosses (De Smet 1993). *Cephalodella gibba* and *C. sterea* (Figure 24) are among the most abundant of the submerged, moss-dwelling rotifers on Hopen, Svalbard (De Smet 1990). In Alaska, *C. gibba* occurred on submerged mosses in the trenches between polygons (Segers *et al.* 1993). Other species on submerged mosses on Hopen included *Cephalodella forficula* (Figure 26-Figure 25) and *C. misgurnus*.

Figure 12. *Cephalodella catellina* from a *Sphagnum* bog. Photo by Jersabek *et al.* 2003, with permission.

Figure 13. *Cephalodella catellina* from a *Sphagnum* bog. Photo by Jersabek *et al.* 2003, with permission.

Cephalodella gibba (Figure 15-Figure 17) is a cosmopolitan planktonic species of small bodies of water (de Manuel Barrabin 2000). It lives in littoral areas of both fresh and brackish water and occasionally lives in branchial chambers of crustaceans. It feeds on single-celled algae, flagellates, and ciliates. It prefers cold water (Segers 2001), but is known from a range of 6.4-18.8°C (de Manuel Barrabin 2000). Its known pH range is 6.6-8.48. In Germany, it is known from habitats with pH <3.0 (Deneke 2000). It typically occurs in the sediments (Hingley 1993; Schmid-Araya 1995), but it also is found among the Antarctic mosses (De Smet 2001).

Figure 24. *Cephalodella sterea* from a pond in Ontario, Canada. This species also occurs on **bog mosses**. Photo by Jersabek *et al.* 2003, with permission.

Cephalodella forficula (Figure 26-Figure 25) is a free-swimming, tube-dwelling species (Dodson 1984) known to live among bryophytes and in bog pools (Figure 2). It is a cosmopolitan littoral species that lives mostly in small bodies of water, occasionally as part of the plankton (de Manuel Barrabin 2000). It occurs in alkaline habitats but prefers slightly "acid" water in a pH range around 8.2 and a temperature near 19°C. Dodson (1984) describes its tubes made of mucus in detritus-rich environments. It closes the tubes at both ends and swims back and forth in its tube, living on bacteria shed from the inner walls. Dodson considers only small rotifers <1 mm can use this feeding strategy because of surface-to-volume considerations. In high food conditions, rotifers removed from the tube immediately build another, but under starvation or low oxygen conditions they leave the tube and swim about.

A number of *Cephalodella* species live in bogs, but their specific affiliation with *Sphagnum* (Figure 41) is not specified. These include *Cephalodella eva* (Figure 42-Figure 43; also with stream mosses; Horkan 1981; Jersabek *et al.* 2003), *C. exigua* (Figure 44) in bogs (Jersabek *et al.* 2003), *C. hoodii* (Figure 20; Horkan 1981), *C. lepida* (Figure 45; Jersabek *et al.* 2003), *C. physalis* (Figure 46-Figure 48; Hingley 1993; Jersabek *et al.* 2003), *C. rostrum* (Hingley 1993), *C. sterea* (Figure 24; Horkan 1981), *C.*

tachyphora (Figure 49-Figure 50; Jersabek *et al.* 2003), and *C. tantilla* (Figure 51; Hingley 1993).

Figure 51. *Cephalodella tantilla* from a *Sphagnum* bog. Photo by Jersabek *et al.* 2003, with permission.

Cephalodella subsecunda (Figure 52) is known from *Sphagnum subsecundum* (Figure 53) (Jersabek *et al.* 2003). Some *Cephalodella* are known from submersed *Sphagnum* (Figure 41), including *C. gracilis* [Figure 54–Figure 55; Bielańska-Grajner *et al.* 2011; Plewka 2016; in streams Madaliński 1961), and *C. inquilina* (Figure 56; Jersabek *et al.* 2003). *Cephalodella ventripes* (Figure 19) occurs not only on *Sphagnum* (Hingley 1993), but as already noted, it also occurs on submerged moss and among the plankton (De Smet 1993; Plewka 2016). On Svalbard, *Cephalodella ventripes* var. *angustior* occurs mostly between submerged mosses (De Smet 1988).

Figure 56. *Cephalodella inquilina* from among submersed *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Other members of *Cephalodella* occur on submersed mosses (*Cephalodella cyclops*; Figure 57; Plewka 2016), including *Fontinalis* (Figure 58) (*C. dorseyi*; Figure 59; Jersabek *et al.* 2003). *Cephalodella megalotrocha* is also a bryophyte dweller (Horkan 1981).

Figure 59. *Cephalodella dorseyi* from among *Fontinalis*. Photo by Jersabek *et al.* 2003, with permission.

Drilophaga

Drilophaga judayi (Figure 60) is an ectoparasitic rotifer (but occasionally free-swimming). In the Poconos Mountains, Pennsylvania, USA, it was found only among

Sphagnum (Figure 41) (Myers 1942). In a genus of only three species, two live in association with *Sphagnum*. The second of these is *D. bucephalus* (Figure 61), an ectoparasite on oligochaetes and a *Sphagnum* dweller (Plewka 2016).

Figure 60. *Drilophaga judayi*, a parasitic rotifer that occurs only among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Figure 61. *Drilophaga bucephalus* from *Sphagnum*. Photo by Michael Plewka (www.plingfactory.de), with permission.

Enteroplea

Enteroplea lacustris (Figure 62-Figure 63) occurs among *Sphagnum* (Figure 41) and in bog pools (Figure 2). Myers (1942) received a collection of a clump of wet *Sphagnum* from the Poconos Mountains, Pennsylvania, USA, and kept it in an aquarium for several months. Then a large number of *E. lacustris* appeared. There has been no report of it in the Poconos Mountains since.

Figure 63. *Enteroplea lacustris* from among *Sphagnum* and in bog pools. Photo by Jersabek *et al.* 2003, with permission.

Eosphora

Eosphora is a genus with only seven known species. Of these, two seem to find bryophytes suitable for habitation. *Eosphora ehrenbergi* (Figure 64) occurs in bog pools (Horkan 1981; Jersabek *et al.* 2003). *Eosphora najas* (Figure 65) is a littoral-planktonic species that eats detritus (Plewka 2016), but it is known to occur among bryophytes in streams (Madaliński 1961) and ponds (De Smet 1993).

Figure 64. *Eosphora ehrenbergi* male from Utah, USA, a species known from bog pools. Photo by Jersabek *et al.* 2003, with permission.

Figure 65. *Eosphora najas*, showing eyespots, a planktonic species that eats detritus. Photo by Michael Plewka (www.plingfactory.de), with permission.

Eothinia

Eothinia has only six species. Only one of these, *Eothinia elongata* (Figure 66), associates with bryophytes by living in bogs (Horkan 1981).

Figure 66. *Eothinia elongata* from Three Lakes, Wisconsin, USA, a species known from bogs. Photo by Jersabek *et al.* 2003, with permission.

Monommata

The bryophyte dwellers in *Monommata* are all associated with *Sphagnum* (Figure 41). Hingley (1993) reported *Monommata actices* (Figure 67), *M. aeschyna*, *M. astia* (Figure 68), *M. longiseta* (Figure 69-Figure 70), *M. maculata* (Figure 71), and *M. phoxa* as *Sphagnum* associates. To these, Plewka (2016) added *M. dentata* (Figure 72) and Jersabek *et al.* (2003) added *M. hyalina* (Figure 73). *Monommata aequalis* (Figure 74; Horkan 1981) and *M. grandis* (Figure 75; Plewka 2016) occur in bog pools and *Sphagnum* ponds (Figure 2), respectively. On Svalbard, De Smet (1993) found a species of *Monommata* exclusively on submerged mosses.

Figure 67. *Monommata actices*, a species that is known from *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Notommata

This genus likewise contributes to the rotifer fauna of *Sphagnum* (Figure 41). Among these *Sphagnum* associates one can find *Notommata allantois* (Figure 76; Hingley 1993; Plewka 2016), *N. cerberus* (Figure 77-Figure 78); Horkan 1981; Hingley 1993; Jersabek *et al.* 2003; Plewka 2016), *N. cherada* (Figure 79; Jersabek *et al.* 2003), *N. contorta* (Figure 80; Hingley 1993; Jersabek *et al.* 2003), *N. copeus* (Figure 81-Figure 83; Horkan 1981; Hingley 1993; Plewka 2016), *N. cyrtopus* (Figure 87; bog pools and other bryophytes; Horkan 1981), *N. doneta* (Myers 1942), *N. falcinella* [Figure 88; on *Sphagnum subsecundum* (Figure 53; Harrington & Myers 1922; Hingley 1993), *N. fasciola* (Figure 89; Jersabek *et al.* 2003), *N. groenlandica* (Figure 90-Figure 91; Hingley 1993; Plewka 2016), *N. pachyura* (Figure 92-Figure 94; Horkan 1981; Hingley 1993), *N. peridia* (Figure 95; Myers 1942), *N. pygmaea* (Figure 96; Myers 1942), *N. saccigera* (Figure 97-Figure 98; Harrington & Myers 1922; Myers 1942; Hingley 1993), and *N. tripus* (Figure 99-Figure 100; bog pools, others; Horkan 1981; Hingley 1993). Horkan (1981) reported *Notommata brachyota* from bryophytes.

Figure 76. *Notommata allantois* with green gut, a species that occurs in *Sphagnum*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Notommata cerberus subsp. *parvida*; Figure 77-Figure 78) is a cosmopolitan species known to inhabit bryophytes

(de Manuel Barrabin 2000) and to live in bog pools (Horkan 1981). It is an omnivore that consumes other rotifers, desmids, diatoms, and flagellates (de Manuel Barrabin 2000). Its known *pH* is around 8.2 and temperature around 18.8°C.

Figure 77. *Notommata cerberus*, a *Sphagnum* dweller. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 80. *Notommata contorta*, known from a *Sphagnum* pool. Photo by Jersabek *et al.* 2003, with permission.

Notommata copeus (Figure 81-Figure 83) is a cosmopolitan, littoral species (de Manuel Barrabin 2000) known to inhabit bryophytes. It also occasionally occurs in the plankton (de Manuel Barrabin 2000) and in bog pools

(Horkan 1981). It is known from a *pH* around 7 and temperature around 6°C (de Manuel Barrabin 2000). Its food is mostly zygnetalean algae – *Mougeotia* (Figure 84), *Spirogyra* (Figure 85), and *Zygnema* (Figure 86), that occur in these pools.

Pleurata

Of the seven species in *Pleurata*, three are associated with bryophytes. All of these are associated with *Sphagnum* (Figure 41) and include *P. chalicodes* (Figure 102), *P. tithasa* (Figure 103), and *P. vernalis* (Figure 104) (Jersabek *et al.* 2003). In Alaska, *P. chalicodes* occurs with submerged mosses in trenches of polygons (Segers *et al.* 1996).

Figure 102. *Pleurata chalicodes* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Figure 104. *Pleurata vernalis* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Pleurotrocha

Although *Pleurotrocha* has eight species, only two of these are associated with bryophytes. *Pleurotrocha petromyzon* (Figure 105) occurs with the aquatic moss *Fontinalis* (Figure 58) (Plewka 2016). The only

Sphagnum (Figure 41) dweller seems to be *P. robusta* (Figure 106-Figure 107; Jersabek *et al.* 2003).

Figure 107. *Pleurotrocha robusta* from a *Sphagnum* bog. Photo by Jersabek *et al.* 2003, with permission.

Pseudoploesoma

Pseudoploesoma is a small genus with only one species, *P. formosum* (Figure 108-Figure 110). It occurs among *Sphagnum* in bog ponds (Figure 2) (Myers 1942; Jersabek *et al.* 2003).

Figure 110. *Pseudoploesoma formosum* from among *Sphagnum* in a bog pond. Photo by Jersabek *et al.* 2003, with permission.

Resticula

Three members of *Resticula* are associated with bryophytes and other submerged plants. *Resticula melandocus* (Figure 111-Figure 113) occurs in *Sphagnum*

bogs (Figure 2) (Hingley 1993), but also is associated with the alga *Nitella* (Jersabek *et al.* 2003; Plewka 2016). *Resticula nyssa* (Figure 114-Figure 115) is a littoral species that lives on plant surfaces, including bryophytes (de Manuel Barrabin 2000), including *Sphagnum* (Figure 41) (Hingley 1993). On Svalbard, it occurs exclusively on submerged mosses (De Smet 1993). It prefers slightly acidic water, although the measured pH was 8.2. Its temperature preference is around 18.8°C (de Manuel Barrabin 2000). *Resticula plicata* (Figure 116) lives in *Sphagnum* ponds (Figure 2) (Plewka 2016).

Figure 116. *Resticula plicata*, inhabitant of *Sphagnum* ponds. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Taphrocampa

Taphrocampa is a genus with only four species. Of these, two are known from *Sphagnum* (Figure 41): *T. annulosa* (Figure 117-Figure 118) and *T. clavigera* (Figure 119) (Hingley 1993; Jersabek *et al.* 2003).

Figure 119. *Taphrocampa clavigera*, a species known from *Sphagnum* in more than one location. Photo by Jersabek *et al.* 2003, with permission.

Proalidae

This family lacks a hardened lorica and instead takes on a wormlike appearance. It lives in freshwater and occurs on plants, on the bottom, and among sand grains of the littoral zone as well as in damp terrestrial habitats (EOL 2012). Some are even **epizoic** on other invertebrates and some live parasitically in algae or on invertebrates.

Bryceella

This genus is **oviparous** (producing eggs that are laid and hatch later). All known species of the genus *Bryceella* live among *Sphagnum* (Figure 41). *Bryceella tenella* (Figure 120-Figure 121) seems to be known only from *Sphagnum* (Myers 1942; Hingley 1993; Jersabek *et al.* 2003; Bielańska-Grajner, *et al.* 2011). On the other hand, *Bryceella perpusilla* (Figure 122; Wilts *et al.* 2010) and *B. stylata* (Figure 123-Figure 124; Hingley 1993; Plewka 2016) both occur on ground-dwelling and epiphytic mosses as well as aquatic habitats, illustrating an ability to tolerate a wide moisture range. Segers *et al.* (1996) reports *B. stylata* from submerged mosses in trenches of Alaskan polygons; on Svalbard, it occurs exclusively on submerged mosses (De Smet 1993). *Bryceella pusilla* (Figure 125), previously known as *Wierzejskiella vagneri*, is known from a *Sphagnum* bog (Plewka 2016).

Bryceella perpusilla (Figure 122) was described as a new species in 2010 from northwest Germany (Wilts *et al.* 2010). Its describers considered it to be one of the smallest rotifers (50-80 µm) and even one of the smallest metazoans known. Even its name, *perpusilla*, means very small. This small size, combined with its narrow body and dorsiventral compression, permits it to live among terrestrial mosses. The individuals glide among the mosses in a "nimble and jerky manner very fast on the moss stalks" and eat the detritus associated with the mosses. Even in the lab, they never leave the moss to swim. But they are not restricted to these terrestrial mosses. They also occur among *Sphagnum* (Figure 41) in Lake Gorbacz in Poland. They seem to prefer cold periods at about 10°C.

Proales

Proales is a somewhat larger genus. A number of its species occur among *Sphagnum* (Figure 41). These include *Proales bemata* (Figure 126; Myers 1942), *P. cognita* [Figure 127-Figure 128; on *Sphagnum*

cuspidatum (Figure 129); Jersabek *et al.* 2003], *P. decipiens* (Figure 130; Horkan 1981; Hingley 1993; Harrington & Myers 1922), *P. doliaris* (Figure 131; *Sphagnum* bogs; Hingley 1993; Jersabek *et al.* 2003), *P. fallaciosa* (Figure 132-Figure 134; Hingley 1993), *P. latrunculus* (current name not located; Hingley 1993), *P. micropus* (Hingley 1993), *P. minima* [Figure 135-Figure 136; on *Sphagnum subsecundum* (Figure 53); Hingley 1993; Plewka 2016], *P. ornata* (Myers 1942), *P. palimmeka* (Figure 137; on submerged *Sphagnum*; Jersabek *et al.* 2003), and *P. sordida* (Horkan 1981).

Figure 131. *Proales doliaris*, a species known from *Sphagnum* bogs. Photo by Jersabek *et al.* 2003, with permission.

Proales fallaciosa (Figure 132-Figure 134) is a **cosmopolitan** (in most of world), benthic-periphytic (and planktonic) species of small water bodies (de Manuel Barrabin 2000). It is known to inhabit bryophytes, including *Sphagnum* (Figure 41). On Svalbard it inhabits submerged mosses (De Smet 1993). It lives in alkaline to slightly acid water with a pH around 8.39 and temperature around 18.8°C (de Manuel Barrabin 2000) where it feeds on bacteria, detritus, algae, and microcrustaceans (Koste & Shiel 1990).

Figure 137. *Proales palimmeka* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

In addition to these *Sphagnum* dwellers, *Proales ardechensis* (Figure 138) lives in a seepage area where wet mosses attach to a vertical rock face that dries up in summer (De Smet & Verolet 2009). The pH there is 7.35 and water temperature of 7°C. *Proales globulifera* (Figure 139) is part of the periphyton on *Fontinalis* (Figure 58) (Plewka 2016), and *P. theodora* (Figure 140-Figure 141) associates with bryophytes in streams and rivulets (Madaliński 1961).

Figure 138. *Proales ardechensis*, a species that lives among wet mosses on rocks in seepage areas. Photo by Michael Verolet, with permission.

Figure 139. *Proales globulifera*, a species periphytic on *Fontinalis*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 141. *Proales theodora*, a plankton species that also occurs among mosses. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Proales laticauda (Figure 142) is the only terrestrial member of the genus that I have found. De Smet and Verolet (2009) first described it from moss on sandstone in a firewood area. Plewka (2016) reported it from mosses where it accompanied mucilaginous green algae.

Figure 142. *Proales laticauda*, a species that occurs on moss with mucilaginous green algae. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Proalinopsis

Proalinopsis is a genus of only seven species. Among these, three are associated with *Sphagnum* (Figure 41) or live in bogs. These are *Proalinopsis caudatus* (Figure 143-Figure 144) in bog pools (Horkan 1981; Hingley 1993; Plewka 2016), *P. phacus* on *Sphagnum* (Myers 1942), and *P. squamipes* (Figure 145) from a *Sphagnum* ditch and bogs (Hingley 1993; Jersabek *et al.* 2003). *Proalinopsis gracilis* (Figure 146) is known from the floating thallose liverwort *Riccia fluitans* (Figure 147) (Jersabek *et al.* 2003).

Figure 143. *Proalinopsis caudatus* from a *Sphagnum* pond. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 147. *Riccia fluitans*, home for *Proalinopsis gracilis*. Photo by Christian Fischer, through Creative Commons.

Wulfertia

On Svalbard, *Wulfertia ornata* occurs exclusively among submerged mosses in a pool (De Smet 1993).

Scaridiidae

This is a segregate family from **Notommatidae** (Segers 1995). At least some of the species are cosmopolitan; some are pantropical. *Scaridium* is the only genus and has only seven species. *Scaridium longicaudum* (Figure 148-Figure 150) is associated with bryophytes. It is occasionally planktonic (Plewka 2016), but it can occur in bogs (Horkan 1981) and typically occurs between vegetation (De Smet, pers. comm. 14 November 2016). *Scaridium montanum* occurs in *Sphagnum* ponds.

Figure 148. *Scaridium longicaudum* lateral view, a periphytic species that can be found in bogs. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 150. *Scaridium longicaudum*, a bog species. Photos by Jersabek *et al.* 2003, with permission.

Synchaetidae

To my mind, this family has some of the most unusual-looking rotifers. It has only four genera, three of which include bryophyte associates.

Polyarthra

Polyarthra (Figure 153, Figure 157-Figure 158) reminds me of a Native American headdress. Many of the species have long blade-like flexible appendages – my association with feathers and headdresses. The members of the genus are planktonic, but a few species have been found among bryophytes. They feed by a grabbing and sucking motion.

Gilbert and Schroder (2004) suggested that the **diapause** (resting) eggs (Figure 151) that develop into amictic females in species like *Polyarthra vulgaris* (Figure 151-Figure 152), occasionally a moss dweller, may be an adaptation for survival in an environment that is unstable. These amictic females have a higher lipid content, reduced digestive tract, and produce a single large egg within hours of hatching, whereas the normal generation time is six days. The diapause eggs are produced by sexual reproduction of a female and small male (from small eggs; Figure 152), thus producing a **diploid egg** (one having two sets of chromosomes). Like many algae and other plants, this behavior of sexual reproduction occurs when the environment becomes unfavorable. The diapause egg is able to remain viable without hatching for extended periods of time.

Figure 151. *Polyarthra vulgaris* with parthenogenetic diploid amictic egg. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 152. *Polyarthra vulgaris* with male eggs (smaller than female eggs). Photo by Michael Plewka (www.plingfactory.de), with permission.

Polyarthra euryptera (Figure 153) is a cosmopolitan planktonic species (de Manuel Barrabin 2000) that is known from bog pools (Horkan 1981). They occur in warm water, but are known from temperatures in the wide range of 5.9-24.9°C (de Manuel Barrabin 2000). They are seasonal, reaching a maximum population size in the summer. They generally do not occur in the hypolimnion, where they would be trapped in cold water. This species may be prey for other rotifers, including *Asplanchna girodi* (Figure 154) and *Ploesoma hudsoni* (Figure 155-Figure 156) (Guiset 1977). Their known pH range is 6.3-9.9.

Figure 153. *Polyarthra euryptera*, a cosmopolitan planktonic species that is known from bog pools. Photo by Jersabek *et al.* 2003, with permission.

Figure 156. *Ploesoma hudsoni* (lateral view), a predator on *Polyarthra euryptera*. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Polyarthra vulgaris (Figure 157-Figure 158) has likewise been found among mosses, including *Sphagnum* (Figure 41), in bogs (Hingley 1993), although it is a planktonic species (de Manuel Barrabin 2000). This species is cosmopolitan and present year-round. To accommodate its year-round activity, it tolerates temperatures 5.9-16-7°C. It prefers high levels of oxygen, a pH range of 6.6-6.9, and lives near the water surface, rarely occurring in the hypolimnion. It feeds on centric diatoms and algae in the **Cryptomonadaceae** (Pourriot 1977) and **Chrysophyceae** (Devetter 1998), as well as bacteria and one-celled **Chlorophyta** (Bogden & Gilbert 1987). Bogden and Gilbert (1987) describe the feeding as a suction that uses pharyngeal expansion. The fecundity is positively related to the amount of chlorophyll *a* present (Devetter & Sed'a 2003). They are especially important in the food web, along with other rotifers, when the hydrological conditions are unstable (Keckeis *et al.* 2003).

Figure 157. *Polyarthra vulgaris* has been found among mosses, although it is a planktonic species. Photo from Malcolm Storey, through Creative Commons.

Figure 160. *Synchaeta pectinata* from plankton. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Synchaeta

The genus *Synchaeta* (Figure 159) is typically planktonic in both freshwater and marine environments, it also has members that live on bryophytes in freshwater (Hingley 1993). It also is one of the few rotifers to live in the marine environment (Brownell 1988; Wikipedia 2012), but not on bryophytes there (bryophytes do not occur in the marine environment). It prefers cold water and is absent in the warm water habitats of southeast Asia (Segers 2001).

Figure 159. *Synchaeta*, a cold-water genus that occurs on bryophytes (Hingley 1993). Photo by Wim van Egmond, with permission.

Figure 161. *Synchaeta pectinata*, typically a cosmopolitan planktonic species, also lives among bryophytes and can live in bog pools. Photo by Jersabek *et al.* 2003, with permission.

Figure 162. *Synchaeta tremula* from a lake in New Jersey, USA. This species also occurs in bogs. Photo by Jersabek *et al.* 2003, with permission.

Synchaeta pectinata (Figure 160-Figure 161) is a cosmopolitan planktonic species (de Manuel Barrabin 2000) that has been collected from bryophytes and can live in bog pools (Horkan 1981; Hingley 1993). Although it survives at temperatures of 5.9-25.5°C, it has its maximum populations at low temperatures (de Manuel Barrabin 2000). It lives in both small and large lakes at pH 6.3-9.3. The food is primarily algae of the **Cryptomonadaceae**, **Chrysophyceae**, and centric diatoms (Pourriot 1970). The species is often infected by the fungus *Plistophora* (*Bertramia*) *asperospora*. *Synchaeta tremula* (Figure 162) occurs in bogs (Horkan 1981).

Tetrasiphonidae

As nearly as I can determine, there is one genus and possibly two species in this family, although Segers (2007) only lists *Tetrasiphon hydrocora* (Figure 163-Figure 164); one species remains undescribed. This species is known from *Sphagnum* (Figure 41) and submersed mosses (Nogrady 1980; Hingley 1993; Plewka 2016).

Figure 163. *Tetrasiphon hydrocora*, a species known from *Sphagnum*, with the desmid *Micrasterias* in its gut. Photo by Wim von Egmond, with permission.

Figure 164. *Tetrasiphon hydrocora*, a species known from *Sphagnum*. Note desmids in the gut. Photo by Jersabek *et al.* 2003, with permission.

Trichocercidae

The members of this family usually have a twisted body and strongly asymmetrical trophi. Some members are parasitic. Some live among bryophytes, including *Sphagnum* (Figure 41).

Elosa

Elosa has a symmetrical body, but the trophi are asymmetrical. *Elosa worrallii* (Figure 165) shares the genus with one other species that is sometimes considered to be conspecific with *E. worrallii* (Segers 2007). *Elosa worrallii* lives among bryophytes, including *Sphagnum* (Myers 1942; Hingley 1993).

Figure 165. *Elosa worrallii* with notch in lorica, a species known from bryophytes, including *Sphagnum* (Myers 1942). Photo by Michael Plewka <www.plingfactory.de>, with permission.

Trichocerca

By contrast to *Elosa*, *Trichocerca* is a larger genus. *Trichocerca bicristata* (Figure 166-Figure 167) is planktonic, but lives in bog pools (Figure 2; Horkan 1981; Hingley 1993). *Trichocerca brachyura* (Figure 168) occurs in bogs in the Pocono Mountains, Pennsylvania, USA (Horkan 1981; Jersabek *et al.* 2003). *Trichocerca cavia* (Figure 169) is likewise a species known from *Sphagnum* bogs, living on submerged mosses (Hingley 1993; Plewka 2016). On Svalbard, *T. cavia* occurs among submerged mosses, but also occurs in the plankton (De Smet 1993). Among others known from *Sphagnum* bogs, Hingley (1993) included *T. collaris* (Figure 170), *T. elongata* (Figure 171), *T. junctipes* (*T. sejunctipes*?), *T. longiseta* (Figure 172-Figure 173), *T. porcellus* (Figure 174-Figure 175; see also Bielańska-Grajner *et al.* 2011) [also from *Fontinalis* (Jersabek *et al.* 2003)], *T. rattus* (Figure 178-Figure 179), (also Horkan 1981; Jersabek *et al.* 2003), and *T. rosea* (Figure 180-Figure 181; also Jersabek *et al.* 2003).

Trichocerca major (Figure 175) and *T. porcellus* (Figure 174) are cosmopolitan species in small water bodies with limited nutrients (de Manuel Barrabin 2000). *Trichocerca major* is known from both a bog and *Fontinalis* (Jersabek *et al.* 2003). Both species typically occur between vegetation as periphyton (De Smet, pers. comm. 14 November 2016). *Trichocerca porcellus* is active in winter at temperatures around 9.5°C and occurs at a pH around 7.1. It lays eggs inside algal mats such as *Aglaucoseria*, *Fragilaria* (Figure 176), and *Dinobryon* (Figure 177). It is known from bryophytes in multiple locations, including collections of the aquatic moss *Fontinalis* (Figure 58).

Figure 174. *Trichocerca porcellus*, a cosmopolitan periphytic species known from the aquatic moss *Fontinalis*. Photo by Jersabek *et al.* 2003, with permission.

Figure 180. *Trichocerca rosea*. This species is known from more than one bog. Photo by Jersabek *et al.* 2003, with permission.

Figure 183. *Trichocerca similis*, a plankton species that lives among bryophytes and in bog pools. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 181. *Trichocerca rosea*, a species that been found in more than one location on *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Trichocerca similis (Figure 182-Figure 183) is a planktonic rotifer, but it also is known from bryophytes and bog pools in Pennsylvania, USA (Myers 1942; Horkan 1981). It is likely to be cosmopolitan, preferring warmer waters (de Manuel Barrabin 2000). It attaches its asexual eggs to other members of the plankton (Pourriot 1970). It prefers a slightly basic pH of 7-9.63 and temperatures of 9.5-26.2°C (de Manuel Barrabin 2000). Food is predominantly Cryptomonadaceae and Chrysophyceae, especially *Mallomonas* (Figure 184) and *Dinobryon* (Figure 177). It is a common food item of predator rotifers such as *Asplanchna* (Figure 154) and *Ploesoma* (Figure 155-Figure 156) (Guiset 1977).

Figure 184. *Mallomonas*, food for *Trichocerca similis*. Photo by Jason Oyadomari, with permission.

Jersabek *et al.* (2003) added several *Sphagnum* (Figure 41) associates. These included *Trichocerca edmondsoni* (Figure 185), *T. ornata* (Figure 186) as a bog species and *T. lata* (Figure 187), *T. parvula* (Figure 188; these two species are easily confused), *T. platessa* (Figure 189), *T. rotundata* (Figure 190), and *T. scipio* (Figure 191) from among *Sphagnum*.

Figure 182. *Trichocerca similis*, a planktonic species that also occurs with bryophytes and in bog pools. Photo by Jersabek *et al.* 2003, with permission, with permission.

Figure 192. *Trichocerca tenuior* from among the thallose liverwort *Riccia fluitans*. This rotifer also occurs on bog mosses. Photo by Jersabek *et al.* 2003, with permission.

Both *Trichocerca tenuior* (Figure 192) and *T. tigris* (Figure 193-Figure 195) occur in bogs (Horkan 1981; Hingley 1993), but they also both live on the thallose liverwort *Riccia fluitans* (Figure 147) in ponds (Jersabek *et al.* 2003). *Trichocerca harveyensis* (Figure 196) lives on *Fontinalis disticha* and seems to be the only bryophyte dweller in *Trichocerca* not known from *Sphagnum* (Figure 41) (Myers 1942; Jersabek *et al.* 2003).

Figure 193. *Trichocerca tigris*, a species that lives among *Sphagnum* and the thallose liverwort *Riccia fluitans* in ponds. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 197. *Trichocerca intermedia*, a species of submerged mosses on Svalbard. Photo by Jersabek *et al.* 2003, through Creative Commons.

On Svalbard, *T. rattus* (Figure 178-Figure 179) occurs on submerged mosses, but also in the plankton (De Smet 1993). Horkan (1981) included *T. similis* (Figure 183-Figure 182) as a species of bog pools. Bielańska-Grajner *et al.* (2011) added *T. musculus*. On Svalbard, *T. intermedia* (rare; Figure 197), *T. longistyla*, *T. obtusidens* (Figure 198), *T. uncinata* (Figure 199), and *T. weberi* (Figure 200) occur on submerged mosses, but they also occur in the plankton (De Smet 1988, 1993).

Figure 198. *Trichocerca obtusidens* Jersabek *et al.* 2003, through Creative Commons.

This family is one that represents the sparse studies on rotifers living on mosses in waterfalls. It is represented by *Trichocerca pusillus* (Figure 201) from a waterfall in Thailand (Savatenalinton & Segers 2008), but this species is more typically a plankton species (De Smet, pers. comm. 14 November 2016).

Figure 201. *Trichocerca pusilla*, a planktonic species that can occasionally occur among wet mosses in waterfalls. Photo by Jersabek *et al.* 2003, with permission.

Trichotriidae

This family is loricate and its surface is marked with facets that have spicules or spines and are mostly granulate (Koste & Shiel 1989). The lorica extends beyond the body to the head, foot, and toes. It typically occurs both on and between aquatic plants, only occurring in the plankton when it is migrating to a new location. There are only three genera, and two of them (*Macrochaetus*, *Trichotria*) have been collected from bryophytes.

Macrochaetus

Macrochaetus collinsii (Figure 203-Figure 202) inhabits bryophytes in bogs (Hingley 1993). *Macrochaetus multispinosus* (Figure 204) lives among *Sphagnum* (Figure 41; Jersabek *et al.* 2003).

Figure 202. *Macrochaetus collinsii*, a species known to inhabit bryophytes. Photo by Jersabek *et al.* 2003, with permission.

Figure 204. *Macrochaetus multispinosus* from among *Sphagnum*. Photo by Jersabek *et al.* 2003, with permission.

Trichotria

Trichotria cornuta (Figure 205), *T. pocillum* (Figure 206-Figure 207), *T. tetractis* (Figure 209-Figure 212), *Trichotria tetractis caudata* (Figure 210), *T. tetractis similis* (Figure 211), and *T. truncata* (Figure 213-Figure 215) all live among *Sphagnum* (Figure 41) in bogs (Horkan 1981; Hingley 1993; Jersabek *et al.* 2003; Bielańska-Grajner *et al.* 2011; Plewka 2016). *Trichotria pocillum* is a cosmopolitan species that lives on plant substrata (de Manuel Barrabin 2000), including bryophytes, and can occur in bogs (Horkan 1981). It eats the organic detritus and algae, particularly diatoms, that accumulate

among the plants (de Manuel Barrabin 2000). It is widely tolerant of mineralization but prefers a narrow pH range of 7.5-8.1. Its known temperatures are in the narrow range of 7.7-9.1, making it active only in winter, at least in Spanish reservoirs. *Trichotria tetractis* is a cosmopolitan species and has ecological relationships with *T. pocillum* (de Manuel Barrabin 2000). *Trichotria tetractis* is known from a pH around 8.1 and temperature around 18.8°C.

Summary

The monogonont order **Ploimida** is continued here from the previous sub-chapter. The **Notommatidae** is a large family with a number of species collected from bryophytes. The **Proalidae** has no hardened lorica; it occurs on freshwater plants. The **Scaridiidae** is a small family with two species from bryophytes reported here. The **Synchaetidae** has mostly planktonic members, but some have been found among bryophytes. The **Tetrasiphonidae** may have only two species, and they are known from bryophytes. The **Trichocercidae** have a twisted body; two genera have species on bryophytes. The **Trichotriidae** are loricate with spicules or spines; two genera occur on bryophytes.

Acknowledgments

Bryonettors have been wonderful in making their photographs available to me and seeking photographs from others. Tom Powers and Walter Dioni helped me obtain images and permission from others. Christian D. Jersabek very generously gave me permission to use the wealth of images from the Online Catalog of Rotifers. My special thanks go to Michael Plewka for his generous permission to use so many of his beautiful online images. Many photographers have been generous with permission for the use of their images and others have provided them online through Creative Commons and public domain sources. Aydin Orstan helped me find email addresses and pointed out errors in an earlier version of the chapter. Claudia Ricci answered my questions and helped me with current nomenclature.

CHAPTER 4-8

INVERTEBRATES: MOLLUSCS

Figure 1. Slug on a *Fissidens* species. Is it eating, or just a casual visitor? Photo by Janice Glime.

The most familiar of the bryophyte inhabitants among the molluscs are the snails and slugs, but you will see that some bivalves also have an interesting relationship with bryophytes.

Mollusca are considered to be **bilaterally symmetrical** (like humans) (Pratt 1935), but they seem to push the definition to the limit. In bivalves, that is not too difficult to understand, but in snails the twisted body and shell seem to twist the definition as well; even organs normally paired, like kidneys, are not paired (Figure 2).

Gastropoda: Snails and Slugs

Most terrestrial and freshwater snails (**Pulmonata**) have spiral shells and these may be taller than the diameter of the opening (**elongate/conical**; Figure 26) or shorter (Figure 148) (Pratt 1935). The inside body is also a spiral, but it is not the same spiral as the one of the shell. This internal spiral affects the digestive system as well. With its mouth to the ground, the snail is infamous for the positioning of the anus above the mouth on the right side of the head (Figure 2).

In snails, the mantle secretes a shell, and this requires calcium carbonate. For this reason, you will find a number

of terrestrial taxa restricted to limestone areas. Slugs (Figure 3), on the other hand, lack shells and exhibit no external twists. Instead they have a thin calcareous plate embedded in the mantle.

Unlike the marine snails, terrestrial gastropods lack an **operculum** to cover the shell opening. Instead, they use a calcified slime (**epiphragm**; Figure 4) for protection in hibernation or aestivation. The **respiratory pore** (Figure 3) is on the right side of the body, and closes to keep out water in aquatic species or to prevent desiccation under dry conditions on land. Both aquatic and terrestrial gastropods have lungs, necessitating return to the surface for aquatic members to get air. Aquatic members have only one pair of non-retractile tentacles, whereas land-dwellers have two pairs and both are retractile. Aquatic species have an eye at the base of each tentacle; the land snails have their eyes on the tips of the rear pair of tentacles.

Most gastropods eat algae and plants, which they scrape with the **radula** (Figure 5), but a few are carnivorous. The radula is made of chitin with rows of minute calcareous teeth. And if you thought bryophytes used minute characters for identification, snail identification is often based on these teeth!

Reproduction

Most terrestrial snails and slugs are **simultaneous hermaphrodites**, mutually exchanging gametes during copulation. This is not true for land-dwelling prosobranch snails (including the Pomatiidae, Aciculidae, Cyclophoridae, and others) – families that have separate sexes (Wikipedia 2012b). The prosobranch snails are the ones that have an **operculum** that can be used to cover the opening when they retreat into the shells.

Some land snails are **sequential hermaphrodites**, being first male, then female (Nordsieck 2012b). Others, such as *Arianta arbustorum* (**Helicidae**; Figure 6), a moss-dwelling snail, have a mechanism that prevents sperm cells from fertilizing the snail's own egg cells before they reach the sperm pouch of the mate. In the aquatic **Lymneidae**, snails can reproduce using unfertilized eggs, permitting

Figure 4. *Helix pomatia* **epiphragm**. Photo by Hannes Grobe, through Wikimedia Commons.

them to multiply rapidly in a new location and causing invasive species problems when they are introduced as aquarium pets.

The reproductive anatomy of the snail is a bit peculiar, with the **penis** and **vagina** everting from near the head (Figure 7-Figure 8). In the hermaphrodites, the penes wrap around each other, sometimes extending to great lengths (Figure 9).

Mating and the Love Dart

The mating process is a combination of love and war (Figure 10). The dart, or more than one in some species, is made of calcium carbonate, chiton, or cartilage (Figure 11). During mating, each snail tries to inject this "dart" into the other snail (Figure 12) (Koene & Chase 1998a; Chase & Blanchard 2006). It might be more appropriate to call this a dagger because it is injected by a thrust, not a shot or a throw. The first mating of a snail stimulates the production of the dart, so it cannot be used until the second mating. Once used, it requires time to generate a new one.

Figure 10. Roman snails (*Helix pomatia*) in full foot contact during mating. This process of contact of foot, lips, and tentacles can take up to 20 hours. Photo through Wikimedia Commons.

Figure 12. Mating garden snails (*Helix aspera*) with love dart in snail on right, just above the antenna of the left snail. Photo by Eynar through Wikimedia Commons.

But what does the dart accomplish? Early hypotheses considered it to be a "gift of calcium" to help in the development of the eggs. Leonard (1992) used a theoretical model to support the hypothesis that the love dart induced the partner to act as a male, hence insuring that the thruster would also be fertilized. Koene and Chase (1998a, b) used an experimental approach to disprove the long-held hypothesis of a "gift of calcium."

Through the work of Koene and Chase (1998 a, b), the role of this dart has become clearer. It carries with it a mix of **hormones** that help to move the sperm cells toward the sperm pouch where they are stored until fertilization (Koene & Chase 1998a, b). This is accomplished by causing changes in the structure of the copulatory canal leading ultimately to the sperm pouch. These changes increase the chances, often doubling them, that sperm from that mating snail are successful in fertilizing eggs, since it is likely that the partner will have multiple mating events. But the dart, preferably aimed at the foot, can miss its ideal target and land in a less desirable location, like the base of the antenna. When that happens, the snail is no longer able to retract or extend the antenna.

Each partner goes through gyrations apparently in an attempt to avoid being recipient of the love dart, or at least to avoid receiving it in an undesirable location. So far, Leonard's (1992) hypothesis of stimulating the partner to carry out its male role does not seem to have been tested experimentally, but with the mix of hormones it could still be a viable part of the story. It appears that this love dart, although not understood at the time, could have been the basis for the story regarding Cupid's arrow (Chase 2010).

Egg and Larval Development

Most gastropods lay eggs, with only a few species bearing live young. In aquatic snails, development of the larva occurs as a planktonic stage once it leaves the egg, but in terrestrial pulmonate snails, development is completed within the egg. Some snails (e.g. *Clausiliidae*) exhibit **ovoviviparity**, wherein the larvae emerge inside the mother's body and emerge from "her" body as juvenile snails (Nordsieck 2012b). This practice permits these snails to live in dry areas where external eggs could not survive the desiccation. Some species of the **oviparous** (egg-laying) species, such *Arion flagellus* (Figure 13), lay their eggs under or among bryophytes (Figure 14).

Figure 13. *Arion flagellus* on a sheet of mosses. Photo © Roy Anderson <habitas.org.uk>, with permission.

Figure 14. *Arion flagellus* eggs in Oaks Wood, Cambourne, Cambridgeshire, UK. Note the bit of moss beside the eggs and on the eggs – remnants of the cover that previously protected them. Photo by Brian Eversham, with permission.

Richter (1972) found that the banana slug (*Ariolimax columbianus*, Figure 15) laid 3-4 mm eggs under moss where soil conditions were neither excessively wet nor dry. Placing eggs under mosses and other loose substrata may be an energy-saving strategy for some species. Bauer (1994) considered the behavior of some snails that dig holes to be an investment in **parental care**, but incurring an energy cost. Other than these preparations, snails do not tend their eggs or hatchlings. *Ariolimax californicus* (Figure 16) also may occur under bryophytes (Peggy Edwards, pers. comm.).

Figure 15. *Ariolimax columbianus* on moss. Photo by Bill Leonard, with permission.

Figure 16. *Ariolimax californicus* exiting a mat of mosses, a suitable location for laying eggs. Photo courtesy of Peggy Edwards.

Bryophyte Interactions

Glistening trails of pearly mucous (Figure 17) criss-cross mats and turfs of green, signalling the passing of snails and slugs on the low-growing bryophytes (Figure 1). In California, the white desert snail *Eremarionta immaculata* (Figure 18) is more common on lichens and mosses than on other plant detritus and rocks (Wiesenborn 2003). Wiesenborn suggested that the snails might find more food and moisture there. Are these molluscs simply travelling from one place to another across the moist moss surface, or do they have a more dastardly purpose (as hunters) for traversing these miniature forests?

Figure 17. *Lehmannia valentiana* with its slime trail on a moss (upper right) in Swavesey, Cambridgeshire, UK. Photo by Brian Eversham, with permission.

Figure 18. *Eremarionta immaculata* in the Riverside Mountains, CA, USA. Photo by William D. Wiesenborn, with permission.

But not all snails and slugs find the bryophyte substrate attractive. Some actually avoid its rough surface. Nevertheless, trails of slime (Figure 19) are not unusual, and we have little insight into the reasons why some find it inviting while others find it repulsive.

Figure 19. Snail or slug trails on *Dicranum viride* on big maple trunk. Photo courtesy of Betsy St. Pierre.

Abundance

Snails can sometimes occur in significant numbers in moss habitats. Their need for a moist environment (Pratt 1935) would seemingly attract snails to the mosses as a moist substrate. Quantitative information on snails and slugs among bryophytes is scarce, and often only mentions that bryophytes are abundant in the habitat (e.g. Nekola 2002).

The study by Grime and Blythe (1969) is helpful in understanding numbers and dynamics of moss-dwelling snail populations, but we need many more studies. They found average morning populations of up to 8.5 per 100 g dry weight of moss in early September for the copse snail *Arianta arbustorum* (Figure 20) at Winnats Pass in Derbyshire, England. In collections totalling 82.4 g of moss, they examined snail populations in a 0.75 m² plot each morning on 7, 8, 9, & 12 September 1966. *Arianta arbustorum* numbered 0, 7, 2, and 6 on those days, respectively, with weights of 0.0, 8.5, 2.4, and 7.3 per 100 g dry mass of moss. This was surpassed only by those on

Urtica dioica (stinging nettle) reaching 14.4 and *Mercurialis perennis* (dog's mercury) reaching 16.2. Nevertheless, it takes a lot of dry moss to make 100 g.

Figure 20. The moss-dwelling copse snail, *Arianta arbustorum*. Photo © Roy Anderson <habitas.org.uk>, with permission.

Nighttime activity by many snails is likely to be greater than that during the day, and little snails may actually seek refuge in mosses during the day (Grime & Blythe 1969). Furthermore, snails like *Arianta arbustorum* (Figure 20) typically climb, often to a considerable height, to obtain food. Bryophytes just don't fit as a refuge for larger snails, so the behavior of the larger *Arianta arbustorum* may not reflect that of the small snails.

Adaptations

Confusing the Predator

In the Pacific Northwest, USA, unusual jumping slugs in the genus *Hemphillia* (Figure 21-Figure 24) prefer coarse woody debris or moss mats on decaying logs (Leonard & Ovaska 2003). They have some remarkable adaptations for their log habitats. One such adaptation appears to be to confuse their predators by smearing their slime trail (Figure 17).

Figure 21. *Hemphillia glandulosa*, the warty jumping slug, on moss. This and the following photo illustrate the variability in its coloration. Photo by Kristiina Ovaska, with permission.

Jumping to Escape

A second adaptation to avoid predation is to "jump." Jumping slugs (*Hemphillia*; Figure 22) don't actually jump. Instead, when they are approached by a predator snail or other predator, they tighten their muscles, coil up, and straighten rapidly, flopping around on their substrate until they are free of it, and fall. This effects a rapid motion that looks like a jump (Leonard 2011). This activity also breaks the slime trail, facilitating their freedom to "jump." The slow-moving predator snails don't have a chance. Leonard says these slugs are potentially successful dispersers of fungal spores. I would think that would work for dispersing bryophytes as well, for spores, asexual structures, and fragments.

Figure 22. *Hemphillia glandulosa*, the warty jumping slug, on moss. This and the above photo illustrate the variability in its coloration. Photos by Kristiina Ovaska, with permission.

In Canada, some of these *Hemphillia* (Figure 21-Figure 24) species seem safe from extinction due to sufficient abundance, but others are endangered due to increasing patchiness of suitable habitats (Leonard & Ovaska 2003). The 1994 NW Forest Plan regulates ground disturbance activities on federal lands in northern California to Washington, protecting "survey and manage" species, including several species of jumping slugs, *Hemphillia*. *Hemphillia dromedarius* (dromedary slug; Figure 23-Figure 24) is officially threatened in both Canada and the United States, where it lives in the state of Washington. Legal protection of these slugs can help in the protection of mosses in these areas. However, the Bush administration was not sympathetic to this protection and it could be lost at any time with a change in administrative philosophy. Perhaps the novelty of its jumping behavior will increase public interest and sympathy and lead to its protection in yet another way.

Keeping It Small

If you want to go clambering among the bryophytes, it helps to be small (Figure 26). One would expect that size would also constrain movement among the bryophytes and restrict larger snails to the surface. But some tiny snails actually occur fairly deep within the bryophyte mat. Such is the elongate snail captured by Jan-Peter Frahm deep within a cushion of *Distichium capillaceum* (Figure 25).

Figure 25. *Distichium capillaceum* with a snail nestled deep within the cushion. Photo by Jan-Peter Frahm, with permission.

Truncatellina cylindrica (Figure 26) is another very small snail. Where it lives at Groomsport, Down, UK, it occurs in yellow dunes among mosses and the roots of vegetation on drier, sunny slopes (Anderson 1996).

Figure 26. *Truncatella cylindrica* on *Tortula* sp. Note the small size of this conical snail. Photo by Stefan Haller, with permission.

Szlavec (1986) determined that snail size plays an important role in their behavior, including food searching. Although one might think that larger animals need to eat more, it seems that the larger *Monadenia hillebrandi mariposa* (Figure 27) instead spends more time crawling and less time feeding, permitting it to travel farther. Although it prefers leaf litter, it consumes mosses as well (Figure 28). This snail lives in cool, mossy forests and sometimes hibernates among mosses, including thick moss on a bigleaf maple branch (Sandelin 2012).

Figure 27. *Monadenia hillebrandi*, a consumer of the mosses *Rhytidiadelphus* sp. and *Grimmia trichophylla*. Photo by John Slapcinsky, through Creative Commons.

Figure 28. Laboratory selection of foods by the snail *Monadenia hillebrandi mariposa*. Upper: all data combined. Lower: juveniles vs adults. Redrawn from Szlavec 1986.

Monadenia fidelis (Figure 29) lives in dry forests as well as prairie wetlands where its presence is indicative of an unburned prairie (Severns 2005). Loubser *et al.* (2005) found it associated with nearby mosses in 33% of their samples. But like many observations of animals with bryophytes, this may mean that they need bryophytes in their habitat, that they prefer the same habitats as bryophytes, or that the relationship is coincidental – the bryophytes are near something they need. In this case, mosses are one of its winter hibernating sites, where they hibernate under mosses in crotches of maple trees (Monadenia 2016).

Conical Shape

The terrestrial conical snails, or at least the smaller of these snails, seem to be more suited to traversing the internal spaces of bryophytes. *Cochlicopa lubrica* (Figure 30) and *Cochlicopa lubricella* (Figure 31), moss snails, have been known from mosses for a long time. In 1840 Turton reported these snails from mosses and grass on the ground and under stones in the British Isles.

Figure 30. *Cochlicopa lubrica* on mosses. Photo by Malcolm Storey, through Creative Commons.

Figure 31. *Cochlicopa lubricella*, moss snail, on mosses. Photo © Roy Anderson <habitas.org.uk>, with permission.

Turton (1840) also reported another tiny conical snail, *Ena obscura* (Figure 32), from mosses and under stones. But this snail has another way to be elusive from would-be predators. It covers itself with mud or debris, rendering it nearly invisible by hiding the shiny shell (The Great Snail Hunt 2012), but might it also provide a means of controlling water loss or temperature?

Figure 32. *Ena obscura*, a snail that lives in forests or on walls, under stones and moss (Turton 1840) in the Sulehay, Northants, UK. It covers itself with mud as camouflage. Photo by Roger S. Key, with permission.

Avoiding Desiccation

Bryophytes remain moist long after their epiphytic and rock substrata, and even those on dry soil can become moist, collecting fog or light rainfall that never reaches the soil. Hence, they can become a refuge for snails and slugs seeking moisture. Such is often the case for the banana slug, *Ariolimax columbianus* (Figure 15), in the Pacific lowlands, USA. This slug leaves its moist cover on a moss-covered fallen log to forage at night, then returns to the moss (Sandelin 2012). Taking advantage of the

moisture at night, this slug can travel nearly 0.5 km in search of more suitable conditions.

The large (up to 13-15 cm) bryophyte-dwelling slug *Arion ater* (Figure 33-Figure 35) forms a ball by contracting its body and humping up (Figure 34) (Sandelin 2012). That reduces its surface area and thus reduces water loss. It can also twist on itself to reduce exposed surface area (Figure 35). This twisting ability is probably also helpful as it climbs moss setae and feeds on the capsules.

Figure 35. *Arion ater* juvenile contracting on itself. Photo © Roy Anderson <habitas.org.uk>, with permission

Bryophytes can offer the snails and slugs yet another means to escape drought and extreme heat or cold. These gastropods can **hibernate** in cold temperatures or **aestivate** in heat or drought (Boss 1974), and this sometimes occurs

among bryophytes. Some snails remain dormant for as many as five or six years. Boss suggests that the ability to hibernate and aestivate may play a strong role in the expansion of geographic range, speciation, and extinction.

The European snail species *Fruticicola fruticum* (= *Eulota fruticum*, *Bradybaena fruticum*; Figure 36) hibernates from October until a time in spring when the weather is suitable for it to become active (Künkel 1928). It accomplishes this hibernation in dead moss or it may burrow into the ground with its aperture facing upward.

Figure 36. *Fruticicola fruticum* with *Polytrichum* nearby. Photo by Michael Becker, through Wikimedia Commons.

No Shell – Slugs

Slugs can be somewhat common on bryophytes and seem to have the same adaptations as snails. Their only advantage would seem to be greater flexibility due to the absence of a hardened and bulky shell, but that brings with it a greater chance for desiccation. For that reason, bryophytes may be a source of hydration. For many species, being small helps in permitting them to hide from predators and to maneuver among the bryophytes (Figure 37).

Figure 37. Keeled slug (*Tandonia budapestensis*), common inhabitant of mosses such as this *Leucolepis* in the Pacific Northwest, USA. Photo courtesy of Jeri Peck.

The **Limacidae** is a family of slugs, and both common genera (*Deroceras*, *Limax*) have members that have been found among mosses. In the sub-Antarctic Marion Island, the slug *Deroceras panormitanum* (Figure 38; originally described as the separate species *D. caruanae*) lives in moist bryophyte communities as well as on decaying bryophytes (Smith 1992). With a totally exposed body, slugs in such harsh environments can find shelter and moisture among the bryophytes.

Figure 38. *Deroceras panormitanum* on what appears to be a species of the moss *Campylopus*. Photo © Roy Anderson <habitas.org.uk>, with permission.

Brain Eversham (pers. comm. 21 March 2012) tells me that the yellow slugs, *Limax flavus* (= *Limacus flavus*; Figure 39) and *L. maculatus* (Figure 40), live mainly on old walls in Britain, where, like many snails, they are night active. They feed primarily on lichens and algae, but will graze on dead plant material if they run out of lichens. They don't generally eat leafy mosses, but they will browse on the capsules. He has observed *Tortula muralis* (Figure 41) and *Grimmia pulvinata* (Figure 42) with the setae remaining but all the capsules nibbled off. Ken Adams (Bryonet 18 March 2020) reports that capsules of *Codonoblepharon forsteri* (= *Zygodon forsteri*) where he does fieldwork in the UK are mostly eaten before they mature (Figure 43). Eversham suggests that the capsules and spores of bryophytes are more nutritious or more digestible than the leaves and stems.

In Search of Food

As just described for two species of *Limax* (Figure 39-Figure 40), snails and slugs may browse on bryophytes. They have a rasping tongue (**radula**) that destroys the epidermis of tracheophytes (Grime & Blythe 1969), but what does it do to moss leaves only one cell thick? Apparently in some cases it makes mosses potential food (Szlavecz 1986), and enables some gastropods to consume even the tough capsule (Davidson & Longton 1987, Davidson *et al.* 1990).

Low Palatability?

Often it appears that the palatability index for bryophytes is low (Jennings & Barkham 1975). Furthermore, snails and slugs seem to be less interested in grazing things with awns than those without. Robin Stevenson (pers. comm. January 2008) has seen *Bryum argenteum* (Figure 44-Figure 45) that is completely grazed over, but never observed such grazing on an awned *Grimmia* species (Figure 42). Could it just be that there is no nutrition in an awn, or do they have trouble gliding across the furry tips of leaves?

Figure 44. *Bryum argenteum*, a moss with no awns and a food source for snails and slugs. Photo by Michael Lüth, with permission.

Figure 45. *Bryum argenteum* showing lack of awns. Photo from UBC website, with permission from Shona Ellis.

But awns, even in *Grimmia pulvinata* (Figure 46), may not deter all snails (Figure 46). Szlavecz (1986) was able to identify the awned *Grimmia trichophylla* (Figure 47) in feces of the California snail, *Monadenia hillebrandi mariposa* (Figure 27) and also demonstrated that the spine tips of the tracheophyte *Selaginella hansenii* (Hansen's spikemoss; Figure 48) did not deter feeding or crawling. Perhaps it depends on the density of the hair tips, since *Grimmia trichophylla* (Figure 47) and *S. hansenii* (Figure 48) have much less dense hairs than *G. pulvinata* (Figure 46), and on the particular species and size of snail or slug. On the other hand, it appears that the slugs are able to graze the lower margins of a clump, apparently resting on the substrate without the need to traverse the awns (Figure 46).

Figure 46. *Grimmia pulvinata* exhibiting grazing that girdles the base of the clump in a pattern typical of snail or slug grazing, but also known for isopods. Photo by Robin Stevenson, with permission.

Figure 47. *Grimmia trichophylla* in Bretagne (Brittany), France, showing somewhat less imposing awns than those of *Grimmia pulvinata*. Photo by Michael Lüth, with permission.

Figure 48. *Selaginella hansenii*, a spine-tipped tracheophyte eaten by the snail *Monadenia hillebrandi mariposa*. Photo by J. E. (Jed) and Bonnie McClellan, © California Academy of Sciences, with permission.

Michael Lüth has observed snails grazing on *Orthotrichum* (Figure 49) and Terry McIntosh has seen slugs grazing on other bryophytes, with both observers indicating that the damage to the moss was similar to that shown for *Grimmia pulvinata* in Figure 46 (Bryonet 12 January 2008). On the other hand, Frank Greven (Bryonet 13 January 2008) has seen this pattern as a result of grazing by isopods (wood lice). Robin Stevenson (pers. comm. 14 January 2008) agrees that isopods might be deterred by the awns, causing them to eat in such a pattern. But in this case, after climbing up a bridge coping, the snail or whatever might have found that this moss provided the best choice available.

Figure 49. *Orthotrichum urnigerum*, member of a genus known to be grazed by snails. Photo by Michael Lüth, with permission.

Low Nutritional Quality?

That rasping tongue is not always enough to accomplish the task of obtaining nutrients from mosses. Oyesiku and Ogunkolade (2006) experimented with snails and the moss *Hyophila involuta* (Figure 50). In their laboratory experiments, the snails (*Limicolaria aurora*; Figure 51) gained the most weight when fed with *Hyophila involuta* paste. The snails that had only unground moss actually lost weight. Those in the field experiment (restricted to *Hyophila involuta*) either lost weight or remained the same. Fecal matter of the field snails had fragments of moss that had lost the chlorophyll from their cells as well as that of abundant algae and Cyanobacteria. The presence of these snails on the moss was seasonal from April until October, when the moisture and lower temperature of the moss may have provided a favorable habitat. This experiment suggests that in this case the snail was unable to penetrate the cells of the moss, making it an unlikely food source in nature. Rather, the researchers suggest that the snails most likely use the moss as a moist and cool habitat.

Oyesiku and Bello (2012) experimented further with the effect of the moss *Hyophila involuta* (Figure 50) as a food for the snail *Limicolaria aurora* (Figure 51). The study was based on an interest in including mosses as feed when breeding snails. The moss was mixed in various ratios with corn pap powders (*Zea mays*). Overall, there was a significant correlation with the feed ratios of decreasing order of moss 50%:corn 50% > moss 25%:corn

75% > moss 0%:corn 100% > moss 100%:corn 0% > moss 75%:corn 25%. The highest weight gain of 15 g peaked at the fourth day in *L. aurora* fed with moss 50%:corn 50%. Furthermore, the snails exhibited a strong positive weight gain correlation with increasing days of feeding with 25% moss to 75% corn.

Chemical Deterrents to Herbivory

Longton (pers. comm. 1996) has speculated that phenolic compounds that protect the leafy gametophytes deter herbivory, especially on perennials. This could account for greater herbivory on the annual *Funaria hygrometrica* (Figure 52) than on perennial *Brachythecium rutabulum* (Figure 66) or *Mnium hornum* (Figure 80). The phenolic compounds in the latter two species were released only after severe hydrolysis, leading Davidson *et al.* (1990) to suspect that the phenolic acids might be tightly bound to cellulose in the cell wall. The greater palatability of the *F. hygrometrica* supports the general theory that perennials invest more resources in defense against herbivory than do annuals such as *F. hygrometrica*.

Figure 52. Young sporophytes of *Funaria hygrometrica* before spores form. Photo by Michael Lüth, with permission.

Food for Some

Clearly for some slugs and snails there are bryophytes that do indeed seem palatable. Ochi (1960) reported that the thallose liverwort *Conocephalum conicum* (Figure 53) served as food for a slug. Merrifield (2000) found evidence of heavy grazing on epiphytic bryophytes, particularly the moss *Syntrichia laevipila* (Figure 54), of Oregon white oaks (*Quercus garryana*) in the Willamette Valley, Oregon, USA, and considered that either springtails or slugs were likely responsible. She considered that the abundance of gemmae on *S. laevipila* may be a response to this grazing.

Figure 53. *Conocephalum conicum* showing feeding damage upper middle) by something, perhaps a slug. Photo by John Hribljan, with permission.

Figure 54. *Syntrichia laevipila* on bark. Photo by Jonathan Sleath, with permission.

Algae growing on mosses, especially in the aquatic habitat, could be a prominent source of food for gastropods. In the Negev Desert, adult desert snails (*Sphincterochila zonata*) fed exclusively on algae on the soil surface, creating an algal turnover of 142 kg hectare⁻¹, despite being active for only 8-27 days in winter during the rainy period (Shachak & Steinberger 1980). Other Negev Desert snails feed on the mosses themselves. *Sphincterochila boissieri* (Figure 55) feeds on shrubs there, but its feces indicate that it also feeds on the moss *Tortula atrovirens* (= *Desmatodon convolutus*; Figure 56) (Yom-Tov & Galun 1971). This is a snail that has color morphs of brown and white, but they apparently don't affect its temperature (Yom-Tov 1971; Slottow *et al.* 1993). However, their rodent predators choose more brown than white snails, enough to exhibit significant differences in their choices (Slottow *et al.* 1993).

Figure 56. *Tortula atrovirens*, a moss that is eaten by the Negev Desert snail, *Trochoidea seetzeni*. Photo by Des Callaghan, with permission.

Szlavec (1986) examined feeding preferences in 31 individuals of the snail *Monadenia hillebrandi mariposa* (Figure 27). Collections of field feces indicated that they consumed the mosses *Rhytidiadelphus* sp. (Figure 57) and *Grimmia trichophylla* (Figure 58) in nature, among other things. In the lab, they preferred shrub and bay litter over mosses, but preferred mosses and lichens over grasses and pine litter. More green moss than brown occurred in the feces, whereas brown material was more common from consumed tracheophytes (Figure 59).

Figure 57. *Rhytidiadelphus squarrosus*, a member of a genus that has been found in feces of the snail *Monadenia hillebrandi mariposa*. Photo by Michael Lüth, with permission.

Grime and Blythe (1969) found bryophytes in the feces of four species of snails out of the six examined from Winnats Pass, Derbyshire, England, on 13 October. But then, tracheophyte foods are often less nutritious as the plants prepare for winter. Studies by Chatfield (1973), Williamson & Cameron (1976), and Richter (1976) indicate that at least juvenile snails might do best on a mixed diet. But for *Cepaea nemoralis* (Figure 60-Figure 61), it appears that even though mosses are part of their habitat, they are seldom part of the diet (Williamson & Cameron 1976).

In the tropical montane rainforest of Brazil, those small, flattened snails in the **Charopidae** (Figure 62) eat bryophytes (Maciel-Silva & dos Santos 2011). Both *Canalohypopterygium tamariscinum* (syn. = *Hypopterygium tamarisci*; Figure 63) and *Lopidium concinnum* (Figure 64) had evidence of leaf herbivory, mostly in the beginning of the rainy season (September to December). A species of snail in the **Charopidae** and a moth larva in the **Geometridae** were the culprits. Using an index of damage (ID) in 2007, 2008, Maciel-Silva and dos Santos found that *C. tamariscinum* had higher damage (68%, 35%) than *L. concinnum* (38%, 23%) in these two years (Figure 65). These rates were lower than those for

tracheophytes. They found no correlation with phenols, proteins, or the ratio between them (Figure 65).

An Avoidance of Gametophores?

Davidson and Longton (1985, 1987; Davidson 1988, 1989) reported that several species of generalist slugs consumed bryophytes. In some cases, the **protonema** (threadlike stage that develops from moss spore) is readily consumed (Grime 1979). In Great Britain, capsules and protonemata of several mosses [*Brachythecium rutabulum* (Figure 66), *Mnium hornum* (Figure 67-Figure 68), and *Funaria hygrometrica* (Figure 69)] were eaten preferentially to leafy gametophores by slug species in the genus *Arion* (Figure 70) (Davidson & Longton 1987; Davidson *et al.* 1990). Cambs (2012) found that the slug *Limax maculatus* (Figure 40) likewise would eat capsules, but the leafy parts seemed to serve only as an emergency food. It appears that some may even eat **calyptrae** (covering over capsule; Figure 71). **Ferulic acid**, present in shoots but absent in young capsules of *Mnium hornum*, is a phenolic compound that is only released after severe hydrolysis. Its antibiotic role as an antifungal agent (Sarma & Singh 2003) and in antiherbivory (Seigler 1983; Smith 2011) may contribute to this preference for capsules, as discussed below. Davidson and coworkers found that older capsules with spores were less preferred than the green ones (Figure 72; Davidson & Longton 1987; Davidson *et al.* 1990).

Figure 72. Relative damage by slugs (*Arion* spp.) of sporophyte stages of two species of bryophytes. n=300-500 at day 0. LCI = late calyptra stage; EOI = early operculum intact; LOI = late operculum intact; OF = operculum fallen; EF = empty and fresh. Redrawn from Davidson *et al.* 1990.

Davidson (1989) found that slugs consumed only trivial amounts of *Brachythecium rutabulum* shoots (Figure 66). *Mnium hornum* (Figure 80) was also ignored, but after 5-7 days of starvation *Arion rufus* (10-15 cm long; Figure 73) and *A. subfuscus* (5-7 cm long; Figure 74) ate significant quantities of shoots of this species. The garden slug *Arion hortensis* (Figure 75) still ignored the moss even after 7 days of starvation.

Figure 75. *Arion hortensis* s.s. at Bridge House, Swavesey, UK. Photo by Brian Eversham, with permission.

Given the choice of capsules or vegetative material, both *Arion rufus* (Figure 3, Figure 70, Figure 73) and *A. subfuscus* (Figure 76) preferred immature capsules (see Figure 77 with a slug on immature capsules of *Leucolepis acanthoneuron*) of all three mosses, with *Mnium hornum* (Figure 80) being top choice (Davidson 1989). Setae were generally ignored, but *A. subfuscus* did occasionally eat *M. hornum* and *Brachythecium rutabulum* (Figure 66) setae. All three slugs also ate protonemata in the laboratory, and for *B. rutabulum* and *Funaria hygrometrica* (Figure 52) the protonemata were eaten just as much by *A. rufus* and *A. subfuscus* as were immature capsules. In fact, dry weight consumption exceeded that of immature capsules. Young shoots were also eaten, but less readily.

Figure 76. *Arion subfuscus*, a slug that prefers immature capsules. Photo by Sanja 565658, through Creative Commons.

Figure 77. Slug browsing on immature capsule of the moss *Leucolepis acanthoneuron*. Photo from UBC website, with permission.

Davidson and Longton (1987) suggested that *Arion hortensis* (Figure 75) was restricted by the physical structure of the capsule to consuming developing spores from broken capsules in *Polytrichum commune* (Figure 78); no spores were eaten from unbroken capsules. When approaching *Mnium hornum* (Figure 80), the slugs would withdraw their tentacles, then retreat, suggesting some sort of chemical deterrent; they behaved similarly in the presence of extracts from the capsule. It is likely that hydroxycinnamic and phenolic acids in this species and in *Brachythecium rutabulum* (Figure 66) provided this chemical protection against herbivory (Davidson *et al.* 1989). Stems of both species were apparently protected by ferulic and possibly m- and p-coumaric acids bound in the cell walls of the shoots (Davidson *et al.* 1989), explaining the preference of the slugs for capsules. On the other hand, when moss extracts were placed on communion wafers, the slugs ate them more readily, suggesting that chemistry alone was not the likely deterrent (Anonymous 1987; Davidson *et al.* 1990). Rather, some physical feature of the mosses, perhaps the cell wall, deterred these slugs.

Figure 78. *Polytrichum commune* capsules showing the persistent hairy calyptra and waxy capsule that is only eaten by snails when the capsule is broken. Photo by Michael Lüth, with permission.

Presence of moss cells of *Brachythecium rutabulum* (Figure 79) and *Mnium hornum* (Figure 80-Figure 81) in the feces of previously starved *Arion* suggest that the leafy mosses are not digested well (Davidson *et al.* 1990). On the other hand, all three species of slugs named above readily consumed *Funaria hygrometrica* (0.4-6.5 mg wet weight per slug; Figure 69) in overnight feeding trials. The importance of mosses as food may rest with the organisms living on the mosses – fungi, bacteria, protozoa, rotifers, *etc.*, making indigestibility of the mosses inconsequential.

Figure 79. *Brachythecium rutabulum* cells as they might be seen in feces. Photo by Tom Thekathyl, with permission.

Mostly indirect evidence suggests that slugs and snails graze capsules of *Buxbaumia viridis* (Figure 84) (Gordon Rothero, Birds feeding on moss capsules, Bryonet-I, 10 April 2003; Figure 84). Michael Lüth (Bryonet 23 September 2017) observed and photographed a slug grazing on the capsule of *Buxbaumia viridis* (Figure 83). Dave Kofranek reports tasting it – to him it tastes like cucumbers (Bryonet 24 September 2017). Infante Sánchez and Heras Pérez (2015) explored the herbivory on capsules

of *Buxbaumia viridis* (Figure 84). They found three types of damage on the sporophytes. In one type the seta and lower part of the capsule remain. For this type, they actually observed slugs feeding on the capsules; the same kind of slug was also feeding on young green capsules of *Herzogiella seligeri* (Figure 85). In a second type, the entire capsule is gone, but the seta remains. This could have been slugs as well, but they were unable to observe them and considered that ants or birds might also feed on them. The capsules are grazed in spring before they mature, thus likely being unable to accomplish a successful dispersal. The third type was destruction by a fungus, causing abortion of the capsule development.

Figure 81. *Mnium hornum* leaf tip cells, what one might see in feces. Photo by Bob Klips, with permission.

It is perhaps not surprising that snails eat the capsules of *Splachnum* (Figure 82). This genus has odors that attract flies, so they may serve as attractants to gastropods as well. However, no studies have attempted to test this hypothesis with snails.

Guy Brassard reported to me that Stéphane Leclerc has taken a picture of a slug in Quebec, Canada, eating a *Buxbaumia aphylla* (Figure 86-Figure 88) capsule!

Figure 86. *Buxbaumia aphylla* that are immature and have not been eaten. Photo by Štěpán Koval, with permission.

Stark (1860) relayed a story of the ill fate of collected specimens of *Buxbaumia aphylla* (bug-on-a-stick moss; Figure 87) on their journey from Scotland to England. A slug had inadvertently been included in the package and it managed to destroy their prized specimens. On the other hand, *B. aphylla* can fool you. After repeated observations with my graduate student, Chang-Liang Liao, we have discovered in the field that what appeared to me to be grazing on capsules of *Buxbaumia aphylla* is really only the splitting of the capsule top as it dries (Figure 87), and that this occurs on nearly every capsule.

Figure 87. *Buxbaumia aphylla* showing exposed green spores in the capsule that has split open. Photo by Janice Glime.

Figure 88. *Buxbaumia aphylla* that may have been damaged by a herbivore. Photo by Janice Glime.

Slugs also eat hornworts (*Anthocerotophyta*; Figure 89). Bisang (1996) reported that they especially eat the green sporophytes.

Figure 89. *Phaeoceros carolinianus*, a hornwort with mostly green sporophytes, a food source for slugs. Photo by Michael Lüth, with permission.

Digestibility

So what did the slugs derive from the consumed mosses? When they consume preferred foods such as lettuce leaf or carrot root, the resulting feces contain macerated, partially pigmented tissue (Davidson 1989). When they consumed bryophytes, on the other hand, large pieces of leaf, whole leaves, and even stem pieces remained intact. Most cells still contained green chloroplasts. Evidently the moss did little more than fill the gut. Even the preferred capsules were poorly digested, with capsule wall fragments, opercula, and peristome teeth remaining. Mature spores seemed unharmed, but immature spores seemed to have experienced some digestion, appearing broken, colorless, and shrivelled. Likewise, the protonemata seemed to be digestible, resembling the lettuce and carrots in being macerated and colorless or brown.

Caution must be used in conducting laboratory experiments with food choices. Jennings and Barkham (1975) found that bryophytes all gave low palatability scores when six species of slugs, including the three in the Davidson (1989) study, had a choice of foods. The wider range of choices in the field may permit them to avoid the less palatable bryophytes.

Role in Bryophyte Competition with Lichens

Rosso and McCune (2003) found that molluscs on shrubs in the Pacific Northwest, USA, exhibited significant herbivore activity on the lichens. Bryophytes, on the other hand, had little change in cover between stems in exclusions and those available for herbivory. It appears that the mollusc herbivory on lichens (Boch *et al.* 2011) may benefit the bryophytes by contributing to the successful competition of the bryophytes over the lichens in the understory of these forests.

Palatable Gametophytes

Des Callaghan (Bryonet 10 June 2011) reports slugs feasting on the gametophytes of *Hookeria lucens* (Figure 90) near a stream. In only six days they completely removed all the plants by dining on them, leaving behind only a stump and a slime trail (Figure 91). This was a research station, so Callaghan needed to find a way to discourage the slugs. Suggestions from Bryonetters included sprinkling ground glass around the study area (Michael Richardson, Bryonet 10 June 2011); putting out cups of beer to attract and drown the slugs or putting curry powder or other hot substance around the mosses (Janice Glime, Bryonet 10 June 2011); copper rings that are effective in gardens and could be made with a coil of wire (David Bell, Bryonet 10 June 2011).

Figure 90. *Hookeria lucens* in healthy condition. Photo by Des Callaghan, with permission.

Figure 91. Temperature/humidity data logger with *Hookeria lucens* eaten by slugs. Photo by Des Callaghan, with permission.

Annie Martin (Bryonet 11 June 2011) is a professional gardener and described her experience in trying to eliminate slugs. She suggested putting salt on the head (if put on the tail the slug continues to live and eat). Her experience with beer is that it just keeps on attracting snails night after night, even though many of them drown, so it is an ineffective waste of money. Brown mulch seems to provide a favorable habitat, so she eliminated it, a technique that worked, but isn't relevant for discouraging snails on mossy rocks.

Aquatic Grazing

Grazing by gastropods (slugs and snails) can be so severe as to define distribution of a bryophyte species. Lohammar (1954) found that in northern Europe *Fissidens fontanus* (Figure 92) was absent in lakes where *Fontinalis antipyretica* (Figure 93) was also absent. Gerson (1982) suggested that scarcity of *Fissidens* in some places is due to snail grazing. In the presence of *Fontinalis*, this smaller moss lives among the *Fontinalis* fronds where it is presumably protected from snail grazing by the inedible forest of *Fontinalis* surrounding it and the density of the *Fontinalis* stems.

Figure 92. *Fissidens fontanus*, a moss that seems to be vulnerable to snail grazing except where it is protected by *Fontinalis* species. Photo by Michael Lüth, modified by Janice Glime, with permission.

Figure 93. *Fontinalis antipyretica*, a moss that apparently protects the smaller *Fissidens* from grazing by snails. Photo by Bernd Haynold, through Wikimedia Commons.

It may be that in the aquatic habitat the snail effect on some bryophytes is much greater than in the terrestrial habitat. But it is not necessarily all bad. Steinman (1994) opined that snail grazing could account for the apparent unresponsiveness of epiphytes following phosphorus enrichment in a woodland stream in Tennessee, USA, where bryophytes were prominent. And some bryophytes seem prepared to fight back. The thallose liverwort *Ricciocarpus natans* (Figure 94) exhibits molluscicidal properties that are active against the snail carrier of schistosomiasis (Wurzel *et al.* 1990).

Figure 94. *Ricciocarpus natans*, a species with molluscicidal properties, floating on the water surface. Photo by Janice Glime.

Bryophyte Antifeedants

Based on the foregoing discussion, it appears that at least some bryophytes are able to discourage browsing by slugs (Frahm & Kirchhoff 2002). Alcohol extracts of the moss *Neckera crispa* (Figure 95) and leafy liverwort *Porella obtusata* (Figure 96) have antifeedant activity against the slug *Arion lusitanicus* (Figure 97). Extracts of 0.5% dry weight of the moss had low activity, whereas

those from the liverwort exhibited moderate activity at only 0.05%. At 0.25% the antifeedant activity of *Porella obtusata* was complete. It is likely that this activity is not specific for slugs and may discourage insects, bacteria, and fungi as well.

Figure 95. *Neckera crispa*, a moss that has antifeedant activity against the slug *Arion lusitanicus*. Photo by Michael Lüth, with permission.

Figure 96. *Porella obtusata*. Photo by Jan-Peter Frahm, with permission.

Figure 97. *Arion lusitanicus*, a slug that traverses mosses, but finds *Neckera crispa* and *Porella obtusata* unpalatable. Photo by Mogens Engelund, through Wikipedia Commons.

On the other hand, *Arion lusitanicus* (Figure 97), also known as the murder slug, easily eats the thallose liverwort

Marchantia polymorpha (Figure 98) (Nils Cronberg, Bryonet 7 April 2016). Cronberg has observed this species feeding on *Marchantia* and has noticed that as the slug had invaded the wetland, *Marchantia polymorpha* had disappeared in parallel with the invasion.

Figure 98. *Marchantia polymorpha* showing a nibbled thallus on the upper left, about 1/3 down and 1/3 over from the corner. It also has a tear that is not likely the result of herbivory. Photo by James K. Lindsey, with permission.

Dispersal Agents

It appears that slugs are not all bad in the bryophyte world and may instead be a necessary vector for some propaguliferous taxa (Stolzenburg 1995). Slugs and snails (Figure 99) leave a trail of mucous as they go, and as you well know if you have handled these molluscs, this secretion can be sticky. It is therefore no surprise that these animals have dispersal abilities.

Figure 99. Snails such as this one traversing epiphytic mosses in Japan may be effective dispersal agents. Photo by Janice Glime.

Slugs are able to disperse the brood branches of *Dicranum flagellare* (Figure 100) (Kimmerer & Young 1995). These tiny branches become entrapped in the secretions and are deposited in the ensuing slime trail. Kimmerer and Young found that these can be transported at least 23 cm from the colony, although the mean distance in their study was only 3.7 cm.

Figure 100. *Dicranum flagellare* showing the tight flagellate branches that can be dispersed by slugs. Photo by Janice Glime.

And it appears that the secretion increases the ability of the propagule to adhere to its substrate without affecting the germination rate. In fact, experiments by Davidson (1989) suggest that passage of spores through the slug's digestive system may enhance germination success. All plates containing mature spores from slug (*Arion* spp.; Figure 97) fecal pellets produced shoots, whereas only 80% of the plates with uneaten mature *Mnium hornum* (Figure 67-Figure 68) spores and 70% of those with uneaten *Brachythecium rutabulum* (Figure 101) spores produced shoots.

Figure 101. *Brachythecium rutabulum*, for which the spores germinate better if they have passed through the gut of a slug (*Arion*). Photo by Michael Lüth, with permission.

For those snails and slugs that nibble on spores, one might assume that not all spores end up inside them. Unless they have perfect aim with that huge foot, their somewhat clumsy feeding method is undoubtedly going to render some spores as passengers in the mucous on the foot. Sooner or later, these will be deposited in a new location.

The ability of snails and slugs to glide across bryophytes and to climb setae to capsules suggests that these animals may be important as dispersal agents. But how widespread are herbivory and dispersal among bryophytes that temporarily host these slow-moving animals?

Although we know that bryophyte spores reach the mollusc gut, experiments are needed to see if spores expelled in feces are able to colonize successfully. Davidson (1989) found that *Brachythecium rutabulum* (Figure 101) and *Mnium hornum* (Figure 80) spores eaten by *Arion* species actually germinated better than controls.

Manfred Türke sent me images of mosses in the feces of the slug *Arion vulgaris* (Figure 102). I was amazed at the size of the fragment of moss in the feces (Figure 103-Figure 104). This is a potential means for dispersal, but the various species of bryophytes must be tested for viability. Digestive enzymes and extreme pH could damage the moss cells. On the other hand, the pathogenic fungi *Phytophthora* spp. (Figure 105) survive as both oospores and filaments and are viable after passing through the digestive system of this slug species (Telfer *et al.* 2015). This was demonstrated by culturing the feces on agar.

Figure 105. *Phytophthora parasitica* zoospores, a genus that survives passage through the gut of *Arion vulgaris*. Photo by Tashkospip, through Creative Commons.

To provide additional information on the potential dispersal ability of slug feces, Boch *et al.* (2013) fed capsules of four bryophyte species [*Bryum pallescens* (Figure 106), *Funaria hygrometrica* (Figure 69), *Leptobryum pyriforme* (Figure 107), *Pellia endiviifolia* (Figure 108)] to three slug species [*Arion vulgaris* (Figure 102), *A. rufus*; Figure 3, Figure 70, Figure 73), *Limax cinereoniger* (Figure 109)]. Among the 117 bryophyte samples, 51.3 % of the spore cultures had germination following gut passage.

Figure 106. *Bryum pallescens* with capsules. Spores of this species pass through the guts of several slugs and retain their viability. Photo by David T. Holyoak, with permission.

Figure 107. *Leptobryum pyriforme* with capsules. Spores are able to pass through the guts of at least some slugs and remain viable. Photo by Michael Lüth, with permission.

Figure 109. *Limax cinereoniger* on a mat of moss. Photo by Michal Mañas through Creative Commons.

Boch *et al.* (2013) found that germination rates did not differ among the bryophyte species, but the species of slug

had strong effects. Among these three slugs, *Limax cinereoniger* (Figure 109) ate the lowest percentage of the bryophytes provided, and even correcting for that, they had the lowest percentage of feces samples (12.9%) producing protonemata. On the other hand, 76% of those of *Arion vulgaris* (Figure 102) and 74% of those of *Arion rufus* (Figure 3, Figure 70, Figure 73) produced protonemata (Figure 110).

Figure 110. Comparison of spore germination from bryophytes cultured from the feces of three species of slugs. White bars = *Arion rufus*; light grey bar = *Arion vulgaris*, dark grey bar = *Limax cinereoniger*. Redrawn from Boch *et al.* (2013).

Türke *et al.* (2013) provide evidence that slugs do indeed disperse fragments of mosses by consuming spores and fragments. For tracheophyte seeds, they suggested an average of 5 m dispersal distance, exceeding the typical less than 1 m in dispersal by ants. In some slugs, the seeds are destroyed in the digestive tract, but in other cases they remain viable propagules.

Boch *et al.* (2015) discussed several ways that slugs benefit bryophytes. Their herbivory on tracheophytes (lignified vascular plants) permits more light to reach the low-growing bryophytes. But they also crawl across bryophytes and some eat the bryophytes. This puts them in the position to disperse spores, fragments, and other propagules.

Nevertheless, documentation of the effect of the slugs on the bryophyte community is meager. Boch and coworkers (2015) designed a factorial common garden experiment to determine some of the effects of slugs on the bryophyte vegetation. They collected sporophytes of 11 native and 1 invasive bryophyte species [*Barbula convoluta* (Figure 111), *Brachythecium rutabulum* (Figure 101), *Brachythecium velutinum* (Figure 112), *Bryum* sp. (Figure 106), *Campylopus introflexus* (Figure 113), *Ceratodon purpureus* (Figure 114), *Funaria hygrometrica* (Figure 69), *Leptobryum pyriforme* (Figure 115), *Marchantia polymorpha* (Figure 98), *Phascum cuspidatum* (Figure 116), *Plagiomnium affine* agg. (Figure 117), *Pohlia* sp. (Figure 118)], representing 8 families. They used three enclosure treatments: slugs previously fed with bryophyte sporophytes, slugs that had not been fed sporophytes, no slugs. The researchers demonstrated that bryophyte cover increased in 21 days from 1.4% to 3.9% in plots where slugs had been fed, an increase that was 2.8 times higher than in the other two treatments. After eight months, the species richness was 2.6X higher (5.8 vs 2.2) than in the other treatments. The researchers concluded that the slugs contributed to

increasing bryophyte cover and diversity by reducing the dominance of tracheophytes. The early increase in cover in the enclosures with slugs fed sporophytes suggests that they also accomplish dispersal.

When the question of bryophyte dispersal by slugs arose on Bryonet, Scott Redhead (Bryonet 26 August 2016) suggested that this might even occur in the **Splachnaceae**. To that suggestion, Michael Lüth posted an image of *Tetraplodon mnioides* (Figure 119) showing one uneaten capsule and one that had been removed by an animal, possibly a slug, documenting his own observations of capsule herbivory. Christian Schröck (Bryonet 26 August 2016) likewise observed grazed capsules in *Voitia* and *Tetraplodon*. However, we need observations of feeding to determine the identity of the herbivores.

Figure 119. *Tetraplodon mnioides* with one capsule eaten by an unidentified herbivore. Photo by Michael Lüth, with permission.

Lüth (2010) suggested that the pre-dispersal stage of the capsules on **Splachnaceae** are likely to attract herbivores that differ from the flies that spread the spores. At this earlier stage, the capsules have a different odor from that during the dispersal stage. This odor lasts for only a short time and is therefore often missed by field biologists. On Bryonet (26 August 2016), Lüth explained that *Splachnum ampullaceum* smells like *Vaccinium oxycoccos* and occurs in the same habitats, often blending with these cranberries. And *Tetraplodon mnioides* (Figure 119) smells like *Vaccinium myrtillus*. Although not all evolutionary successes are linked to adaptation, it makes one wonder if these early odors are adaptive to facilitate a longer dispersal and subsequent deposition in dung, although one might assume that would require a larger mammal, not a slug.

Figure 120. *Splachnum ampullaceum* sporophytes with a cranberry of similar color to the right. Photo by Michael Lüth, with permission.

I think most people would consider dispersal by snails and slugs to be distance-limited. But perhaps, with the help of birds, this is not so limited. Kawakami *et al.* (2003) demonstrated that the Japanese White-eyes (*Zosterops japonicus*; Figure 121) and the Brown-eared Bulbuls (*Hypsipetes amaurotis*; Figure 122) are birds that eat snails. In fact, five species of snails are able to remain in their shells and appear in the feces. If these snails had eaten moss spores, those spores might be transported a considerable distance, yet be viable in the gut of the snail. It is probably a rare event. Lots of questions remain in this relationship, but the scenario brings up interesting hypotheses.

Malone (1965) discovered another possibility, exemplified by the Killdeer (*Charadrius vociferus*; Figure 123). Malone found two species of freshwater snails attached to the feet of the Killdeer. These were able to remain attached and viable long enough to effect dispersal. The snail *Galba obrussa* was able to survive 14 hours on Killdeer feet out of water. But the likelihood that an aquatic snail is carrying bryophyte spores is small due the rarity of capsules. Nevertheless, if a wetland snail has similar behavior, it has a better chance of having consumed spores from wetland mosses.

Figure 123. *Charadrius vociferus*, a species that disperses snails on its feet. Photo by Andrew C, through Creative Commons.

One additional factor determining the suitability of a slug for spore (or fragment) dispersal is the habitat where feces are likely to be deposited. Researchers have made the first steps in understanding the role of slugs in bryophyte dispersal, but much remains to be explored.

Bryophytes as Home

Because of their small movement space, bryophytes can serve as safe sites for smaller snails. Birds can be significant consumers of snails, particularly during migration (Shachak & Steinberger 1980), and bryophytes can make the snails less conspicuous, if not hiding them completely. In terrestrial habitats, arachnids such as spiders and daddy-long-legs (**Opiliones**) are also predators on snails (Nyffeler & Symondson 2001). While some spiders can probably navigate the spaces within the moss mat, it seems unlikely that most mature daddy-long-legs could manage without getting caught. In addition to the arachnids, carabid beetles prey on terrestrial gastropods (Symondson 2004). Some of these beetles use a pump mechanism to extract the gastropod remains from its shell.

Even snails are predators on slugs. The shell of the snail makes navigation among the bryophyte branches more difficult, potentially making the bryophytes a refuge for the smaller or vulnerable slugs.

In a study of bryophyte inhabitants in the Bükk Mountains of Hungary, Varga (2008) found the tiny gastropods *Punctum pygmaeum* (Figure 124) and *Pupilla muscorum* (Figure 154) among the terrestrial mosses *Plagiobryum zieri* (Figure 125), *Hypnum cupressiforme* (Figure 126), and *Tortella tortuosa* (Figure 127). Standen (1898) found *Punctum pygmaeum* from moss shakings. From my own observations, it appears that snails and slugs are common on and even in bryophyte clumps, but finding documentation on the use of bryophytes by these small species evades even the aggressive Google search.

The European snails *Azeca goodalli* (Figure 128), *Euconulus fulvus* (Figure 129), *Columella edentula* (Figure 130), *Discus* (subgen *Goniodiscus*) *rotundatus* (Figure 131), *Lauria cylindracea* (Figure 132-Figure 133), *Vertigo pusilla* (Figure 134), and *Vitrina pellucida* (Figure

135) live among mosses, among other substrata (Cloudsley-Thompson & Sankey 1961). *Carychium tridentatum* (Figure 136), *Discus rotundatus*, *Cepaea hortensis* (Figure 137), *Oxychilus navarricus* (formerly *O. helveticus*; Figure 138), and several rare species of *Aegopinella* (formerly in *Retinella*) [*A. pura* (Figure 139), *A. nitidula* (Figure 140-Figure 141)] are known under mossy brick rubble (Verdcourt 1954). *Clausilia bidentata* (10-11 mm; Figure 142) is also rare, but can be found under moss. Standen (1898) reported on *Clausilia rugosa* (Figure 143) swarming on mossy walls in the UK and feeding on mosses and lichens. Standen (1898) found the snail *Acme lineata* on a patch of the thallose liverwort *Marchantia* sp. (Figure 98).

Eucobresia diaphana (Figure 144) lives in humid, cool places on mountains and in forests of Europe, where it is likely to encounter mosses, as seen in Figure 144 (Welter Schultes 2012b), but other than this picture, I can't verify what use it might make of them.

Figure 144. *Eucobresia diaphana* on a species of the moss *Tortula*. Photo by Stefan Haller, with permission.

On the South Pacific Kermadec Islands, Iredale (1913) remarked that in dry weather one must look for the snails among the mosses, where they hide from the dryness. He commented that they are quite variable in choice of trees, with one bole producing a dozen or more while the next half dozen adjoining trees disclose none.

Not surprisingly, new species still lurk amid the bryophytes. Efford (1998) found a new species of the carnivorous New Zealand endemic genus *Rhytida* (Figure 145), and reported observations by others of *R. patula* and *R. meesoni perampla* crawling on mosses and tree trunks at night. These and other New Zealand snails often fall prey to introduced predators. *Wainuia urnula* (Figure 146), another night-active snail on mosses, tree trunks, and rocks, was readily eaten by possums, rats, and hedgehogs in captivity. Efford (2000) found that 82% of the 315 *W. urnula* snails examined had an unusual food in the feces and gut – terrestrial amphipods. Its relative, *W. edwardi* (Figure 147), did not consume amphipods, and no other gastropod is known to consume them. The adaptation for consuming amphipods appeared to be largely behavioral, although there were some differences in the teeth.

Epiphytic

Wiesenborn (2003) observed snails in the Riverside Mountains of California and found that the active snails preferred epiphytic mosses (Figure 148) and lichens compared to plant detritus and four sizes of rocks as habitat. They suggested that the epiphytes could provide these snails with food or moisture. Tree bark soon becomes a desert after the rain dries up, but mosses remain moist much longer, permitting the snails to be active longer and to search there for food where other small invertebrates likewise take refuge from desiccation.

Figure 148. *Monachoides incarnatus* on bark where it often encounters bryophytes. Photo by Stefan Haller, with permission.

Tropical islands, especially Hawaii, are particularly vulnerable to invasive species. With all the visitor traffic and import/export business, hitchhikers easily reach the islands. Snails are among these, and may be one of the causes of the apparent extinction of the bird called Po'ouli (*Melamprosops phaeosoma*; Figure 149) (Mountainspring *et al.* 1990). This native Hawaiian bird is especially adapted to feeding on land snails and insects on branches and under mosses, lichens, and bark. Its toes are large and are used for prying up moss and bark to acquire tree snails. The bill is stout, withstanding the force needed for manipulating the snails. Its demise is due largely to increased activity and habitat modification by feral pigs, avian disease, and possible gene pool impoverishment due to low numbers. But it also suffers competition for food by the introduced garlic snail (*Oxychilus alliarius*; Figure 150), a native of northwestern Europe (Welter Schultes 2012a) that emits a garlic odor when it is disturbed. This species is likewise a moss-dweller of mountain slope forests. It feeds on living and dead plant tissue, but it also consumes small snails and the eggs of other snails and slugs (Oxychilus 2011).

The slug *Prophysaon vanattae* (scarletback tailedropper; Figure 151) is one of those slugs that seems to find a safe site under mosses on trees on Vancouver Island, Canada (Kristiina Ovaska, pers. comm. 30 June 2009). But it also hangs on epiphytic moss mats in the moist deciduous forest there and may even lay eggs there (Figure 152).

Calcareous Areas

Because of the need for calcium to make the shell, many snails are dependent on limestone habitats to obtain this important resource. Hence, this is a good place to look for snails on mosses growing there.

Pupilla muscorum (Figure 154) is named for its occurrence among mosses in Great Britain, although it also occurs under stones and in leaf litter (Ehrmann 1956). This tiny (3-4 mm high shell) moss snail often prefers calciferous ground, but others describe it as indifferent to limestone content (Nordsieck 2012a). These snails are **ovoviviparous**. The eggs can survive over winter inside the female's body and are laid in the favorable conditions of spring. At that point, it is not the eggs that must survive because the juveniles usually hatch during oviposition.

Pupilla triplicata (Figure 155) is likewise a moss dweller in Hungary and elsewhere (Deli *et al.* 2002).

Figure 154. *Pupilla muscorum*. Photo by Malcolm Storey, through Creative Commons.

Figure 155. *Pupilla triplicata*, a European moss dweller. Photo by O. Gargominy, through Creative Commons.

Another tiny conical snail (2-3 mm) of calcareous areas is *Acicula fusca* (Figure 156) in moss on chalk cliffs at Ballycastle, and on chalk underlying basalt at Black Head, Antrim, UK (Anderson 1996). And *Pomatias elegans* (Figure 157) occurs on mosses in limestone areas in the Burren, County Clare, UK (Platts *et al.* 2003).

Figure 156. *Acicula fusca*, a tiny snail that lives among mosses on chalk cliffs. Photo © Roy Anderson <habitas.org.uk>, with permission.

Figure 159. *Trochulus villosus* on mosses in Germany. Photo by Stefan Haller, with permission.

Figure 157. *Pomatias elegans* at Cheddar, Somerset, UK. Photo by Roger S. Key, with permission.

Trochulus (formerly *Trichia*) *plebeia* (Figure 158) occurs in wet mossy areas by springs in limestone areas (Gilbert *et al.* 2005). *Trochulus villosus* (Figure 159) lives in the German Alps and requires high moisture (Welter Schultes 2010), making bryophytes useful for maintaining that moisture. This strange genus of snails has hairs on its shell that help to hold it against wet surfaces (Gilbert *et al.* 2005). I don't have any indication that these hairs offer any particular help for living among bryophytes, but if they have any tactile properties, they could help keep it from getting stuck between branches by warning that the passage was getting too narrow.

Figure 158. *Trochulus plebeia*, a hairy snail, at Sugley Wood, UK. Photo by Brian Eversham, with permission.

The European family **Clausiliidae**, known as door snails, derive their name from the "sliding door" that covers the opening of the shell (Wikipedia 2012a). This calcareous door is known as a **clausilium**, hence the family name. It permits the snail to retreat into its shell and seal it off against predators. *Cochlodina laminata* (Figure 160), the plaited door snail, lives "between mosses" as well as leaf litter, but may also be found climbing trees in deciduous forests and montane pine forests (Welter Schultes 2012b). *Clausilia dubia* (Figure 161) is a calciphilic inhabitant of humid, shady rocks and old walls, but also lives on tree trunks "full of moss." Michael Proctor (pers. comm. 23 April 2016) informed me that this species is very common on Carboniferous limestone in Yorkshire Dales, UK, in the bryophyte and lichen habitats. *Macrogastra ventricosa* (Figure 162), the ventricose door snail, lives in places with plentiful mosses on the forest floor or on tree trunks, mostly in the mountains (Welter Schultes 2012b). *Macrogastra attenuata* (Figure 163) lives between moss-covered rocks as well as on stones, rocks, and leaf litter in montane forests.

Vertigo meramecensis (Meramac River snail), unlike a number of other members of the genus, is a strict calciphile (Nekola & Coles 2010). It is a species of special concern that lives in Iowa and Missouri, USA, and dwells in decomposed leaf litter of moss-covered ledges and shaded carbonate cliffs, among other places.

Bogs and Mires

True bogs are acid, poor fens are acid, intermediate fens have intermediate pH levels, and rich fens are basic. For a snail, that pH range is an important consideration in choice of habitat because of the need for calcium in forming a shell. Because of this relationship, most malacologists have considered *Sphagnum* (Figure 164) peatlands, heathlands, and pine forests as unsuitable habitats for snails and consequently have poor snail biodiversity (Karlín 1961; Kerney & Cameron 1979; Horsák & Hájek 2003).

In fact, Nekola (2010) found that highly and even moderately acidic sites had significantly ($P < 0.000000005$) lower richness and abundance than did neutral and calcareous habitats. Nevertheless, the typical acid site supported 5-10 species.

But some snails actually thrive in the low pH of bogs and other acid habitats. One such snail is *Vertigo malleata* (Figure 165), an extreme **calcifuge**. The degree to which snails have been overlooked in these habitats is exemplified by finding this new species in 60 sites out of 100 acid sites investigated from Maine to Florida, USA (Coles & Nekola 2007). In the bogs it was found primarily in leaf litter on top of the *Sphagnum* (Figure 164). Nekola (Jeff Nekola, pers. comm. 16 April 2012) informed me that *Vertigo malleata* was virtually absent in the *Sphagnum* itself, occurring only where there was leaf litter on top of the *Sphagnum*. It would be interesting to watch its behavior if it is placed amid the *Sphagnum*. Is it avoiding *Sphagnum*, or seeking food only found among the litter? In more northern locations, *V. cristata* (Figure 166) or *V. perryi* may be present in bogs, but again, they only occur in the leaf litter, not among the *Sphagnum* (Jeff Nekola, pers. comm. 16 April 2012). *Vertigo cristata* is likewise common in pine and spruce forests, heaths, and *Sphagnum* peatlands (Nekola & Coles 2010).

Figure 165. *Vertigo malleata* from Lewis Ocean Bay, South Carolina, USA. This snail lives in *Sphagnum* peatlands, but avoids the *Sphagnum*, living in patches of leaf litter on top of it. Photo by Jeff Nekola, with permission.

Figure 166. *Vertigo cristata*, a species that lives on leaf litter, but not *Sphagnum*, in bogs. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

It appears that other snails that live in bogs and poor fens likewise typically avoid the *Sphagnum* (Figure 164). Like *Vertigo malleata* (Figure 165), *Gastropoda tappaniana* occurs in decomposing leaf litter of fens, pocosins, and *Sphagnum* bogs (Nekola & Coles 2010). Even *Vertigo perryi*, a resident on the sides of *Sphagnum* hummocks, occurs on sedge leaf litter there. And *Vertigo ventricosa* (Figure 167) occurs in well-decomposed graminoid and broadleaf plant litter in the *Sphagnum* peatlands and poor fens.

Slugs have much less need for that important element – calcium (Ca). In boggy habitats, these gastropods would seem to have little choice but to travel across bryophytes (Stanisic 1996). *Deroceras laeve* (Figure 168) is among the slugs that traverse the complicated topography of bogs and mires. But their specific relationships to the bryophytes seems unknown. On the other hand, another member of the genus, *Deroceras reticulatum* (Figure 169), is a ubiquitous slug, but Anderson (2010) points out that raised and blanket peat or exposed ground above 300 m are the only habitats where it is not likely to be found. Hence, it appears that physiological differences are important in separating these slugs.

Figure 167. *Vertigo ventricosa*, a species of litter in peatlands. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Aquatic

In streams, it is likely that snails find mosses as a safe site from the current. Habdija *et al.* (2004) rarely found any gastropods on bryophytes at velocities of greater than

70 cm s⁻¹, whereas oligochaetes became more abundant at higher velocities. Flow rates are much slower within the moss mats, thus providing a haven for feeding where the current is unlikely to dislodge the snails and slugs. This also provides them protection from predators such as fish (mostly), ducks, shore birds, and amphibians (Pennak 1953).

Frost (1942) found a strong difference in gastropod inhabitants among bryophytes between an acid and an alkaline stream in her River Liffey survey in Ireland. In the limestone stream, she found 17 snails among the bryophytes, but she found none in the acid stream. Moss inhabitants in the limestone stream included *Ancylus fluviatilis* (Figure 170) and a species of *Planorbis* (Figure 171). She pointed out that these molluscs were only occasionally found among the mosses.

Figure 170. *Ancylus fluviatilis* showing its close adherence to the substrate. Photo by Mauro Mariani, through Wikimedia Commons.

Figure 171. *Planorbis corneus*. Photo © Roy Anderson <habitas.org.uk>, with permission.

Invasive species such as the carnivorous *Euglandina rosea* (Figure 172), a native of tropical North America, can have severe effects on native snail species elsewhere (Kinzie 1992). In Hawaii, this species has endangered the aquatic **endemic** (Hawaii only) lymnaeid snails due to its seek and capture behavior. The few surviving individuals are primarily restricted to streamside seeps or damp mosses and liverworts covering rocks near waterfalls.

Figure 172. *Euglandina rosea*, an invasive carnivore. Photo through Wikimedia Commons.

Plant Protectors

Not all slugs and snails seem to share a love of bryophyte habitats. As already noted, some seem to avoid them. Heinjo During has shared with me a story that unravelled in the Netherlands, published by Bart van Tooren (1990). To quote van Tooren, an increasing number of *Linum* (flax) seedlings correlates with an increasing number of bryophytes and other plants. Presumably, the slugs that were eating the seedlings would not traverse the bryophytes to get to these vulnerable young plants. They experimented by comparing plots with >70% cover of bryophytes with those having <20% cover. Their results were complicated by superimposing treatments of added water and/or NPK nutrients. In the control plots (no additions), the survival of *Linum* (flax) seedlings was greatest in plots with low bryophyte cover. However, in all three treatments at Vrakelberg the survival was greatest in plots with >70% bryophyte cover, whereas at Laamhel the addition of water plus nutrients was the only treatment that resulted in a large shift to greater survival with high bryophyte cover.

Although van Tooren (1990) was unable to demonstrate significant effects of bryophytes in his 1990 study, he and his coworkers did find them on the same slope in the 1981 study (Keizer *et al.* 1985). Bryophytes under the growing conditions of that year significantly reduced mortality of the tracheophytes *Linum catharticum* and *Carlina vulgaris*. Apparently, bryophytes may serve as deterrents to slugs in some years when weather conditions might otherwise encourage herbivory, but provide little support for them in years when nutrients and/or water availability are different. Such interactions between species that change with the weather require further investigation.

Getting and Staying Connected

Snails require calcium for their shells (Hotopp 2002). Hence, acidic bogs and poor fens with acidic *Sphagnum* species are inadequate habitats for them (Peterka *et al.* 2021). Those that are able to find enough calcium to

survive there are further endangered by birds that are unable to find enough calcium for their eggshells, forcing those that are able to do so to seek out snails for food so they can fortify their calcium intake (Mänd *et al.* 2000).

It is therefore not surprising that snails are scarce in acidic bogs and are negatively related to the *Sphagnum* (Figure 173) species (Horsák & Hájek 2003; Peterka *et al.* 2021). But when Peterka *et al.* (2021) examined the relationship of snails to age of rich fens, they found no correlation, whereas there was a correlation with tracheophytes. Nevertheless, fen age had a significant effect of snail diversity, and particularly on two dominant snails. These two snails [*Euconulus alderi* (Figure 174), *Vertigo geyeri* (Figure 175)] displayed significant ($P < 0.05$) non-random affinity to older fens than would be expected by chance. Peterka and coworkers suggested that the lack of correlation of bryophytes with fen age was due to the ability of their spores to disperse (Frahm 2012; Sundberg 2013) and the ability to establish more quickly through fragments (Mälson and Rydin 2007; Wilkinson *et al.* 2017) than the seeds of flowering plants and conifers.

Figure 175. *Vertigo geyeri* on moss, a snail species for which abundance is significantly affected by rich fen age. Photo by Roy Anderson, through Creative Commons.

Mussels (Bivalve Molluscs)

Mussels are not common bryophyte inhabitants, but can occasionally occur there in aquatic environs. Frost (1942) found *Sphaerium corneum* (Figure 176) and four species of *Pisidium* (Figure 177) among the mosses in the limestone stream in her River Liffey, UK, survey, but their typical niches were elsewhere in the stream.

Some bivalve molluscs and other organisms can actually turn the relationship around and provide a home for the bryophytes. Yes, some of these animals actually have mosses growing on them. Neumann and Vidrine (1978) found *Fissidens fontanus* (Figure 92) and *Leptodictyum riparium* (Figure 178) growing on freshwater mussel shells.

Figure 176. *Sphaerium corneum* on an aquatic plant. Photo © Roy Anderson <habitas.org.uk>, with permission.

Figure 177. *Pisidium amnicum*. Photo © Roy Anderson <habitas.org.uk>, with permission.

Figure 178. *Leptodictyum riparium*, a moss known to grow on freshwater mussels. Photo by Michael Lüth, with permission.

ECHINODERMATA

I refuse to create a chapter for this marine phylum, but one observation is interesting enough to note here. Claudio Delgadillo-Moya (pers. comm. 30 March 2016) reported to me that a student who is working on sea urchins has found moss tissue in the gut of one and leafy liverwort fragments in another! There is no bryophyte known to be marine, but some do tolerate sea spray and live near the water. Most likely one of these, no, two of these, fell into the water or washed in from a stream or river. Resourceful urchin!

Summary

Snails and slugs (gastropods) have often been observed on bryophytes. They are adapted to land with a calcified slime **epiphragm** to cover the shell opening and **respiratory pore** in the body. A **radula** of many teeth permits them to scrape their food. Reproduction is mostly by **simultaneous hermaphroditism**. This may be facilitated by a **love dart** that facilitates movement of sperm cells to the sperm pouch by injecting hormones. Larvae develop within the egg in most so that the gastropods are typically **oviparous**. A few are known to deposit eggs in mosses.

The white desert snail, *Eremarionta immaculata*, is common on bryophytes and seems to prefer them as a habitat. The copse snail, *Arianta arbustorum* is a

night-active inhabitant. More quantitative studies have shown that some slugs and snails prefer bryophytes. More active snails might be found at night, whereas tiny snails might take refuge in the bryophytes during the day.

Adaptations include "jumping" (*Hemphillia*), small size, conical snail, hibernation/estivation, and no shell (slugs). Snails might use them as a safe site to escape spiders, daddy-long-legs, and beetles, whereas other predators may lurk among the bryophytes. In streams, bryophytes may protect them from fish, ducks, shore birds, and amphibians.

Bryophyte leafy plants and capsules can serve as food for snails and slugs, but some of these molluscs seem to avoid leaves with **awns**. Nutritional quality may be poor in some, and some have antiherbivore compounds that interfere with development, digestion, and palatability. In some cases the moss structure is such that the snails actually lose weight, whereas moss paste fosters a weight gain. But the gastropods may gain their nutrition from adhering algae and Cyanobacteria. In some cases protonemata and green capsules are preferred to leafy plants. *Fissidens fontanus* can be virtually eliminated by snails in lakes where there is no *Fontinalis antipyretica* to protect it. And some leafy mosses are palatable.

But some slugs won't eat the moss even when they have been starved for 7 days. They have even been observed retreating from a moss. Various phenolic compounds seem to be involved in their reluctance to eat some bryophyte species. *Ricciocarpus natans* has molluscicidal properties that are effective against snail vectors of schistosomiasis.

The moss may not offer any nutrition. Intact cells of leaves, capsules, and mature spores pass through the gut, and it seems that only young spores and protonemata become pale during their trip through the digestive system.

Because of their mucous trail, slugs and snails are able to disperse some bryophytes, including brood branches, spores, and leaf fragments. And it appears that the mucous helps the dispersed fragment to adhere to its new substrate. Spores can even pass through the digestive system and survive, thus adding another form of dispersal.

Gastropods can be common among epiphytes, avoid acid habitats, and abound in limestone habitats. The acidity produced by poor fen species can exclude them because of inability to produce a hard shell.

Tiny mussels are able to live among bryophytes in aquatic habitats. *Fissidens fontanus* and *Leptodictyum riparium* can live on the shells.

Echinoderms generally have no association with bryophytes, but if a bryophyte falls into the marine water it may occasionally be eaten.

Acknowledgments

Bryonettors have been wonderful in making their photographs available to me and seeking photographs from others. Paul Davison has been helpful in providing

suggestions and offering images. And a long time ago Allen Neumann sent me a specimen of a clam shell with *Fissidens fontanus* growing on it. Numerous photographers and malacologists have been helpful in providing images and information. Michael Lüth's photographs are a valued contribution. I thank all those photographers who have made their images available through the public domain.

CHAPTER 5-1

TARDIGRADE SURVIVAL

Figure 1. *Dactylobiotus* sp. on the green alga *Spirogyra*. Photo by Yuuji Tsukii, with permission.

Tardigrades – Water Bears

Tardigrades (*tardus* = slow, *gradus* = step, or slow walkers), also known as water bears or moss piglets, are close relatives of the arthropods (Garey *et al.* 1996, 1999; Giribet *et al.* 1996).

Water bears resemble small bears (0.1-1 mm), complete with claws, but a few too many legs (4 pairs) (Figure 1). They are either armored (**Heterotardigrada**) or unarmored (**Eutardigrada**). The aquatic ones are usually a translucent white, whereas the terrestrial ones are often colored. Each of the eight legs has claws, which, when combined with their slow gait, makes them look very much like miniature polar bears with some extra legs. The very common *Macrobiotus hufelandi* (Figure 2) lumbers along at a maximum of 17.7 cm h⁻¹ (Ramazzotti & Maucci in Mach 2010). Tardigrades are just the right size to move among the bryophyte leaves, they lumber along slowly like bears, and they are downright cute!

Tardigrades, comprising about 900 species (Garey *et al.* 2008), can be found in marine, aquatic, and terrestrial habitats (Goeze 1773; May 1948; Greven 1980; Maucci 1986; Kinchin 1994). On land they frequently live in association with bryophytes (Figure 3; Figure 4) and lichens (Mihelčič 1967; Mehlen 1969; Utsugi 1984; Meininger *et al.* 1985; Mancardi 1988; Szymanska 1994; Bertolani & Rebecchi 1996; Tarter *et al.* 1996; Miller

1997; Jerez Jaimes *et al.* 2002; Boeckner *et al.* 2006; Bartels *et al.* 2009; Meyer & Hinton 2009; Rossi *et al.* 2009; Simmons *et al.* 2009). In water, algae, as well as bryophytes, provide homes.

Figure 2. *Macrobiotus hufelandi*, a common tardigrade that is among those inhabiting mosses. Photo by Paul Bartels, with permission.

These terrestrial tardigrades depend on the water drops that adhere to mosses and liverworts (Hingley 1993) and are therefore often termed **limnoterrestrial** (living in terrestrial habitats, but requiring a water film). Aquatic bryophytes can also house tardigrades (Hallas 1975; Kinchin 1987b, 1988; Steiner 1994a, b), as do the algae. However, of the ~1000 tardigrades reviewed by Guidetti

and Bertolani (2005) and Garey *et al.* (2008), only 62 were truly aquatic. The others depend on water associated with the interstitial spaces of terrestrial algae, lichens, bryophytes, soil, and leaf litter. Water bears are found in habitats from hot springs to layers under the ice (in cryoconite holes in glaciers) and occupy every continent of the world.

Most of the terrestrial tardigrades are bryophyte inhabitants (Nelson 1991a). These terrestrial bryophyte taxa have a life span ranging 3-4 months (Franceschi *et al.* 1962-1963), 3-7 months for *Macrobiotus hufelandi* (Figure 2; Morgan 1977), up to about 3 months for roof-moss-dwelling *Echiniscus testudo* (Figure 5; Morgan 1977), to about 2 years (Altiero & Rebecchi 2001) of active life (not counting dormant periods). The bryophyte-inhabiting taxa are more common in temperate and polar zones than in the tropics (Nelson 1991a). Some, as for example *Echiniscus testudo* (Figure 5), live almost exclusively on bryophytes (Corbet & Lan 1974).

Despite their cosmopolitan distribution (Romano 2003), broad habitat requirements, and relative visibility (compared to protozoa, for example), the tardigrades remain poorly known. As late as 1985, Hidalgo and Coombs reported that 16 states in the USA had no records of tardigrades. Species not previously described are easily discovered by those who know where to look for them.

The environmental conditions that affect tardigrades are likewise poorly studied (Guil *et al.* 2009), despite the extensive studies on a few species that have become travellers of the universe in space. Among those conditions

that have been studied, altitudinal gradients and micro-environmental variables (including substrate choice among vegetation, bryophytes, and leaf litter) seem to have gotten the bulk of the attention (Guil *et al.* 2009). Guil and coworkers found a unimodal distribution relative to altitude for species richness, but it was closely tied to habitat variation. The best predictor of the distribution of tardigrades in the Sierra de Guadarrama Mountain Range, Spain, was bioclimatic classification. Soil, climate, vegetation structure, and leaf litter type worked both separately and in combination to determine species richness, explaining nearly 60% of the species richness in micro-scale plots. Abundance, on the other hand, was significantly influenced only by soil composition and leaf litter type. The macro-environmental gradients seemed to be unimportant in determining abundance (*e.g.* Figure 6).

Suitability of Bryophytes as Habitat

The importance of bryophytes as a tardigrade habitat is evident by the number of publications on "moss" tardigrade fauna: Mihelčič 1967; Hallas 1975; Pilato & Sperlinga 1975; Morgan 1976; Brueggemann 1977; Morgan 1977; Maucci 1978, 1980; Bertolani 1983, 2001; Binda 1984;

Utsugi 1984; Meininger *et al.* 1985; Hofmann 1987; Hofmann & Eichelberg 1987; Kinchin 1987a, b, 1988, 1994; Meininger & Spatt 1988; Mancardi 1988; Bertolani *et al.* 1990; Tarter & Nelson 1990; Kathman & Cross 1991; Nelson 1991a, b; Utsugi & Ohyama 1991; Moon *et al.* 1994; Szymanska 1994; Miller & Heatwole 1995; Adkins & Nelson 1996; Tarter *et al.* 1996; Hooie & Davison 2001; Guidetti & Jönsson 2002; Jönsson 2003; Meyer *et al.* 2003; Hooie 2005), to name a few. It appears that when tardigrade lovers want to collect a lot of them, they collect bryophytes and lichens – or just bryophytes (generally lumped into "mosses").

Unfortunately, the authors rarely name the bryophytes from which their prizes were extracted. However, some evidence suggests that little specificity exists for bryophyte species, and lichens are as suitable as bryophytes, with no apparent differences in tardigrade species (Meyer & Hinton 2007). I have to wonder, however, why reports on tardigrades from liverworts are so scant (Figure 7). Perhaps it is just as suggested to me by Łukasz Kaczmarek, that most zoologists do not understand the differences between mosses and liverworts. (Neither do my students when they begin looking at them.)

Figure 7. SEM view of tardigrades on the lower sides of leaves of a leafy liverwort. Photo by Łukasz Kaczmarek and Łukasz Michalczyk, with permission.

Ramazzotti and Maucci (1983) considered mosses suitable habitat based on three needs of the **limnoterrestrial** tardigrades:

1. a structure that allows sufficient oxygen diffusion
2. the ability to undergo alternate periods of wetting and drying resulting from solar radiation and wind
3. a medium that contains sufficient food.

Based on these criteria, bryophytes are particularly good habitats for tardigrades in several ways (Ramazzotti & Maucci 1983; Claps & Rossi 1984; Adkins & Nelson 1996). Their structure permits sufficient oxygen diffusion, both in aquatic and terrestrial habitats. Bryophytes experience drying, which most do slowly, permitting the tardigrades likewise to dry slowly, and both have a tolerance to dehydration that permits them to survive adverse conditions (Kinchin 1994). Furthermore, the

tardigrades have a prolonged life span when it is interrupted by such a dormancy period. And bryophytes contain food items, such as algae, protozoa, and nematodes, as well as the bryophytes themselves, sufficient for the tardigrades. Most likely, the small chambers among the bryophyte branches also afford protection from larger would-be predators. And when fragments of bryophytes disperse, they may carry tardigrades with them.

It is the interstitial water of bryophytes that provides the suitable habitat for tardigrades (Hallas 1975). This water is typically found in leaf sheaths of bryophytes. Hallas investigated the drying of "cushions" of *Hypnum cupressiforme* (Figure 8). It required 19 hours for the moss to dry to a stable weight. The water retention relative to the weight of the cushion decreased linearly with the density of the cushion. However, the rate of drying can change with the temperature, saturation of the air, and air movement. He concluded that all compartments dry at the same rate, independent of the initial water content of each pocket, and the small variation in drying time is of no consequence for the tardigrades and other inhabitants. The tardigrades were concentrated in the living, chlorophyllous layer (compared to deeper, senescent layers) where there was more moisture. The water pockets connect vertically from one leaf to the next, but only connect horizontally when it rains. Therefore, horizontal migration of the tardigrades is only possible when the moss becomes saturated during rainfall. In *H. cupressiforme* (Figure 8), such bridges are formed only when rainfall exceeds 3 mm. Hallas considered that nighttime and morning dew were not sufficient for the most common tardigrade [*Macrobiotus hufelandii* (Figure 2) – a species that comprised 91% of the 386 tardigrades] to become active, suggesting that it would take ten times that amount of water to bring the moss to saturation levels.

Figure 8. Mat of *Hypnum cupressiforme*. Photo by Dick Haaksma, with permission.

But bryophytes do pose their problems for the tiny tardigrades. These animals are quite light weight, so imagine their struggle to control their movements when they encounter fully hydrated bryophytes with a continuous bath of water surrounding them. Greven and Schüttler (2001) observed these slow-moving creatures [*Macrobiotus* sp., *Echiniscus testudo* (Figure 5) on *Encalypta streptocarpa* [= *E. contorta*] (Figure 9) when the bryophyte was fully hydrated. The poor bears could barely

move and had difficulty maintaining the direction of their movements in the water. They could easily become dislodged by rainwater unless they are able to nestle in a leaf axil or other protected niche. And that is often a good place to look for them.

Figure 9. *Encalypta streptocarpa*, a tardigrade habitat that can be difficult to navigate when it is fully hydrated. Photo by Michael Lüth, with permission.

On the other hand, *Polytrichastrum* [= *Polytrichum*] *formosum* (Figure 10) did not sustain a continuous water film and the tardigrades seemed also unable to move in this "dry" habitat (Greven & Schüttler 2001). Rather, they seemed confined to the leaf axils, where water collected. As water receded, the animals ceased movement and formed a **tun** (protective dormant stage of tardigrade that is altered both chemically and physically) right there, permitting it to survive without water for up to 10 years (Jönsson & Bertolani 2001)! Perhaps tardigrades were the inspiration for the Rip Van Winkle story.

Figure 10. *Polytrichastrum formosum*, a moss that does not maintain a water film and is thus a poor tardigrade habitat. Photo by Des Callaghan, with permission.

Moisture seems to be the greatest determinant of species distribution among bryophytes. Richness among epiphytic bryophytes in the Cincinnati, Ohio, USA area was greatest in areas of high humidity (Meininger *et al.* 1985). Hofmann and Eichelberg (1987) found that the tardigrades lacked correlation with bryophyte species but that their distribution could be predicted by the degree of moisture they prefer. It is therefore not surprising that some bryophytes housed no tardigrades.

Tardigrades in association with roads along the Alaska pipeline demonstrate a moisture relationship (Meininger & Spatt 1988). Dust resulting from gravel roads associated with the pipeline alters the habitat for both mosses and tardigrades. Those tardigrades living among mosses near

roads were species adapted to xeric habitats. These species typically fed on fungi and algae, whereas those farther from the road were more likely to be omnivores or carnivores, presumably because they had more freedom to move about in a somewhat more moist environment.

Adaptations of Tardigrades

One might ask if these bryophyte-dwelling creatures have any special adaptations that permit them to live where they do. Their greatest adaptation is that they live in a habitat that permits them to dry slowly and go into a dormant state, as we will discuss shortly – a kind of behavioral/physiological adaptation. In fact, it appears that limnoterrestrial species actually require a habitat where they have dormant periods. And for many, the stylets permit them to suck the contents out of bryophyte cells, among other things, making them one of the few organisms specially adapted for obtaining nutrients from bryophytes.

Like insects, tardigrades have chitin, in this case in the innermost layer of the cuticle. The chitinous armor of some terrestrial tardigrades (heterotardigrades) may slow drying and offer protection from damage while dry. Of course small size is essential for living in the miniature world of bryophytes. And their claws (Figure 11-Figure 13) may permit them to clamber about more easily among the leaves and branches of the bryophytes. But Bertolani and Biserov (1996) consider that the reduction of claws on the fourth pair of legs is an adaptation to moving among the interstitial spaces in the soil. Does this same adaptation pertain to those among bryophytes?

Figure 11. Claws on four of the eight legs of *Echiniscoides sigismundi* (a tidal zone species). Photo by Martin Mach, with permission.

Figure 13. Claws of *Echiniscus* sp., a genus with many bryophyte-dwelling species. Photo by Martin Mach, with permission.

Their light weight facilitates tardigrade dispersal. Their bodies are flexible, permitting them to nestle in leaf axils or move in small spaces. But most of these as adaptations to the bryophyte habitat are speculation. There have been no tests to determine if any of these traits actually increases their survival among bryophytes compared to other habitats. Some very interesting experiments could be designed.

Let's examine one of the bryophyte-dwelling tardigrades as an example of potential adaptations. Martin Mach (The Water Bear) found *Cornechiniscus cornutus* (Figure 14) among bryophytes on a mountain top in Hungary. This cute little bear has two horns on its head (Figure 15) and a nice salmon color. But it is slow and clumsy, out-classed by the faster-moving and more abundant *Ramazzottius* (formerly *Hypsibius*) *oberhaeuseri* (Figure 25). Do such ornamentations as horns and hairs help to reduce predation in this habitat? Is that an advantage to offset the slower movement? Does the bright color protect the water bear from UV damage, especially while it is dry?

Figure 14. *Cornechiniscus cornutus*. Photo by Martin Mach, with permission.

Survival of Hazardous Conditions

The biggest hazard a bryophyte imposes on a tardigrade is intermittent desiccation. But in addition to that desiccation, the organism may be subjected to high or low temperatures, low oxygen conditions, and UV light for prolonged periods. With little ability to move elsewhere, it needs some other type of protection.

Figure 15. *Cornechiniscus cornutus* showing one of its two head horns. Photo by Martin Mach, with permission.

Aquatic organisms rarely need to be concerned with desiccation. However, if an animal is to survive among terrestrial bryophytes, it must be prepared for drying when the bryophyte dries out, and many of the tardigrade habitats are in dry places, including **cryptogamic crusts** (assemblages of Cyanobacteria, algae, lichens, & mosses) in the prairie and desert, and among epiphytes on trees. These bring with them the very hazards mentioned above – UV light in the absence of water for protection, and extremes in temperature. And the watery body must be hydrated for oxygen to enter it.

To unravel the relative importance of these stressors related to desiccation, Wright (1991) studied fifteen species of tardigrades and their responses to insolation, elevation, standardized desiccation rate, and hydration capacity of the plant substrate. There was considerable variation in ecotype among seven species with xeric associations. *Macrobiotus hufelandi* (Figure 2) and *Hypsibius dujardini* (Figure 16), both hygrophilic species, are absent from habitats that desiccate rapidly. On the other hand, the xerophiles *Milnesium tardigradum* (Figure 51) and *Ramazzottius oberhaeuseri* (Figure 25) avoid locations with high insolation and rapid desiccation rate, but also avoid poorly drained sites and sites with prolonged hydration. Despite these differences, *Milnesium tardigradum* often associates with the two *Hypsibius* species and may use them for food. The lack of association among *Macrobiotus hufelandi*, *Paramacrobiotus* (formerly *Macrobiotus*) *richtersi* (Figure 17), and *Hypsibius prosostomus* may be due to competitive exclusion.

Physical Adaptations

The soft-bodied tardigrades appear to have few structural adaptations to survive drought. Some, like *Echiniscus*, have long hairs (Figure 18-Figure 19), but the hairs are so few that one can hardly imagine they are of any help to reduce water loss or protect the dry animal. Hmm...What might their function be? Or are they a non-detrimental left-over? One interesting idea is that they might serve as straws to draw water into the body – a hypothesis requiring both experimentation and TEM examination. But suppose that is true. It could be a way to cause water to enter without drowning the animal – *i.e.*, permitting maintenance of an air layer on the surface. On the other hand, they could serve as fine hairs to collect dew and fog on their surface and direct it to the skin, thus increasing surface area and collection surface for the water. Or the hairs could act like whiskers on a cat, facilitating navigation among the mosses. More interesting experiments are needed!

Figure 18. *Echiniscus trisetosus*, illustrating the sparse but long hairs and plates of armor. Photo by Łukasz Michalczyk and Łukasz Kaczmarek, with permission.

Oxygen availability can be a problem, and for this reason the tardigrades avoid dense bryophytes and usually remain in the top few centimeters of soil where more oxygen is available (Ramazzotti & Maucci 1983). Hence, another possibility for the long hairs is that they could be

tactile extensions to warn of an environment that is too tight, or chemical sensors to aid in finding food or sensing predators – or sensing a low-oxygen environment. Hypothesis testing is needed!

Figure 19. Two of the long hairs of *Echiniscus*. Photo by Martin Mach, with permission.

Echiniscus viridianus (Figure 20) seems to do well among bryophytes. It was originally described from mosses in Alabama USA (20 individuals) and later collected in New Mexico and the Azores Islands, again among mosses (Pilato *et al.* 2007). As in other members of the genus, this species bears armor and long hairs.

Figure 20. *Echiniscus viridianus*. Photo by Paul J. Bartels, with permission.

Spines/hairs and body armor may offer a bit more protection. Some bryophyte-dwelling species such as *Cornechiniscus cornutus* (Figure 21) and some members of the genera *Echiniscus* (Figure 22-Figure 23) and *Ramazzottius* (Figure 24-Figure 25) (and others) have "armor" on their bodies that is somewhat leathery. I am aware of no studies that demonstrate the ability of the armor to reduce water loss, but it would appear to be a good possibility. Other possible advantages of this armor-like **cuticle** may include protection from fungi and other pathogens and some kinds of predators, particularly while in cryptobiosis, and it most likely would afford limited UV protection. How little we know!

Pigments

Terrestrial tardigrades come in green, brown, yellow, orange, pink, red, purple, or black, whereas aquatic ones are white (Hebert 2008). Bonifacio *et al.* (2012) pointed out that despite the many studies on tardigrades relative to space travel, little is known about the nature or function of their pigments. They described the carotenoid nature of the pigments and the ability of these pigments to decrease under high oxidative stress. They hypothesized that these pigments had an anti-oxidant function and could possibly protect the animals during extreme environmental conditions.

It is possible that the wonderful colors of some tardigrades (Figure 26-Figure 27) are adaptations against UV damage to DNA, especially during prolonged periods in a cryptobiotic state. Such pigmentation advantages have been demonstrated in bryophytes (Martínez Abaigar & Olivera 2007) and copepods (Byron 1982), so it is reasonable to expect them to serve similar functions in tardigrades, particularly in those more open habitats such as **cryptogamic crusts**. It would be an interesting study to examine the relationship of color with habitat in tardigrades. I am aware of no such study, but Martin Mach (pers. comm. 18 October 2012) pointed me to the publication of Ernst Marcus (1929). Marcus suggested that pigments were a response to UV light. He cited as support the findings that pigmentation varies with winter vs summer UV radiation. Experiments are needed to support this hypothesis, and one must wonder how this relates to those living among bryophytes. Marcus pointed out that insolation does not penetrate well into the moss colony, making bright pigments unnecessary for these tardigrades.

Physiological Adaptations

Light Response

Tardigrades have a pair of eyes, although at times they may be "ghost eyes" (Figure 28) that cannot be seen

through ordinary observation (Mach 2012). These eyes respond to light, and at least in *Macrobotus hufelandi* (Figure 2) the response changes with size and age (Beasley 2001). The smaller, younger size group had a significantly negative response to light. Beasley hypothesized that this behavior serves to conserve body moisture in small individuals that have a larger surface area to volume ratio than do larger ones. The response is not a phototaxis (directional response to light), but rather was photokinesis (non-directed, random movement), resulting in either an increase in speed or a change in direction when exposed to light. Such behavior would seem to support finding a "safe" place away from light.

Cryptobiosis

Albert Szent-Gyorgyi, a 20th Century Hungarian biochemist, once stated "Water is life's mater and matrix, mother and medium. There is no life without water." In their cryptobiotic state, tardigrades come close to disproving that statement. Anthony van Leeuwenhoek first described cryptobiosis in 1702, but it was not until 1959 that Keilin coined the term **cryptobiosis** (Wright 2001). Cryptobiosis is a reversible ametabolic state that can be induced by dehydration and cooling, and possibly osmotic stress and anoxia.

Metazoans such as tardigrades use **glycerol** and the disaccharide sugars **sucrose** and **trehalose** (Wright 2001) as protectants. Before entering the cryptobiotic state, these substances must be synthesized from glycogen reserves, hence requiring a preparatory period. Certain behavioral adaptations may help to delay the desiccation, thus permitting these compounds to be synthesized.

One of the factors that contributes to the tolerance of desiccation is the ability to reduce surface area during tun formation (Wright 1991), hence slowing the process. Those that are most desiccation tolerant have the greatest infolding. This means those species with thick dorsal plates (Figure 29) are at a disadvantage. As Wright showed for *Echiniscus testudo* (Figure 5), there is very little surface area reduction possible.

Figure 29. *Echiniscus mauccii* showing the plates that make shrinkage during desiccation all but impossible. Photo by Diane Nelson and Paul Bartels, with permission.

Moss cushions help to make survival of this cryptobiotic state possible. The small spaces among mosses hold static air that can slow the dispersion of water vapor (Wright 1989). This permits the slow drying that is necessary for survival of the tardigrade in the desiccated state. Mosses in exposed positions may desiccate rapidly. Some mosses [e.g. *Polytrichum* (Figure 30), *Dawsonia* spp. (Figure 31)] are able to slow this process by folding their leaves (van Zanten 1974).

Wright experimented with tardigrades on mosses in their natural habitat. **Eutardigrada** species were hydrated at least 24 hours before the experiments. As expected, there is considerable variation among species in their ability to tolerate desiccation. But they also differ in the lethal humidities (53-78%) for initial desiccation. Those species that are best able to tolerate rapid initial drying are also those most able to acquire tolerance to low humidities of 25-31% following drying in high humidity.

Figure 30. *Polytrichum formosum* showing open leaves (left & right) and folded leaves (center). Photo by Michael Lüth, with permission.

Figure 31. *Dawsonia superba*, a moss that seems unfavorable for tardigrade feeding and rolls its leaves when dry. Photo by Jan-Peter Frahm, with permission.

Typically, tardigrades are desiccated in 80% relative humidity (Wright 1991). In this condition, they dehydrate rapidly, then abruptly reduce water loss (the **permeability slump**). This slump occurs in both live animals prior to tun formation and in extended dead animals, so it is not a physiological phenomenon. This slump permits the animals to retain considerable water in their desiccated state. Crowe (1972) examined the humidity effects on *Paramacrobiotus areolatus* (Figure 32). He found that at humidities lower than 70% this species became flattened and crumpled. Above this level, dehydrating animals form tuns. This appears to be an active process that is not as effective in anesthetized animals. Tuns of active animals lose water at only 0.3 times the rate of anaesthetized animals. The anaesthetized animals reach moisture equilibration with the environment within one hour, whereas tuns do not reach that equilibrium within 100 hours. In dry air, tardigrades can reach as little as 2-3% water content without dying if they are able to dry properly.

Literally meaning "hidden life," **cryptobiosis** is a state of suspended animation in which the organism is able to survive unfavorable conditions while expending little energy. During that state, the organism does not feed,

reproduction stops, and metabolism is extremely reduced and may possibly even cease. For the **limnoterrestrial** (living in water films on land) tardigrade, it appears to be an essential part of survival and life, and it stops the aging clock.

Figure 32. Head region of *Paramacrobiotus* [= *Macrobiotus*] *areolatus*. The bulbous oval to the right of the three filaments (stylets and buccal tube) is the pharynx. Photo by Martin Mach, with permission.

Despite the apparent absence of structural adaptations, desiccated tardigrades, like their mossy habitats, have great survival capabilities. They have two forms of **dormancy**: **cryptobiosis** and **encystment** (Guidetti *et al.* 2006). The cryptobiosis of tardigrades is exhibited in several forms:

- **anhydrobiosis** (induced by loss of water)
- **cryobiosis** (induced by declining temperatures)
- **anoxibiosis** (induced by insufficient oxygen)
- **osmobiosis** (induced by loss of water due to higher external salt concentrations) (Bertolani *et al.* 2004).

To be active, tardigrades must stay in a water film in order to breathe (Bordenstein 2008). But in a cryptobiotic state, as discussed below, tardigrades can survive not only desiccation, but temperatures as low as 0.05K (-272.95°C) for 20 hours or -200°C for 20 months (Miller 1997). They have even survived 151°C for a few minutes (Lindahl & Balser 1999). They become active again after living with 0% hydration (Lindahl & Balser 1999). This desiccated dormant state also permits them to survive pressures of 6000 atmospheres (Seki & Toyoshima 1998), *i.e.* six times the pressure of the deepest part of the oceans! Yet they can also survive the vacuum and UV radiation of space (Jönsson *et al.* 2008), a feat not known for any other animal. The ability of tardigrades to undergo **cryptobiosis** is more widely known than their encystment behavior. True cryptobiotic states are survived as a **tun** (Figure 33-Figure 43). The tardigrades will be the ones to survive when everything else is deceased.

Tun Formation

When they undergo desiccation, the **tardigrades** form a **tun** (Figure 33-Figure 43) (Lindahl & Balser 1999). The **tun** is a barrel-shaped, dry, dormant tardigrade. Tuns are

formed in the process of entering true cryptobiosis, *i.e.*, in anhydrobiosis, osmobiosis, and cryobiosis, but not in anoxybiosis. Although the stimulus differs among these, each ultimately involves the loss of free water.

Figure 41. Tun of *Echiniscus* sp. on a moss leaf. Photo by Martin Mach, with permission.

Figure 42. Tun of *Echiniscus* sp. Photo by Martin Mach, with permission.

Figure 43. Tun of *Echiniscus* sp. Photo by Martin Mach, with permission.

This tun is a little ball in which the tardigrade can survive 0% relative humidity! However, it only requires a reduction to 70-95% humidity to trigger the **tun** formation,

a resting form in a cryptobiotic state in which the tardigrade appears to be dead (Crowe 1972). During tun formation, loss of free and bound water is greater than 95% (Bertolani *et al.* 2004). The body folds and the appendages are withdrawn (Lindahl & Balser 1999). Wax is extruded onto the surface and most likely reduces water loss (Wright 1988a, b). Those tardigrades with the most variability in the thickness of this **cuticle**, making them more pliable, are those able to have the greatest surface area reduction when they form tuns (Wright 1988a, 1989). The thin areas would permit greater infolding. Lipids of the inner cuticle are thickest in the species that are best able to tolerate rapid drying. Crowe (1972) demonstrated that the cuticle of *Paramacrobiotus areolatus* (Figure 32) is removed from air contact during tun formation and becomes less permeable to water. Crowe likewise suggested that this loss of permeability might be due to a lipid phase change.

Despite the waxy cuticular protection, the water content is reduced to less than 1% (Lindahl & Balser 1999) and the tun becomes shrivelled and wrinkled (Hingley 1993). *Echiniscus testudo* (Figure 5), an armored tardigrade, has much thicker **dorsal** (back) plates, apparently compensating for its limited ability to reduce surface area as it is drying (Wright 1988a, 1989).

The tardigrade bodies synthesize cell protectants such as **trehalose**, **glycerol**, and **heat shock proteins** that contribute to successful recovery from the tun state (Wright 1989). Trehalose is typically found in high concentrations in animals in a state of cryptobiosis (Crowe & Crowe 1984). Trehalose is able to bond with DPPC and alter the spacing of polar head groups, apparently stabilizing the dry cell membranes. Hengherr *et al.* (2008b) determined that levels of trehalose varied considerably among species. In fact, they detected no changes in trehalose levels in any Heterotardigrada, and *Milnesium tardigradum* (Figure 51) apparently had no trehalose at all. They did demonstrate that tardigrade embryos can accumulate high levels of trehalose, seemingly explaining the high level of desiccation tolerance in that life cycle stage.

Tun formation is essential to tardigrade survival under desiccating conditions. For *Paramacrobiotus areolatus* (Figure 44), and probably most tardigrades, if the humidity is low (<70%) or **anoxic** (lacking oxygen) during its desiccation, it is unable to form a tun and cannot be revived (Crowe 1972). It must have sufficient energy (requiring oxygen), hydration, and time to enter the tun stage.

Figure 44. *Paramacrobiotus areolatus*. Photo by Martin Mach, with permission.

Tardigrades revive (Figure 45) almost as quickly as a moss when water returns (Crowe & Higgins 1967), in as little as 4 minutes (Hingley 1993), or several hours, depending on how long they have been dehydrated (Lindahl & Balser 1999). One marine tardigrade has been induced to alternate between a cryptobiotic state and activity on a 6-hour cycle.

Dangers in a Tun

One concern that comes to mind is the possible damage that could happen to these organisms while in the tun stage. I am reminded of the frozen frogs and toads during the winter. They are very susceptible to physical damage if they are disturbed. I would think an animal such as the amphibians hiding under a rock or clump of moss would experience no more physical abuse than the tiny tardigrade among the moss leaves. Ice crystals could poke holes in cells, larger animals could eat them, or they could get knocked off into a hole where conditions were not favorable to their maintenance and survival. I have to wonder just what dangers these dormant organisms do face, and how many actually survive these in the wild to become once again active. It seems we currently have no idea.

Certain dangers include cell degradation and DNA damage. As the tardigrades exist longer and longer, they accumulate cell degradation and DNA damage (Rebecchi *et al.* 2009b), ultimately accumulating too much for successful repair. Hence, the tun does not completely protect them, and chances of survival decrease with time.

Effects of Size

Jönsson *et al.* (2001) found that size influenced survival of cryptobiotic tardigrade species, but that direction of influence differed among species. The common *Ramazzottius oberhaeuseri* (300 μ m length; Figure 46) had a much higher survival rate (66%) (Figure 47) than did *Richtersius coronifer* (40%) (up to 1 mm length; Figure 48). *Ramazzottius oberhaeuseri* (Figure 46) has a high ability to retain water, perhaps with a physiological adaptation to reduce water loss in this smaller organism with a high surface area to volume ratio.

Within *Richtersius coronifer* (Figure 48), large individuals were less likely to survive cryptobiosis than medium-sized ones (Figure 49); reproductive state had no effect (Jönsson & Rebecchi 2002). Better energetic

conditions increased survival. Jönsson and Rebecchi suggested that larger organisms had greater energy constraints when entering and leaving anhydrobiosis, decreasing survival rate.

Figure 47. Comparison of survival during encystment for *Richtersius coronifer* and *Ramazzottius oberhaeuseri* from Italy and Sweden. Vertical line represents standard error. Redrawn from Bertolani *et al.* 2004, based on Jönsson *et al.* 2001.

Figure 48. *Richtersius coronifer*, clinging to an algal cell. Photo by Martin Mach, with permission.

Figure 49. Probability of survival from anhydrobiosis for large and medium-sized *Richtersius coronifer* as a function of storage cell size. Probability is based on the predicted values from a logistic regression model, using buccal tube length, category, storage cell size, and interaction between the last two categories. Redrawn from Jönsson & Rebecchi 2002, in Bertolani *et al.* 2004.

Jönsson and Rebecchi (2002) likewise found that medium-sized tardigrades had a better chance of survival than did large ones in *Richtersius coronifer* (Figure 48). Large storage cell size was an important parameter to predict greater survival in the large tardigrades (Figure 49).

Reuner *et al.* (2010) described the storage cells as free-floating cells in *Milnesium tardigradum* (Figure 51), *Paramacrobrotus tonollii* (Figure 50), and *Macrobrotus sapiens* that apparently store and release energy as glycogen, protein, and fat. These stores provide energy during cryptobiosis. Storage cell size did not relate to body size, except that the largest tardigrade, *Milnesium tardigradum* (Figure 51), also had the largest storage cells. After seven days of anhydrobiosis (tun stage resulting from desiccation), this species had decreased cell size, but the other two species did not. Food sources used in the study did not seem to affect cell size.

Longevity

Tardigrades are often credited with century-long survival in a cryptobiotic state. This is due to the report that one herbarium specimen of a moss housed a tardigrade that began cellular activity after 120 years of being dry in the herbarium (Franceschi 1948; Brusca & Brusca 1990; Jönsson & Bertolani 2001)! But, sadly, this record has been called into question, and the tardigrade never fully recovered despite its cellular activity. At the very best, even this faint degree of survival is probably a rare occurrence (see Jönsson & Bertolani 2001). Jönsson and Bertolani (2001) reviewed the evidence and considered that ten years is a more realistic estimate of survival time for tardigrades in a cryptobiotic state.

Rebecchi *et al.* (2008) decided to test this claim of longevity further, using five species of tardigrades from lichens. They collected wet lichens with active tardigrades and permitted them to dry in the ambient conditions of the lab. Among these, *Ramazzottius oberhaeuseri* (Figure 25), *Echiniscus testudo* (Figure 5), and *E. trisetosus* (Figure 18), species that also occur on bryophytes, were sufficiently abundant to permit statistical conclusions. At the beginning of the experiment 91% of *R. oberhaeuseri* and 72% of *Echiniscus* spp. were active. *Ramazzottius oberhaeuseri* (Figure 25) survived up to 1604 days, whereas *Echiniscus* spp. lived only 1085 days. Nevertheless, this may not reflect going into the tun stage under natural conditions, which is likely to be slower among mosses. This could be particularly important for tardigrades that increase trehalose levels.

To test the longevity of tuns vs eggs under anhydrobiosis, Guidetti and Jönsson (2002) examined 63 different moss samples from stored collections, ranging in anhydrobiotic state 9-138 years. Eggs survived longer than dry adults (tuns), with those of *Ramazzottius oberhaeuseri* (Figure 25) surviving nine years. Much more work is needed to determine what factors account for such differences in survivorship and how it relates to individual species and habitats. The ability to survive unfavorable conditions permits the tardigrades to live in such places as *Grimmia pulvinata* tufts (Figure 52) on house roofs (Corbet & Lan 1974) or among branches of the epiphyte *Orthotrichum cupulatum* (Figure 53) (Jönsson *et al.* 2001).

Figure 52. *Grimmia pulvinata*, a moss that can support tardigrade communities on roofs. Photo by Michael Lüth, with permission.

Figure 53. *Orthotrichum cupulatum*, an acrocarpous moss that provides habitats for tardigrades. Photo by Michael Lüth, with permission.

Like the rotifers, tardigrades suspend their aging clock while they are dormant (Hengherr *et al* 2008a). *Milnesium tardigradum* (Figure 51) that was subjected to alternating periods of drying and activity exhibited similar longevity of active periods to that of animals of the species that had not experienced dry periods.

Ramazzotti and Maucci (1983) estimated that freshwater species such as those of *Hypsibius* (Figure 54) and *Macrobiotus* (Figure 55) live about 1-2 years. Terrestrial bryophyte-inhabiting species of the same genera live much longer, averaging 4-12 years. This extended life is due largely to their periods of cryptobiosis, during which the biological clock stops.

Dangers and Protective Mechanisms

One contributing factor in their survival of drying is the ability of tardigrades to alter their cell membranes (Brave New Biosphere 1999). They replace the water in the cell membranes with sugar, thus preventing radiation from causing ionization. Like the nematodes and rotifers, some tardigrades prepare for desiccation by producing **disaccharide** sugars, including **trehaloses** (Bordenstein: Tardigrades; Westh & Ramløv 1991). Disaccharides like trehalose and **sucrose**, as well as **glycerol**, are used as membrane protectants by metazoans such as tardigrades, whereas plants typically use **oligosaccharides** such as **stachyose** and **raffinose** (Wright 2001).

This water replacement by sugars also protects invertebrates during freezing because crystallization cannot occur (Brave New Biosphere 1999). The accumulation of trehalose of 0.1-2.3% of dry weight occurred within 5-7 hours during desiccation in *Richtersius coronifer* (Figure 48; Westh & Ramløv 1991). This accumulation was reversed within 6 hours upon rehydration. Both water loss and sugar replacement prevent the rupture of the cell membrane that would result in death. But trehalose has multiple properties that help to stabilize desiccated cells (Table 1).

Table 1. Properties of trehalose that benefit dehydrating cells. From Watanabe 2006.

Non-reducing activity
Low tendency to crystallize
Stable glass formation
High vitrification temperature
High ability of water replacement
Structuring activity of intracellular water with HSP
Stabilization of dry membranes
Antioxidant activity of protein and fatty acids
Free-radical scavenger

Nevertheless, tardigrades accumulate trehalose at the low end of the scale for anhydrobiotic organisms – about 2% (Watanabe 2006). This lower level in tardigrades and absence of trehalose in rotifers is coupled with their ability to enter anhydrobiosis within one hour, whereas organisms with larger accumulations (up to 40%) can take at least two days.

Trehalose is not a cure-all for desiccation effects in tardigrades. High temperatures and high humidity may lead to destruction of trehalose (Rebecchi *et al.* 2009a). In other cases, or in consort, oxidative damage may occur. Using *Paramacrobiotus richtersi* (Figure 17) as an experimental organism, Rebecchi *et al.* demonstrated that DNA changes can occur during desiccation. Neumann *et al.* (2009) likewise demonstrated a slight increase in DNA damage during drying, but they also found that DNA damage increased with duration of anhydrobiosis. Furthermore, high temperatures and relative humidity have negative effects on both survival and time to recover after rehydration, with effects increasing with duration of exposure. One reason for this is that damages are not repaired during anhydrobiosis and therefore accumulate with time.

Anhydrobiosis

The most common of the cryptobiotic states is **anhydrobiosis** (state of dormancy brought on by dehydration). In their state of **anhydrobiosis**, tardigrades can remain inactive during unfavorable conditions such as prolonged dryness (Kinchin 1987b). **Anhydrobiosis** is usually restricted to animals less than 1 mm in length (Watanabe 2006). Hence, some invertebrates are only able to enter this state during early developmental stages. Tardigrades and rotifers, being less than 1 mm when fully developed, are able to do so at any developmental stage.

In order to survive anhydrobiosis, tardigrades must dry very slowly (Hingley 1993; Collins & Bateman 2001). To form the tun, they must retract their head, legs, and hind end, forming a rounded tun, thus reducing surface area. In this state of anabiosis, they are able to withstand extremes of temperature and desiccation. Nevertheless, water arouses them in as little as four minutes.

It appears that continuously hydrated conditions may be detrimental to the survival of tardigrades (Jönsson 2007). Using bryophyte populations from Island Öland, Sweden, Jönsson subjected the tardigrades to two treatments of 6-month duration over an 18-month period. These experimental treatments increased hydration, decreased hydration, or remained as controls. The total population was significantly smaller (barely so) under increased hydration. But effects were not the same for all tardigrades. *Richtersius coronifer* (Figure 48) and *Echiniscus spiniger* failed to respond to the treatment, whereas *Milnesium tardigradum* (Figure 51) declined under increased hydration. But even *Richtersius coronifer* experienced reduction in the density of eggs (Figure 56-Figure 57) under the watering treatment. Hydration did not significantly increase density in any of the tardigrades. This adds further support to the idea that periods of dormancy (cryptobiosis) are necessary to increase longevity of the tardigrade. This would, in turn, increase variability of conditions, offering an array of conditions for reproduction.

Richtersius coronifer (Figure 48) can increase its survival rate by forming **aggregates**, a mechanism barely known for tardigrades but common in nematodes (Ivarsson & Jönsson 2004). The clustering reduces exposed surface area and thus slows drying. It is possible that this is used more in tardigrades than is realized; its use among bryophyte fauna is as yet unknown.

Figure 57. *Macrobiotus magdalenae* egg showing the highly decorated nature that is typical of eggs laid free from the **exuvia** (shed body shells). In this state the organism can survive as well as in a tun. Photo by Łukasz Kaczmarek and Łukasz Michalczyk, with permission.

Schill and Fritz (2008) examined the desiccation tolerance of the embryonic stages of *Milnesium tardigradum* (Figure 58), a potential means of surviving desiccation that has been neglected. They rehydrated this species after treatment at eight different humidity levels (10, 20, 31, 40, 54, 59, 72, 81%). They found that the less developed stages were more susceptible to desiccation damage. In the first three days of development, low humidity caused a decrease in hatching rates following rehydration. Later stages fared better, but when older embryos were dried fast at low humidity levels, development was delayed and hatch rates were lower after rehydration. Nevertheless, older embryos fared better than younger ones.

Even in 2011, Schokriæ *et al.* still considered the survival mechanisms of tardigrades to be poorly understood. They considered the possibility that heat shock proteins (HSPs) might protect them from irreversible aggregation and degradation during anhydrobiosis. They found that *Milnesium tardigradum* (Figure 51) had HSPs in several major chaperone families, suggesting the ability

of the tardigrade to use these for protection when dehydrated.

Figure 58. *Milnesium tardigradum*, a bryophyte dweller whose younger stages are the most susceptible to desiccation. Photo by Yuuji Tsukii, with permission.

The cryptobiotic state of anhydrobiosis has a significant impact on the ecological role of the tardigrades. It affects their role in the food chain, their ability to disperse, and their survival through a longer period of time (see reviews by Pilato 1979; Wright *et al.* 1992; Kinchin 1994). Bryophytes often play a significant role in achieving that state.

Osmobiosis

Osmobiosis is a special case of cryptobiosis that permits some species to tolerate high salinity and to form a tun (Lindahl & Balser 1999). It is initiated when the animal experiences an external salt concentration that is higher than that inside the organism. However, for tardigrades, while possible, osmobiosis is typically not necessary as most tardigrades already have a high salt tolerance.

Anoxybiosis

Anoxybiosis is another special case where the tardigrade has the ability to survive low oxygen (Lindahl & Balser 1999). Tardigrades are very sensitive to changes in oxygen tension, and prolonged reduction of oxygen leads to **osmoregulatory** failure.

Anoxybiosis is not a true state of cryptobiosis and does not involve tun formation (Figure 59). Unlike true cryptobiosis, anoxybiosis involves the uptake of water. The lack of oxygen results in the inability to control osmosis, causing water to enter the cells in excess. The animals become turgid, immobile, and retain fully extended bodies that are perfectly bilaterally symmetrical (Figure 60). Even animals in a molt can enter anoxybiosis (Figure 61).

Figure 61. Tardigrade induced into **anoxybiosis** during its molt. Photo by Martin Mach, with permission.

Revival to normal state (Figure 62) relates to the duration of the dormant state. However, the success of that recovery is controversial (Wright *et al.* 1992), with some researchers finding that they can survive for only 3-4 days (Crowe 1975) and others finding survival of *Echiniscoides* (a tidal zone genus) up to six months in closed vials (Kristensen & Hallas 1980).

Figure 62. This tardigrade was caught by low oxygen during molt and entered **anoxybiosis**. Here it has recovered and is moving within the swollen cuticle to complete its molt. Photo by Martin Mach, with permission.

Cryobiosis

Cryobiosis is another special case of cryptobiosis that results when the temperature decreases and the water in the cells has frozen (Wikipedia: Cryptobiosis 2009). Molecular mobility stops (Wikipedia: Cryptobiosis 2009), permitting the tardigrades to survive very low temperatures (Westh *et al.* 1991; Westh & Kristensen 1992; Ramløv & Westh 1992; Sømme 1996; McInnes & Pugh 1998). They do this by actually freezing, but the freezing is ordered (Lindahl & Balser 1999) and the result once again is a tun.

Cryobiosis in tardigrades differs from anhydrobiosis (Wright 2001). First of all, tun formation is not necessary for survival. The important process is that intracellular freezing must be avoided. But tardigrades, unlike many arthropods, are freeze-tolerant. This can be accomplished by **ice-nucleating proteins** that are located outside the cells. These proteins act like water magnets, drawing water out of the cell. Also unlike many other arthropods, the extracellular freezing, promoted by the ice-nucleating proteins, occurs at temperatures near 0°C. In *Richtersius coronifer* (Figure 48), **trehalose** synthesis is not part of this process, although there may be other cryoprotectants in the cell. The details of freeze protection are not fully understood, but the loss of water from the cells may cause the cells to become "unfreezable." Glycerol contributes as an antioxidant. Being imbedded in ice probably also prevents oxidation damage. In this cryobiotic state, the tardigrades can survive for decades.

Tardigrades often experience wide temperature fluctuations while in an active state. In particular, they can be subjected to subzero temperatures. Their ability to tolerate these sub-zero conditions requires either tolerance of freezing body water or having a mechanism to lower the freezing point. Hengherr *et al.* (2009) subjected nine species from polar, temperate, and tropical regions to cooling by 9, 7, 5, 3, and 1°C h⁻¹ down to -30°C, then returning them to ambient temperature at a rise of 10°C h⁻¹. Survival was better at fast and slow cooling rates, with low survival rates at intermediate cooling rates. Hengherr *et al.* suggested that this relationship may indicate a physical effect during fast cooling and possible synthesis of **cryoprotectants** during slow cooling. The increased survival with slower cooling indicates that tardigrades protect their cellular structure from freezing injury without altering their freezing temperature.

As indicated above, at least some protection seems to be accomplished by using **ice-nucleating proteins** in the body fluids (Westh *et al.* 1991). Such proteins serve as centers for crystal formation, a technique used to make snow for ski hills. This cryoprotective mechanism permits tardigrades to survive rapid freezing and thawing cycles such as those experienced in the Arctic and Antarctic. Usually this type of protection means that the nucleating centers are small, permitting only small crystals to form, consequently reducing damage to the cell membranes.

The ice-nucleating activity in the body fluid from *Richtersius coronifer* (Figure 48) is reduced by 50% following *ca* 7x10³ times dilution (Westh *et al.* 1991). Heating to temperatures above 68°C induces an abrupt decrease in the activity, suggesting that the nucleators are proteinaceous.

Westh and Kristensen (1992) examined *Richtersius coronifer* (Figure 48) and *Bertolanius* [= *Amphibolus*]

nebulosus (see Figure 63) and compared their cryoprotective strategies. *Richtersius coronifer* (Figure 48) lives in drought-resistant mosses and overwinters in a frozen or dry state (cryptobiosis). *Bertolanius nebulosus*, on the other hand, lives among moist mosses and algae and spends its winter frozen in a cyst or as eggs. Both species can supercool to as low as -7°C. But these two species have distinctly different heat stability, resulting from differences in ice-nucleating proteins. In both cases, ice formation is rapid, but crystallization most likely stops within a minute of nucleation. This protects the cells from damage caused by large, sharp crystals. Nevertheless, ice constitutes 80-90% of the body water. Winter acclimatization of *R. coronifer* results in a 10% lower ice formation than summer acclimatization. The thaw point was unaffected by winter vs summer, suggesting that there is no accumulation of low molecular weight cryoprotective substances.

Figure 63. *Bertolanius volubilis* type A cyst. Photo by Roberto Bertolani from Bertolani *et al.* 2004, with permission.

Despite their seeming indestructibility, not all tardigrade individuals fare well at low temperatures, and some species fare better than others. Bertolani *et al.* (2004) demonstrated this for three species of tardigrades (Figure 64). *Ramazzottius oberhaeuseri* (Figure 25) seems to be almost indestructible down to -80°C, whereas *Hypsibius dujardini* (Figure 16) had only 20% survival at that temperature. In fact, it had less than 80% survival at -9°C.

Figure 64. Comparison of survival of three bryophyte-dwelling tardigrades subjected to sub-zero temperatures. Redrawn from Bertolani *et al.* 2004.

Holmstrup *et al.* (2002) considered the problem of low temperatures in soil environments. Most of the work had been done on insects, but tardigrades are ideal for this kind of study. Insects often have the ability to supercool and to retain water in a dry environment. But non-insect soil invertebrates have resistance to desiccation that is orders of

magnitude less than that of terrestrial insects. This suggests that the other invertebrates may use an entirely different mechanism for surviving desiccation and cooling. Dehydration results because the water vapor pressure of supercooled water is higher than that of ice under the same temperature. A drop in temperature of even a few degrees of supercooling will cause considerable water loss. This loss continues until the vapor pressure of body fluids and that of surrounding ice are equal. When this is achieved, there is no longer any danger of ice formation in the tissues, permitting the invertebrate to survive at subzero temperatures. Holmstrup *et al.* (2002) showed that soil invertebrates do not use supercooling to survive. Instead, they dehydrate, changing their body-fluid melting point to that of the ambient temperature. This mechanism works even in the extreme cooling conditions and rapid rates seen in the polar soils.

Tardigrades live in many habitats that experience such cold temperatures. The widely fluctuating temperatures of the polar regions subject them to extremes while they are still in the active state. Thus they must either have the ability to tolerate the freezing of their body tissues or a means to lower their tissue freezing point (Hengherr *et al.* 2009).

Temperature

Rebecchi *et al.* (2009) pointed out that most stress studies on tardigrades had involved terrestrial tardigrades. Hence, they examined the limnic boreo-alpine species *Borealibius zetlandicus* for its stress responses. This species is able to survive freezing in lab experiments by entering a cryptobiotic state. Faster cooling rates lead to greater death from freezing. It furthermore is able to survive relatively "hot" water, having an experimental heat-shock LT50 of $33.0 \pm 0.5^\circ\text{C}$. On the other hand, no members of this species were able to survive desiccation in the experiments. It is likely that in its natural habitat it is able to survive drying conditions by behavior – finding locations among moss leaves or in other plants or in muds where it does not dry as completely.

Ramløv and Westh (2001) studied *Richtersius coronifer* (Figure 48) and found that when this species enters anhydrobiosis it accumulates the disaccharide **trehalose**, with the maximum content of 2.3% of the dry weight. This species was able to survive temperatures up to 70°C in a moss cushion for an hour with no effect on survival rate. However, above that temperature, survival decreased rapidly, with no survival at 100°C . Ramløv and Westh suggested that heat shock proteins may be involved in the high temperature survival.

Diapause (Encystment)

Tardigrades are especially endowed with the physiological ability to survive. They are among the few organisms that can use both **anhydrobiosis** and **diapause (encystment)** as a means of dormancy to survive unfavorable conditions (Guidetti *et al.* 2008). Diapause is common among aquatic tardigrades, but there are some terrestrial species that experience diapause (Westh & Kristensen 1992; Nelson 2002). Whereas cryptobiosis is well studied, the role of diapause (encystment) is not well known in tardigrades. It appears that it is not an essential

part of the life cycle – only a means to survive some unfavorable conditions.

Węglarska (1957) found that *Dactylobiotus dispar* (Figure 65-Figure 68) was induced to encyst by environmental conditions that gradually became worse. Interestingly, when there was a rapid change to poor conditions, this tardigrade went into **anoxymbiosis**. When a tardigrade is about to encyst, it ingests large amounts of food that is stored in the body cavity cells (Nelson 1991a). The remaining material in the gut is defecated.

Figure 65. *Dactylobiotus* sp. Photo by Yuuji Tsukii, with permission.

Encystment is more complex than **tun** formation (Bertolani *et al.* 2004). The **cysts** are ovoid and are composed of a series of cuticles that surround the sleeping animal (Figure 69; Guidetti *et al.* 2006). They are described as resembling an onion or a Matryoshka Russian doll.

Figure 66. *Dactylobiotus dispar*. Photo by Martin Mach, with permission.

Figure 67. Eggs of *Dactylobiotus dispar*. Photo by Martin Mach, with permission.

During encystment, new cuticular structures are synthesized (Guidetti *et al.* 2006). Encystment starts with the discharge of the sclerified portions of the buccal-pharyngeal apparatus without the loss of cuticle. Rather, they produce two or three new cuticles. In *Bertolanius* [= *Amphibolus*] *volubilis* (Figure 69), the new cuticle is similar to that found on the non-encysted organisms, whereas in *Dactylobiotus parthenogeneticus* (Figure 70-Figure 72) the ultrastructure of the new cuticle differs. The tardigrade retracts within the cuticle (Nelson 1991a).

Figure 68. Egg of *Dactylobiotus dispar*. Photo by Martin Mach, with permission.

Tardigrade encystment is known for only a few species, although it may be more widespread than is currently known. There are at least three types of cysts (Guidetti *et al.* 2006). *Bertolanius volubilis* has two types (Figure 69); *Dactylobiotus parthenogeneticus* (Figure 70-Figure 72) exhibits only one. Having two types of cysts in the same species seems to be a terrestrial character (Bertolani *et al.* 2004). Type 2 cysts have an additional layer of cuticle compared to type 1 cysts. Although only a few species have been described, it appears that a type 1 cyst never shows a modified buccal-pharyngeal apparatus, whereas a type 2 cyst does.

Figure 69. **Upper:** Type 1 cyst. **Lower:** Type 2 cyst (surrounded by several layers of cuticle), both of *Bertolanius volubilis*. Photos by Roberto Bertolani in Bertolani *et al.* 2004, reproduced with permission.

Figure 70. *Dactylobiotus* sp., a member of a genus with only one type of diapause. Photo by Yuuji Tsukii, with permission.

Figure 71. *Dactylobiotus* sp., a tardigrade with only one type of diapause cyst. Photo by Martin Mach, with permission.

Figure 72. *Dactylobiotus* sp. cyst. Photo by Roberto Bertolani in Bertolani *et al.* 2004, reproduced with permission.

Conditions that cause emergence from the cysts are not understood. Unlike those in an anhydrobiotic state, the encysted tardigrades are not drought-resistant. Nor can they withstand high temperatures, because they have continuous water content. Nevertheless, the cysts can survive in nature for more than a year on their food reserves (Westh & Kristensen 1992).

Using the tardigrade *Bertolanius volubilis* (Figure 69) from the mosses *Racomitrium sudeticum* (Figure 73) and *R. elongatum* (Figure 74) on sandstone in the Northern Apennines of Italy, Guidetti *et al.* (2008) examined the factors involved in the inducement of diapause. They learned that in *B. volubilis* the type of diapause cysts produced in April differed from those produced in November. The April cysts are produced during a warm season, whereas the other type is present during the cold season. Temperature is responsible for induction, maintenance, and termination of the cyst. Both exogenous (temperature) and endogenous (physiological) factors serve as stimuli.

Eggs

Eggs that are laid externally are typically ornamented (Figure 75-Figure 76) (Nelson 1991a). These may be laid singly or in groups.

Figure 75. Egg of a tardigrade, a stage that helps it survive desiccation. Photo by Martin Mach, with permission.

As already noted, eggs can provide a long-lasting escape from unfavorable conditions. At least some tardigrades can produce both **subitaneous** (non-resting) and **resting eggs** (Bertolani *et al.* 2004). Altiero *et al.* (2009) examined the eggs of *Paramacrobiotus richtersi* (Figure 17) and found that the percentage of hatching was high (75-93%), but that four different patterns were discernible. Subitaneous eggs hatched in 30-40 days. Delayed hatching eggs hatched in 41-62 days. Some eggs required 90 days or more if the culture was wet and 13% of these (**diapause resting eggs**) required a dry period followed by rehydration. The remainder (87% of this last >90-day category) never hatched. They considered this variable hatching time to be a form of **bet-hedging**.

Migration?

Anhydrobiosis is not the only strategy available to organisms to escape drying conditions. Some organisms migrate to deeper levels of the moss or soil to escape

drought. However, it appears that this option might not be available to many of the slow-moving tardigrades.

Wright (1991) found that those tardigrades living in the interstices of the moss habitat migrate vertically to the **soil C-zone** (layer just above bedrock) as a means of escaping or slowing desiccation. The exception to this behavior is *Echiniscus testudo* (Figure 5).

Nelson and Adkins (2001) examined this depth relationship in cushions of the moss *Schistidium rivulare* (= *Grimmia alpicola*; Figure 77). They found that among five species, only one (*Echiniscus viridissimus*) was more frequent in the top layer, regardless of the wet or dry condition of the moss. (Hmmm... Could the green that gives it its name indicate it has a photosynthetic symbiont that requires light, or just a penchant for green food?)

Nelson and Adkins (2001) concluded that none of the *Schistidium* (Figure 77) inhabitants used migration as a means to escape reduction in moisture. They speculated that for tardigrade inhabitants of xeric mosses, there was no advantage to migration. Rather, they stayed put and went into a state of anhydrobiosis in both upper and lower layers.

Figure 77. *Schistidium rivulare*, a moss where excessive hydration can cause death to its tardigrade inhabitants. Photo by Michael Lüth, with permission.

Summary

Tardigrades (water bears) are common in both aquatic and terrestrial bryophytes. The land dwellers require a water film and thus are called **limnoterrestrial** tardigrades. Despite their worldwide distribution, they are not well known.

The bryophyte habitat offers sufficient oxygen, wetting and drying, sufficient food, a dispersal vehicle, and protection. Moisture is probably the most important factor in their distribution. Species of bryophytes do not seem to affect the types of tardigrades species.

Tardigrades are adapted to the bryophyte habitat by their small size, stylets that permit sucking contents from bryophyte cells, flexible bodies, and a very responsive life cycle. Colored **pigments** in some may offer UV protection, especially during dry periods. Tardigrades can **encyst** or go into a **cryptobiotic** state as a **tun**. Cysts may differ between summer and winter. Tardigrades must dry slowly to survive the cryptobiotic

state. While in it, they are resistant to high and low temperature extremes, absence of water, extreme pressure, vacuum, and radiation. **Anhydrobiosis** is induced by diminishing hydration; **cryobiosis** is induced by low temperatures near 0°C; **osmobiosis** is induced by a change in salinity; **anoxybiosis** is induced by low oxygen. Tardigrades form **trehaloses** that protect the cell membranes while dehydrated or at low temperatures. They typically can survive about 10 years in the tun, but one specimen resumed physiological activity after 120 years on a herbarium moss specimen, then died. Nevertheless, **DNA damage** accumulates during cryptobiosis; survival seems to be based on **DNA repair**. Furthermore, high temperatures and high humidity destroy trehalose.

Another means of long-term survival is by producing resistant eggs. Variable hatching times may provide a form of **bet-hedging** in some species.

Acknowledgments

Like all of my chapters, this one is really the product of the efforts of many biologists. Roberto Bertolani provided an invaluable update to the tardigrade taxonomic names, offered several suggestions on the text to provide clarification or correct errors, and obtained permission to use his published photographs from the Journal of Limnology. Paul Davison and Des Callahan have been helpful in providing suggestions and offering images. Filipe Osorio has sent me images several times, thinking of this project even when I was not soliciting help. Martin Mach and Yuuji Tsukii have given permission to use their many images that illustrate the species and life cycle stages. Martin Mach's website has been invaluable. Łukasz Kaczmarek has provided me with references, images, contact information, and many valuable comments on early stages of the manuscript. Martin Mach was kind enough to send me corrections for typos in the previous online version. Marty Janners and Eileen Dumire provided me with the views of two novices in the readability of the text. Thank you to Michael Lüth for permission to use his many images and to all those who have contributed their images to Wikimedia Commons and other public domain sites for all to use. I fear I have forgotten some who have helped – I have worked on this chapter for too many years!

CHAPTER 5-2

TARDIGRADE REPRODUCTION AND FOOD

Figure 1. *Echiniscus*, a parthenogenetic genus with at least 146 described species (Guidetti & Bertolani 2005). This genus is common on bryophytes and reproduces there. Photo by Martin Mach, with permission.

Life Cycle and Reproductive Strategies

One means by which organisms survive in such changeable habitats as bryophytes is by progressing to a different life cycle stage to wait out the storm – or lack of one. Tardigrades are especially adept at this, as seen in Chapter 5-1 (diapause and cryptobiosis). In tardigrades, diapause and cryptobiosis can occur at any time and developmental stage. Here we will look at reproduction and its role in further providing an escape route, at least for the species, if not the individual, an even that often occurs on bryophytes (Figure 1).

Hofmann (1987) considers that tardigrades must be able to reproduce quickly and in sufficient numbers when conditions are favorable because their life style is one of intermittent activity and inactivity, the latter in either a state of dormancy or cryptobiosis. This constraint of brief reproductive periods and the necessity for a few individuals to have sufficient offspring makes them **r-strategists**. They lack a defined carrying capacity and the population density is dependent upon the length of time since establishment in that location.

Life history of tardigrades can differ among species, presumably providing somewhat different adaptive strategies. For example, *Paramacrobiotus tonollii* (Figure 2) requires 16 days for its embryonic development whereas

Macrobiotus sapiens requires only 12 days (Lemloh *et al.* 2011). *Paramacrobiotus tonollii* is larger than *M. sapiens* but the latter has a longer life span of 83 days.

Figure 2. *Paramacrobiotus tonollii*. Photo by Paul Bartels, with permission.

Reproductive Strategies and Habitat

Reproductive mechanisms do differ among tardigrades in different habitats (Bertolani 2001). Those living among bryophytes, as well as those of freshwater, leaf litter, and soil, commonly are **parthenogenetic** (Figure 1), or more rarely **hermaphrodites** that self-fertilize. Marine species, on the other hand, have separate sexes. Bertolani hypothesized that organisms living in isolated and unstable habitats (including bryophytes) have evolved **cryptobiosis**, **parthenogenesis**, **self-fertilization**, and **passive dispersal**, benefitting them in their challenging living conditions.

Passive wind dispersal of tardigrades with mosses is already known and may be their primary dispersal strategy (Pilato 1979). As is common among many mosses, those tardigrades that have **parthenogenesis** (equivalent to vegetative reproduction in mosses, *i.e.* reproduction without males) do not also have self-fertilization. These reproductive strategies, as in bryophytes, permit tardigrades to reproduce when only one individual, or its egg (Figure 3), arrives to colonize a new location.

Figure 3. Eggs of a species of *Dactylobiotus*. The clustering of eggs may be beneficial in protecting each other, but their inherent resistance to almost everything suggests that is probably not important. Photo by Yuuji Tsukii, with permission.

Dispersal in tardigrades seems independent of the tardigrade because it is passive dispersal. But Bertolani *et al.* (1990) considered that the differences in distribution and frequency of members of the genus *Ramazzottius* relate to their differences in reproductive modes. In their study of *Ramazzottius* species on bryophytes and lichens, they found that the sex ratio was strongly influenced by the type of reproduction, but also differed when samples were collected from tree trunks and limited rocky areas versus extensive rocky outcrops. Bertolani *et al.* found that bryophyte-dwelling *Ramazzottius* tardigrades from tree trunks or slightly rocky areas exhibited parthenogenesis and absence of male tardigrades. Among the rocky outcrops, there were always at least some males, although some parthenogenesis still occurred. Males are only useful if there is sufficient opportunity for contact with females. Perhaps the rocky outcrops provided less of a labyrinth and permitted the needed contact? Eggs provide light-weight, windborne propagules to disperse the species (Figure 3).

[To clarify for botanists, some references tend to use the term egg for the zygote and sometimes even the developing organism (embryo) until it has hatched, like the hatching of a bird egg. Since I found the term egg used in my references, I shall use egg here as well.]

Eggs

Depending on the species, there are two ways tardigrade eggs (including embryos) may be deposited. Some lay free eggs on their substrate (Figure 3), but others deposit them in the shed **exuvia** of a molt (Mach: The Water Bear; Figure 4).

Figure 4. A number of eggs can develop within one shed **exuvia**, as shown here for *Hipsibius* sp. Photo by Yuuji Tsukii, with permission.

Macrobiotus hufelandi (Figure 5) has two sexes – males do exist (Figure 5) (Mach 2010). It is one of the species having free eggs (Figure 6). Eggs deposited outside the exuviae generally have decorative processes (Figure 7) (Mach 2010). Kinchin (1994) suggests that the functions of the egg processes include anchorage of the egg to a substrate or a transporting medium, defensive structure against being eaten by other animals, water reservoir which slows down the desiccation process, and regulation of gas exchange between egg and environment.

Figure 5. *Macrobiotus hufelandi* male. Photo by Martin Mach, with permission.

Figure 7. Egg of *Macrobiotus* sp., demonstrating the highly decorative surface that is typical of eggs laid free of the organism. Photo by Martin Mach, with permission.

When healthy adult tardigrades discard their outer covering, many taxa deposit eggs in these shed **exuviae** (outer "skins") (Figure 8-Figure 11) (Bertolani *et al.* 2009). The eggs may be few or many (up to 30-40) and may differ even within the same species, as can be seen for *Milnesium tardigradum* in Figure 9-Figure 11 (Altiero *et al.* 2006). The number of eggs depends on the species, but also on the nutritional status of the individual female (Mach: The Water Bear). And it seems that some bears may even ingest their own eggs to improve their nutritional status.

Egg development is poorly known. In *Paramacrobiotus* [= *Macrobiotus*] *richtersi* (Figure 12) it can be prolonged to 90 days or more if the eggs undergo desiccation and become resting eggs (Altiero *et al.* 2009). The non-resting (**subitaneous**) eggs may hatch in as little as 30-40 days.

Figure 8. These eggs reside in the shed exuvial "armor" of the parent and permit the tardigrade species to survive winter and desiccation. Photo by Martin Mach, with permission.

Figure 11. Developed eggs of *Milnesium tardigradum* with the buccal apparatus visible, indicating nearness to maturity. Photo by Martin Mach, with permission.

Figure 12. *Paramacrobiotus richtersi*. Photo from Science Photo Library, through Creative Commons.

The eggs generally develop within the exuvia until the fully-formed tardigrade is ready to leave the egg, as shown here for individuals in the genus *Echiniscus* (Figure 13-Figure 19), requiring several weeks for completion (Mach: The Water Bear). The eggs are able to survive the same drying conditions as the adult; development stops during that dry state. The young tardigrades resemble the adults (Figure 20-Figure 23), but are smaller, requiring a series of molts as they grow. Growth occurs by cell enlargement rather than by addition of cells. Since the eggs often remain in the exuvia until they hatch (Figure 21), size would tend to reduce wind-dispersal of the pollen-grain-sized eggs except when they are dispersed along with a substrate such as mosses.

Figure 18. This mature "egg" of *Echiniscus* can be found among bryophytes, and its smooth surface is typical of eggs that are kept within the exuvia. Note the buccal apparatus that signifies its late developmental stage. Photo by Martin Mach, with permission.

In soil-dwelling *Paramacrobiotus richtersi* (Figure 12; also a known bryophyte dweller), temperature played a role in rate of development, survival rate, body growth, and generation time (Figure 24; Hohberg 2006). On the other hand, hatching time, first to fourth molts, and maturation time were dependent upon body size alone.

Figure 19. *Echiniscus* hatching from its eggs. Photo by Martin Mach, with permission.

Figure 22. *Echiniscus* young and old. Note the long "hairs" extending from the body, giving the genus its name. Photo by Martin Mach, with permission.

Figure 23. *Echiniscus* young. Photo by Martin Mach, with permission.

Some tardigrades have found another safe site for their eggs. They can use the capsule of a moss as an egg depository (Mach: The Water Bear; Figure 25-Figure 26).

Figure 24. Effects of temperature on the development of *Paramacrobrius richtersi* (Figure 12), starting with the day the tardigrades hatched. Body lengths are for hatching and first oviposition only. Redrawn from Hohberg (2006).

Figure 26. This egg is protected by a moss capsule. Based on the decorations on the eggs, they appear to be close to *Macrobiotus hufelandi*. Photos by Martin Mach, with permission.

Molting

Like its relatives in the Arthropoda, the tardigrade must **molt** (Figure 27-Figure 35). This process usually requires 5-10 days and occurs several times throughout its life (Walz 1982), including after sexual maturity while the body is still increasing in size (Nelson 1982). During molting, the old cuticle, claws, and lining of the fore- and hindgut are shed (Figure 28), causing a stage known as the **simplex** stage (Figure 35). Lacking its sclerified parts of the buccal-pharyngeal apparatus, the tardigrade cannot feed. It appears that tardigrades molt 4-12 times during their 3-30 months of active lives (Nelson 2002).

Figure 29. Eggs in the shed exuvia of *Milnesium tardigradum*. Photo by Martin Mach, with permission.

Figure 30. *Milnesium tardigradum* eggs in its shed exuvia. Photo by Martin Mach, with permission.

Cyclomorphosis

It appears that **cyclomorphosis** (annual cycle of morphological change) occurs in tardigrades, although it has been demonstrated in only a few species. It has been documented in the marine species *Halobiotus crispae* (Kristensen 1982; Halberg *et al.* 2009). Likewise, Dastych (1993) demonstrated cyclomorphosis in a cryoconite-dwelling species of *Hypsibius* (Figure 31), and in a bryophyte dweller. Furthermore, Rebecchi and Bertolani (1994) did demonstrate it for one species in the genus *Bertolanius* [= *Amphibolus*] (Figure 33), which does have moss-dwelling species.

Kristensen (1982) studied the marine *Halobiotus crispae* cycle and found two morphs. In winter there is a **pseudosimplex** stage that hibernates and is sexually immature. These winter forms gather in large **aggregations** in protected areas where the aggregations increase chances for survival of the freezing temperatures. The population experiences synchronous development of gonads, hence all reaching sexual maturity and breeding simultaneously. But the cycle for other taxa and habitats, including bryophytes, remains to be explored (Nelson 2002).

Bryophytes as Food Reservoirs

Bryophyte-dwelling tardigrades include both bryophyte-eating tardigrades and those with a variety of other feeding strategies, including carnivory. The tardigrade has a specially adapted pair of **stylets** (Figure 49) and a muscular pharynx (Figure 50-Figure 52) that produces a suction into the gut, permitting the tardigrade to suck fluids from the interior of a bryophyte or algal cell (Figure 53) or even small animals such as rotifers (Figure 54) and nematodes [Tardigrada (Water Bears) 2005]. In the family Echiniscidae (Figure 36), a common family on

bryophytes, the stylet may be very long, permitting penetration of the thick cellulose walls of bryophytes. For example, *Echiniscus testudo* (Figure 37) feeds primarily on bryophytes (Morgan 1977). *Diphascon* (Figure 52), also a bryophyte dweller, has a flexible buccal tube with spiral rings resembling the extension on a vacuum cleaner. Small bryophyte dwellers may subsist on diatoms and bacteria that live epiphytically among the bryophytes [Bartels 2005; Tardigrada (Water Bears) 2005].

Figure 37. *Echiniscus testudo* tun. Photo by Power & Syred through Creative Commons.

Schill *et al.* (2011) consider the bryophytes to be a "rich food supply for both carnivorous and herbivorous species." These food sources include nematodes, rotifers, plant cells, algae (Figure 38), yeast, and bacteria, and for some, bryophytes. Schill and coworkers conducted a genetic tracer study (*rbcL*) on the guts of tardigrade species from various sites in Europe that demonstrated the presence of mosses from the **Erpodiaceae** [*Aulacopilum hodgkinsoniae*, *Venturiella sinensis* (Figure 39)] and **Pottiaceae** [*Syntrichia* (= *Tortula*) *obtusissima* (Figure 40)] in the guts of field-collected *Macrobiotus sapiens*, **Grimmiaceae** [*Grimmia elongata* (Figure 41), *Coscinodon cribrosus* (Figure 42), *Schistidium strictum* (Figure 43)] from *Macrobiotus persimilis* and *Echiniscus granulatus*, and the green alga *Trebouxia* (Figure 44) from *Richtersius coronifer* (Figure 38). For *Macrobiotus sapiens* they found no *rbcL* sequence demonstrating presence of the families **Pottiaceae** or **Orthotrichaceae**. It appears that *Macrobiotus sapiens* will only eat these latter two moss families when **Grimmiaceae** is not available, or that others had been digested completely before samples were extracted. The small tardigrade stylet makes it difficult for them to obtain cell contents from the moss genera *Polytrichum* (Figure 45), *Dicranum* (Figure 46), *Leucobryum* (Figure 47), and *Racomitrium* (Figure 48). Digestion in tardigrades is aided by the gut pH, with the foregut having an acidic environment and the midgut having a basic environment (Marcus 1928).

Figure 49. *Echiniscus* with the stylets protruding (out of focus). Photo by Martin Mach, with permission.

Tardigrades even consume smaller tardigrades. Larger species such as those of *Macrobiotus* (Figure 5) and *Milnesium* (Figure 9, Figure 51) consume smaller members such as *Diphascion* (Figure 52) and *Hypsibius* (Figure 64), as exhibited by remains of claws and buccal apparatus (Figure 57) in the gut (Nelson 2002). Large carnivorous Eutardigrada such as *Paramacrobiotus richtersi* (Figure 12), *Milnesium tardigradum* (Figure 9, Figure 10, Figure 51, Figure 54), and *Bertolanius*

nebulosus are widespread in many habitats, including bryophytes [Tardigrada (Water Bears) 2005]. They eat nematodes, rotifers, and smaller tardigrades, but still use the stylet to suck out cell contents. Suzuki (2003) reared *Milnesium tardigradum* from the moss *Bryum argenteum* (Figure 55), using only rotifers [*Lecane inermis*, common in wet *Sphagnum* (Miller 1931)] as food.

Figure 50. This tardigrade has the stylets withdrawn into its head. The pharynx is in the center behind the stylets. Photo by Paul Davison, with permission.

Figure 55. *Bryum argenteum*, a moss known to house *Milnesium tardigradum*. Photo by Michael Lüth, with permission.

Suren (1988) attempted to determine the importance of bryophytes as food vs. simply substrate by using artificial mosses in high alpine New Zealand streams. When artificial structures were used, similar communities of invertebrates developed, but tardigrades appeared to be affected negatively by the absence of the bryophytes, a

difference Suren interpreted to reflect a loss of bryophytes as a food source. It seems to be one of the few animals specifically adapted to obtaining the good stuff from the insides of the cells of bryophytes. Its stylets (Figure 49-Figure 50) serve as a miniature needle and straw to puncture the cell and suck the nutrients from it. The pharynx (Figure 52) serves as a pump to draw fluids in through the stylets (Tardigrades, Bears of the Moss).

It appears that eating bryophytes requires more than just the equipment to suck the good stuff out of the cell. The excretory system seems also to be altered. Węglarska (1990) found that in four genera of tardigrades, those that live among bryophytes have larger excretory organs relative to body size than do the freshwater species. The purpose of this added size remains a mystery.

Ramazzotti and Maucci (1983) suggested that excretion probably occurs in four ways in tardigrades. At molting it occurs through the salivary glands. Likewise, when the cuticle is shed it removes accumulated excretory granules. It can occur through the wall of the midgut. And in the eutardigrades, it occurs through excretory glands. There is no study to determine how these various mechanisms might relate to a diet of bryophytes.

Role in Food Web

As seen above, tardigrades typically are either plant eaters or are carnivorous (Garey *et al.* 2008), including protozoa, nematodes, and rotifers (Figure 54), but also consume bacteria and fungi (Kinchin 1988). As noted in the earlier chapter on nematodes, they can be predators on nematodes that live in the same clump of moss (Sánchez-Moreno *et al.* 2008), making them important consumers and often the top carnivore.

Both *Paramacrobiotus* [= *Macrobiotus*] *richtersi* (Figure 12) and *Macrobiotus harmsworthi* (Figure 56-Figure 57) caused significant declines in the nematode populations, thus regulating the food web. In fact, a single *P. richtersi* dined on an average of 61 nematodes in a day! Unlike many of the slow-walking water bears, these carnivorous water bears are able to move swiftly to attack and devour their prey (Kristensen & Sørensen 2005).

Davison (2005) reports that tardigrades lumber across the substrate, swinging their heads back and forth in search of food. When he offered them nematodes and rotifers, the tardigrades made no attempt to eat them. When he offered them a larger choice, the annelid *Lumbriculus* sp., a genus with known members that inhabit mosses, he found that they immediately approached it and began eating it.

Figure 56. *Macrobiotus harmsworthi*, a nematode predator. Photo by Paul J. Bartels, with permission.

Figure 57. *Macrobotus harmsworthi* buccal apparatus. Photo by Paul Bartels, with permission.

Tardigrade specialists have assumed that the **buccal apparatus** (Figure 58-Figure 60) indicates characteristics of the food, but no studies exist on the relationships of buccal apparati among the limnoterrestrial taxa (Nelson 2002).

Figure 58. The three "filaments" and pharynx are the buccal apparatus of this *Echiniscoides sigismundi*. The **pharynx** resembles a pair of kidneys in contact with the three filaments. The outer two filaments are the stylets; the inner one is the buccal tube. The gut contains algal or plant material that has been ingested by this tidal zone species. Photo by Martin Mach, with permission.

Figure 59. The three "filaments" and oval behind them are the buccal apparatus of *Paramacrobotus* [=Macrobotus] *areolatus*. The bulbous oval to the right of the three filaments (stylets and buccal tube) is the pharynx. Photo by Martin Mach, with permission.

Figure 60. *Dactylobiotus dispar* has a buccal apparatus similar to that of *Paramacrobotus areolatus*. Photo by Martin Mach, with permission.

But tardigrades can have their predators too. Snails that live among the moss leaves could enjoy a meal of tardigrades (Fox 1966). The land snail *Bulimulus guadalupensis* (Figure 61) from Puerto Rico had evidence that all life cycle stages of the tardigrade *Echiniscus molluscorum* (see Figure 62) live in its feces (Fox & Garcia-Moll 1962). It is not clear if these passed unharmed through the gut or if they took advantage of the feces as a food source after defecation. It is even possible that eggs passed through the gut and hatched in the feces.

Figure 61. The land snail *Bulimulus guadalupensis* is a known predator on moss-dwelling tardigrades. Photo by Gary Rosenberg at <www.discoverlife.org>.

Tardigrades have smaller predators as well. The fungus *Ballocephala pedicellata* (Figure 63) is known from the tardigrades *Hypsibius dujardini* (Figure 64) and *Diphyscon pingue* complex (Figure 65) living in the moss *Atrichum angustatum* (Figure 66) (Pohlad & Bernard 1978). In this study, tardigrades with the fungus were only

present in January and February in the collecting area in southeastern USA.

Summary

Life cycle stages often provide a means of surviving changes in the environment. Bryophyte-dwelling tardigrades are usually **parthenogenetic**. They rarely are **hermaphrodites**, and parthenogenetic individuals do not self-fertilize.

Tardigrade species may either lay free eggs or deposit them inside the exuvia as it is shed. External eggs are usually highly decorated, whereas those laid inside the exuvia tend toward smooth. The number of eggs varies up to 40, with the number depending on the species and nutritional status. Time required for development of the fertilized egg may be up to 90 days. Variability in development time permits **bet-hedging**. Temperature affects development rate, survival rate, and body growth, as well as affecting generation time. Young tardigrades resemble the adults and continue to grow by cell enlargement. Molting permits the tardigrade to expand its size and requires 5-10 days during which the tardigrade cannot eat and is less protected. Some species have more than one morph, where the winter morph may form aggregations that enhance survival of freezing conditions.

Tardigrades consume algae, bryophytes, fungi, protozoa, nematodes, rotifers, and smaller tardigrades. In many cases this is accomplished using a **stylet** that forms a straw for sucking cell contents. They suck in their prey with the pair of stylets, with the muscular pharynx producing suction. For whatever reason, bryophyte dwellers also have larger excretory organs than do tardigrades of other substrata.

They play an important role in regulating the food web of bryophytes in some circumstances. Tardigrades are subject to predation by snails and even larger tardigrades. Fungi may extract nutrition from them.

Acknowledgments

Like all of my chapters, this one is really the product of the efforts of many biologists. Roberto Bertolani provided an invaluable update to the tardigrade taxonomic names and offered several suggestions on the text to provide clarification or correct errors. Bryonettors have been wonderful in making their photographs available to me and seeking photographs from others. Paul Davison has been helpful in providing suggestions and offering images. Martin Mach and Yuuji Tsukii have given permission to use images that illustrate the species and life cycle stages. Łukasz Kaczmarek has provided me with references and contact information. Claudio Delgadillo was kind enough to take the picture of *Syntrichia obtusissima* just for this chapter. Martin Mach was kind enough to send me corrections for typos in the previous online version. My sister, Eileen Dumire, read and edited an earlier version of the chapter for me from the viewpoint of a non-biologist. And a big thank you goes to Michael Lüth for permission to use his many images and to all those who have contributed their images to Wikimedia Commons for all to use. I fear I have forgotten some who have helped – I have worked on this chapter for too many years.

CHAPTER 5-3

TARDIGRADE HABITATS

Figure 1. *Echiniscus* sp., member of a genus that is common on bryophytes. Photo by Martin Mach, with permission.

Bryophyte Habitats

Tardigrades exist in both aquatic and terrestrial habitats worldwide, and in both cases can be found with bryophytes (Figure 1) (and lichens and leaf litter) (Utsugi *et al.* 1997). The tropics seem unfavorable (Mathews 1938), perhaps for the same reasons that temperate stream bryophytes are uncommon in lowland tropical waters – they are warm and wet at the same time, encouraging bacterial and fungal growth.

Most of the more than 900 known tardigrade species are **limnoterrestrial** (Garey *et al.* 2008). That is, they live in a thin surface film of water, most commonly on bryophytes, lichens, algae, and other plants. They can only remain active while this film of water exists. Of the 910 species reviewed by Garey *et al.* (2008), only 62 species, in 13 genera, are truly aquatic and unknown from limnoterrestrial habitats. Nevertheless, many of the limnoterrestrial species can at least occasionally be found in freshwater. In these terrestrial habitats, pH of the substrate, oxygen tension, moisture content of the bryophyte, thickness of the bryophyte mat or cushion, and altitude (and its attendant conditions) all contribute to the habitat distribution.

I have taken the liberty of changing the word "moss," used in many tardigrade studies, to "bryophyte." I have

learned from one of my kind tardigrade reviewers that people who study tardigrades often do not understand leafy liverworts and lump them into mosses. Hence, unless I could determine that the researcher definitely had in mind only mosses (and not also liverworts), I used the term bryophytes. I also learned that many ecologists include mosses in the category of "soil"! Others include them in "litter." While this lumping can be a useful concept for some aspects of functional ecology, one needs to be aware of it when searching for bryological literature or interpreting soil literature.

Tardigrades are especially common on tree bark bryophytes (**epiphytes**), presumably due to having similar tolerances to drying (Crum 1976). They are known from all seven continents and up to 6600 m altitude in the Himalayas (Ehrenberg 1859 in Fontoura *et al.* 2009). Collins and Bateman (2001) examined factors affecting tardigrade distribution in Newfoundland and learned that in this case altitude and type of bedrock were important in determining tardigrade distribution. Moisture and rate of drying further defined their distribution. And in some cases, competitive exclusion or interspecific competition seemed to be determining factors for community composition.

Specificity

Species assemblages seem to be similar throughout the world. Is this due to lack of taxonomic understanding or to widespread dispersal? In the following sections we will examine what we know about factors affecting tardigrade communities under different circumstances.

It appears that many tardigrades have little preference for bryophytes versus lichens (Meyer & Hinton 2007). But even those cryptogams, supporting their wet-dry requirements, are usually not unique habitats for the tardigrades, with the same species of bryophytes and lichens also present in soil, leaf litter, and additional habitats. Several studies have attempted to show any species preferences for bryophytes, but typically with no success (Kathman & Cross 1991; Miller & Heatwole 1995; Meyer & Hinton 2007). Further evidence of non-specificity is in their distribution. Meyer and Hinton (2007) report that the Nearctic realm shares 82 species of tardigrade with the Neotropical realm. Everything is everywhere! On the other hand, 30% of the Nearctic species are known from only one site. One of the problems in describing the tardigrade habitat is that substrate records are inconsistent or absent for many collections.

But some studies have indicated that lichens and mosses may be preferred over other substrata. Working in China, Beasley *et al.* (2006) found 18 species of tardigrades from three provinces, primarily in lichens and bryophytes.

One of the most common tardigrades among bryophytes is *Milnesium tardigradum* (Figure 21) and the less common *Macrobiotus hibiscus*. Hinton and Meyer (2008) reported these among liverworts (*Jungermannia* sp.; Figure 2) in a suburban lawn in central Georgia (USA).

Figure 2. *Jungermannia atrovirens*, member of a genus where tardigrades have been found in a lawn in Georgia, USA. Photo by Michael Lüth, with permission.

Liverworts are rarely mentioned in tardigrade studies. However, Hinton and Meyer (2007) reported *Echiniscus virginicus* and *Milnesium tardigradum* from liverworts. In their study, they collected handfuls of mosses, liverworts, and lichens from 54 parishes in Louisiana, USA. They found 51 species in the region: 19 in Texas, 16 in Louisiana, 10 in Mississippi, 33 in Alabama, 3 in Georgia, and 15 in Florida. Of these 51 cryptogam dwellers, 20 are widely distributed in the region and 18 are

apparently cosmopolitan. Hinton and Meyer suggested that *Biserovus bindae*, *Echiniscus cavagnaroi*, *Echiniscus kofordi*, *Hexapodibius christenberryae*, *Minibiotus fallax*, and *Parhexapodibius pilatoi*, along with a new variant of *Macrobiotus* cf. *hufelandi*, may represent a distinctive southeastern USA regional fauna living among cryptogams. On the other hand, *Echiniscus cavagnaroi* and *Echiniscus kofordi* are known only in the Neotropical Region and in the Galapagos Islands, but *Minibiotus fallax* was described in Australia. These three species are frequently encountered in mosses and lichens.

Habitat Differences

Several tardigrade researchers have considered five types of bryophyte habitats (Mihelčič 1954/55, 1963; Ramazzotti 1962; Hofmann 1987):

- bryophytes that are submerged
- bryophytes that are permanently moist
- bryophytes growing in shady places and rarely dry
- bryophytes that dry out frequently and receive direct sunlight regularly
- bryophytes that are extremely exposed and often dry for a longer period.

Ito (1999) was able to identify six groupings of tardigrades, based on habitat preference, in his altitudinal study on Mt. Fuji, Japan. Kaczmarek *et al.* (2011) likewise found altitudinal relationships in Costa Rica. They furthermore found a higher diversity among mosses than among lichens or liverworts, although they admitted to a possible bias due to unequal sampling. Tardigrades from these substrates were most common from 2000 to 2400 m asl and above 3200 m asl.

Tardigrades do not have much control over their dispersal, typically depending on dispersal of the substrate. This may help to explain the observations on two morphotypes of the moss *Grimmia*. In this case, the tardigrade distribution was very patchy. There were no differences in distribution patterns on the two *Grimmia* morphotypes, despite their representation of different moisture conditions (Bettis 2008). Bettis suggested that the greater rainfall during the winter of observation might account for the lack of difference. But tardigrades are well known for their great tolerance of extremes, so their greatest limitation may be dispersal.

Acid or Alkaline?

Bartels (2005) reported greater diversity in limestone habitats than elsewhere. It appears that acid can be an uncomfortable or lethal milieu. *Hypsibius dujardini* (Figure 13) had reduced activity after only five minutes at pH 3 and died at pH 2.8. Even at pH 4.0, it had reduced activity after 30 hours.

But in Giessen, Germany, Hofmann (1987) found a somewhat different relationship. The four most abundant species [*Macrobiotus hufelandi* (Figure 7), *Ramazzottius* (formerly in *Hypsibius*) *oberhaeuseri* (Figure 3), *Milnesium tardigradum* (Figure 21), and *Echiniscus testudo* (Figure 4)] had similar preferences for alkaline substrata, but the remaining species, as a group, had a preference for the acidic habitats, thus presenting greater tardigrade species diversity among the acid substrata and the mosses that inhabited them.

Figure 3. *Ramazzottius oberhaeuseri*, a bryophyte dweller that cannot tolerate constant moisture. Photo by Martin Mach, with permission.

Hingley (1993) found only two genera in her acid peatland studies: *Diphascon* (*D. scoticum*) (Figure 29) and *Macrobiotus* (Figure 6). To that Pilato (2009) added *Bindius triquetrus* from *Sphagnum* (Figure 5) in Sicily. Distribution is patchy (Romano *et al.* 2001), requiring greater sampling effort. One must wonder, is the paucity of reports of aquatic tardigrades on bryophytes a realistic representation of a meager aquatic fauna, or are there simply too few studies that have looked for them?

Figure 4. *Echiniscus testudo* tun on a bryophyte leaf. Photo by Power & Syred, through Creative Commons.

Figure 5. *Sphagnum fuscum*, a species that forms hummocks where a tardigrade could find moisture but usually avoid being flooded. Photo by Michael Lüth, with permission.

Altitude

Many researchers have shown a relationship between altitude and the distribution of tardigrades (Rodríguez-Roda 1951; Nelson 1973, 1975; Ramazzotti & Maucci 1983; Dastych 1985, 1987, 1988; Beasley 1988), suggesting that species richness increases with altitude. Bertolani and Rebecchi (1996) found that some species were typical of high altitudes or latitudes. Some researchers have even classified the tardigrades based on

altitudinal groupings (lowland, upland, montane, etc.) (Ramazzotti & Maucci 1983; Dastych 1987, 1988). Collins and Bateman (2001) found that in Newfoundland, Canada, the lowland class could be further divided into locations up to 100 m and those above (101-200 m).

Table 1 compares the altitudinal abundance of 45 species of tardigrades associated with bryophytes on mountains in British Columbia, Canada (~48-60°N), with those of **riparian** epiphytes (inhabiting trees on banks of natural water courses) in Alabama, USA (~33°N). Although the latitudes are quite different, six species are common to both, but six species differ. The three most abundant Alabama species were common to both, but the very common *Macrobiotus hufelandi* (Figure 7) was absent in the Alabama collections. These data suggest that there may be more than just chance determining the species and abundance differences.

But not all altitudinal studies have supported these conclusions (*e.g.* Kathman & Cross 1991). It is interesting that Meininger and Spatt (1988) found that altitude was not influential in determining distribution and abundance of moss-dwelling tardigrades in Alaska, USA. Likewise, Guil *et al.* (2009) found that the altitudinal differences could be explained by differences in soil, climate, vegetation structure, and litter type. Nevertheless, Ramazzotti and Maucci (1983) considered certain species to occur only above 500 m. This may simply be a lack of sufficient collecting – they claimed that *Macrobiotus harmsworthi* (Figure 6) was one of these "montane" species, but Dastych (1985) later reported it from locations between 0 and 1100 m altitude on Spitsbergen Island, Norway. Furthermore, Dastych (1980, 1988), showed a large correlation between Tardigrada species and altitude in the Tatra Mountains in Poland. Certainly latitude must be considered in making comparisons of altitude. And local moisture regimes are likely to play a major role in altitudinal relationships.

Using PCA analysis, Kathman and Cross (1991) also reported no relationship between altitude and abundance on Vancouver Island, British Columbia, on the western coast of Canada (Table 1 suggests a decreasing trend in number of individuals might be present). Collins and Bateman (2001) later reported that altitude was one of the major determining factors in tardigrade distribution in Newfoundland, eastern coast of Canada. Rodriguez-Roda (1951 in Kathman & Cross 1991) found that altitude had a distinct effect on the abundance of tardigrades in Spain, with numbers increasing with altitude and reaching a maximum between 1000 and 2000 m. Dastych (1980) likewise found that tardigrades in the Tatra Mountains of Poland increased with altitude, again with the maximum numbers between 1000 and 2000 m. In one of his later studies, Dastych (1985) reported a seemingly opposite effect, demonstrating that the number of species and individuals decreased with increasing altitude in West Spitsbergen, Norway. The differences between studies may be a matter of scale and the fact that only some species are affected by altitude within the study range, but moisture regimes are likely to differ as well.

Nelson (1973, 1975) found that only seven of the 21 bryophyte-dwelling species on Roan Mountain, Tennessee, USA, were affected by altitude. Bertrand (1975) found three altitudinal groups in the Aigoual Mountains of France. Beasley (1988) divided the tardigrades from 1052-3567 m in New Mexico, USA, into altitudinal ranges. Ito (1999) examined tardigrades at 17 stations on Mt. Fuji, Japan, finding little distributional pattern related to altitude (950-2380 m). Rather, the distribution related to habitat.

Collins and Bateman (2001) found that tardigrades of Newfoundland, Canada, were affected by both altitude (Table 2) and type of bedrock, but that moisture content and rate of desiccation of the mosses and lichens where they live also contributed to their distributional pattern.

Table 2. Decline in number of species with increasing altitude in Newfoundland. From Collins and Bateman 2001.

Altitude	Total number of species found at each altitude	Mean number of tardigrade species at each site
0->100 m	28	2.75
101->200 m	15	1.75
200+ m	8	1.88

Differences in techniques, lack of or differences in statistical analyses to support purported differences, and misidentification could contribute to the apparent differences in relationships among these studies, but moisture regimes most likely play a major role. In some cases, competitive exclusion appears to play a role (Collins & Bateman 2001). Nevertheless, it is likely that the effect of altitude, if it exists, depends in part on both latitude and scale.

Polar Bryophytes

Because of their relative abundance, and the predominance of mosses and lichens in the Antarctic flora,

we have learned some interesting aspects of their faunal ecology and physiology there.

As early as 1976, 23 species of tardigrades were known from Antarctica (Jennings 1976). That's not bad for that early date in a place with limited vegetation, harsh climate, and limited opportunity for collecting, not to mention the distance to be travelled for colonization. Most of these tardigrade species have worldwide distribution (Venkataraman 1998). In the short Antarctic summers, the tardigrades multiply quickly, using parthenogenesis.

Unlike most habitats elsewhere, the tardigrades in the Antarctic moss turf do exhibit a vertical zonation pattern. Schwarz *et al.* (1993) found that protozoa, rotifers, nematodes, and tardigrades dominated the moss-dominated flushes at Canada Glacier, southern Victoria Land, Antarctica. Mites were of less importance. These invertebrates occurred in the range of 5 to 10.83 mm depth in the moss clumps. Post melt samples had a greater percentage of all groups of organisms in the upper 5 mm of mosses compared to those at that depth range in the pre-melt samples, suggesting either migration or rapid reproduction once melting occurred.

Venkataraman (1998), in clumps of *Bryum argenteum* (Figure 9) from continental Antarctica, found that the tardigrades only live down to 15 cm depth in the 30 cm deep turfs. If they prefer to eat rotifers, they can only find those down to 10 cm. Their slow movement could limit the distance they can reasonably move downward and still return for food in a timely manner. Ramazzotti (1972) estimated that tardigrades could travel an average of 17.7 cm h⁻¹, seemingly enough speed to travel another 10 cm, but perhaps not in the cold and not during the daytime feeding period when downward movement would be most beneficial to avoid drying.

Temperature may play a role in the zonation of these Antarctic bryophytes. Bryophyte temperatures in the Antarctic can differ considerably from those of the air and may provide a warm refuge for activity even on cold days. Bryophytes exhibit a sharp temperature zonation on sunny days when there is no snow cover (Jennings 1979). The surface is subject to evaporative cooling in the polar winds while the moss layer immediately below that interface is quiet and often dark in color, absorbing the heat like a black body, as seen by the temperatures shown in Figure 10. Hence, in summer the moss turf has temperatures much higher than that of the air and at the beginning and end of the summer season the temperatures fluctuate around freezing for a considerable time, even if the mosses are snow-covered.

Sohlenius and Boström (2006) described tardigrade communities from moss cushions on four ice-free mountains (nunataks) in Antarctica. Tardigrades occurred in 32% of the 91 samples of mosses. No invertebrates at all occurred in 8% of the samples. They considered stochastic processes (random events) accounted for the uneven colonization of the moss cushions, most likely as a result of random dispersal. They suggested that nematodes seem to offer competition, whereas the rotifers seem to provide a food choice.

Figure 9. *Bryum* sp. cushions in Antarctica, demonstrating the deep turfs that can house tardigrades. Photo courtesy of Catherine Beard.

Tardigrades manage to survive the extreme cold of the long Antarctic winter as a **tun** (see Chapter 4-6). But other physiological adaptations are needed to combat the extremes of temperature that can be experienced in a single Antarctic day (see for example Figure 10).

Both *Bertolanus nebulosus* and *Richtersius coronifer* (Figure 11) endure ice formation as they proceed through the onset of freezing temperatures (Westh & Kristensen 1992). Both are able to supercool to -6 or -7°C before they succumb to freezing. These two tardigrades are common in Polar areas, as well as elsewhere. *Richtersius coronifer* (Figure 11) spends its Arctic winters in drought-resistant mosses as a frozen or dry individual. *Bertolanus nebulosus* has adopted a somewhat different strategy, spending its cold period in moist mosses and algae as a frozen cyst, or occasionally as an egg or adult.

Figure 10. Comparison of moss surface temperature with that of 1.5 cm depth in moss cover on Signy Island in the Antarctic on three days in February, 1973. Redrawn from Jennings 1979.

Figure 11. *Richtersius coronifer*, a tardigrade that survives Arctic winters on mosses in a frozen state. Photo by Martin Mach, with permission.

It appears that adapted tardigrades can survive extreme conditions for a long time. Newsham *et al.* (2006) experimented in a way that might be considered cruelty to animals (but not unlike Mother Nature herself). They partially dried a bit of the leafy liverwort *Cephaloziella varians* from Rothera Point on the Wright Peninsula, Adelaide Island, western Antarctic Peninsula, then stored it frozen at -80°C for six years and two months. They then rapidly thawed the liverwort at 10°C. You guessed it! Tardigrades survived, along with nematodes and a bdelloid rotifer. Only two individuals [*Diphascon* sp. (see Figure 12), *Hypsibius* cf. *dujardini* (Figure 13)] out of fifteen tardigrades (13%) made it, but that is still remarkable! The eleven individuals of *Macrobiotus furciger* (Figure 14) and one of *Echiniscus* sp. did not. Nematodes fared a bit better, with 31% survival out of 159 individuals.

Figure 12. *Diphascon scoticum*, a moss-dwelling representative of a genus in which one member survived storage at -80°C for six years! Photo by Łukasz Kaczmarek, with permission.

Figure 13. *Hypsibius dujardini*, a species that survived -80°C for six years. Photo by Rpgch, through Wikimedia Commons.

Figure 14. *Macrobiotus furciger*. Photo by Smithsonian Institution, through EOL Creative Commons.

Sømme and Terje Meier (1995) examined *Echiniscus jenningsi* (Figure 15), *Macrobiotus furciger* (Figure 14), and *Diphascon chilense* from Mühlig-Hofmannfjella, Dronning Maud Land, Antarctica to ask similar winter survival questions. They compared both hydrated and dehydrated individuals. After 600 days at -22°C , both hydrated and dehydrated tardigrades had high survival rates. After 3040 days, the dry individuals still had a high rate of survival. However, at -80°C hydrated *Echiniscus jenningsi* (Figure 15) did not fare as well as the others, decreasing in survivorship as time increased from 7 to 150 days. At -180°C , all hydrated individuals of these three species rapidly died, but all dehydrated species had good survivorship after 14 days at -180°C .

Figure 15. *Echiniscus jenningsi*. Photo by Smithsonian Institution, through EOL Creative Commons.

It is incredible that some Antarctic tardigrades can survive temperatures as low as -80°C in a **hydrated** state (Sømme & Meier 1995; Sømme, 1996)! The ability to survive short periods in a hydrated condition just below a freezing temperature is important to survival in bryophyte clumps that regularly warm in the day and freeze at night. Ice crystals on the bryophytes would most likely help to dehydrate the tardigrades as temperatures plummeted to well below freezing, facilitating their survival during the long and very cold winters. Furthermore, the ability to survive low temperatures for years would permit tardigrades to survive dispersal across the ice or remain viable within it until a suitable habitat or conditions are reached.

But how do the rapidly changing temperatures of the environment affect the ability of the tardigrade to move about on the bryophyte to seek food? The **beneficial acclimation hypothesis** (BAH) predicts that animals will have their best performance at the temperature to which they are acclimated. Li and Wang (2005) tested this hypothesis with the moss-dwelling species *Macrobiotus hufelandi* (Figure 7, Figure 19), collected from the Qinling Mountains in central China. They acclimated the water bears to 2 and 22°C for two weeks. Using walking speed and percentage of time moving, they compared performance at the acclimation temperature with that at the alternate temperature. They found that both walking speed and percentage of time moving was significantly faster when the tardigrades were kept at their acclimation temperature than when they were placed at the higher or lower experimental temperature.

But in the Antarctic, we have seen that such extreme temperature fluctuations within a single day are not unusual. Could this be a threat to the water bears, who must find food, often adhering bacteria and algae, on the moss? And others eat nematodes and other moving targets. One factor to consider is that in the experiments of Li and Wang, only 1.5 minutes acclimation were provided at the new temperature before measurements began, lasting another 3-5 minutes. This seems unrealistic as a representation of nature. The next question to ask is how fast can the tardigrades acclimate to a new temperature?

Danger may lurk among the Antarctic bryophytes. Gray *et al.* (1982) isolated eighteen taxa of predaceous fungi from among Antarctic mosses and soil samples. Among these eight different trapping mechanisms were present. The fungus *Monacrosporium ellipso sporum* seemed to be associated primarily with calcicolous mosses. Although these are nematode-trapping fungi, they may also catch the occasional tardigrade. More importantly, it indicates that the moss habitat is suitable for parasitic fungi that might attack other invertebrate groups such as tardigrades.

Miller *et al.* (1996) actually looked at the role of bryophytes vs other cryptogamic substrata in harboring tardigrades on the Windmill Islands in East Antarctica. *Pseudechiniscus suillus* (Figure 16), *Macrobiotus* sp. (see Figure 7, Figure 19), *Hypsibius antarcticus*, *Ramajendas frigidus*, *Diphascon chilense*, and *Diphascon pingue* (Figure 17) occurred among mosses and lichens. Three of these had positive associations with each other and with bryophytes: *Pseudechiniscus suillus*, *Hypsibius*

antarcticus, and *Diphascon chilense*. These three species had a strong negative association with algae and lichens.

Forest Bryophytes

Forests have a much more tempered climate than the Antarctic. Trees reduce the rate of water loss and shade the bryophytes and their fauna from the heat of the bright sun.

Jönsson (2003) examined bryophytes in Swedish forests and found sixteen species of tardigrades, five of which were previously undescribed for that region [*Murrayon dianeeae* (Figure 36), *Isohypsibius sattleri*, *Platicrista angustata* (Figure 18), *Diphascon belgicae*, *D. pingue* (Figure 17)]. Jönsson found that the pine forest had the most species compared to clearcut areas, but that abundance differed little from that of clearcut areas. Of the sixteen species of tardigrades recorded, the cosmopolitan *Macrobiotus hufelandi* (Figure 19) was by far the most abundant. The weft growth form seemed to harbor more tardigrades than did other bryophyte growth forms.

Figure 18. *Platicrista angustata*. Photo by Michael Collins, with permission.

Figure 19. *Macrobiotus hufelandi*. Photo by Martin Mach, with permission.

Schuster and Greven (2007) conducted a 54-month study of the tardigrade fauna of the moss *Rhytidiadelphus squarrosus* in the Black Forest of Germany. They found 24 species, dominated by *Macrobiotus hufelandi* (56%), *M. richtersi* (18%), and *Diphascon pingue* (12%). Diversity tended to be higher in winter, but the three dominant species generally declined in winter and increased from spring until fall. Rainfall, humidity, and temperature seemed to play a major role in changes in seasonal abundance.

Epiphytes

Whereas forest floor bryophyte dwellers are protected by snow in winter, bryophytes on trees (**epiphytes**) are often above the winter snow level. In summer they have intermittent wet and dry periods and in winter they often have exposures to extreme temperatures, lacking the protective cover of snow. In the Cincinnati, Ohio, USA area, bark-inhabiting bryophytes provide homes to numerous tardigrades, with the greatest species richness in environs of high humidity and clean air (Meininger *et al.* 1985). Hence, cities afford a less hospitable environment due to the lower humidity and decreased air quality.

Despite their seemingly unfriendly habitat, epiphytic bryophytes are particularly suitable as a tardigrade habitat. Indeed, this habitat seems to house the most species. The frequency of wetting and drying of these bryophytes seems to be most suitable to the tardigrade life cycle. Richness seems to run about 4-16 species. Hooie and Davison (2001; Hooie Tardigrade diversity) found the following tardigrades associated with the epiphytic moss *Ulota crispa* (Figure 20) on four tree species (*Acer saccharum*, *Acer rubrum*, *Betula lenta*, *Tilia americana*) in the Great Smoky Mountains National Park, USA:

Echiniscus cf. *oihonnae*

Echiniscus virginicus

Hypechiniscus gladiator

Macrobiotus hufelandi (Figure 19)

Milnesium tardigradum (Figure 21)

Minibiotus cf. *pustulatus*

Paramacrobiotus tonollii (Figure 23)

Pseudechiniscus (Figure 22)

Figure 20. *Ulota crispa*, an epiphytic moss that houses a number of tardigrade species. Photo by Michael Lüth, with permission.

In a study of riparian tardigrades, Romano *et al.* (2001) reported on the tardigrades on epiphytic bryophytes in Alabama, USA. Using 108 samples, they extracted 1588 tardigrades from three tree species on six sampling dates. Like Riggan (1962) for forest bryophytes, Romano *et al.* (2001) found that *Macrobiotus* species (Figure 6-Figure 8) were the most abundant (1358 of the 1588 tardigrades, 86%). They found no differences among tree species, bryophyte species, or seasons, but there were site differences, possibly suggesting dispersal limitations. Although relative humidity and temperature did not seem to influence abundance, precipitation did. Interestingly, as precipitation increased, the number of tardigrades decreased. Beasley (1981) found that higher humidity resulted in lower tardigrade abundance in the Caribbean National Rain Forest at Luquillo, Puerto Rico. This further supports the hypothesis that periods of anhydrobiosis are required in the life of a tardigrade and that lack of them shorten the length of life. However, if only active periods are considered, there may be little difference.

Figure 23. *Paramacrobiotus tonollii*, a tardigrade known from *Ulota crispa* in the Smoky Mountains. Photo by Martin Mach, with permission.

Briones *et al.* (1997) suggested that during periods of high precipitation the film of water surrounding the bryophytes may become anoxic, killing the tardigrades. This could especially be a problem in the riparian zone, where the bryophytes, and hence the tardigrades, were under water during several collection periods. Diversity of tardigrades was somewhat low in the Alabama, USA,

riparian sites (Table 1), with only twelve species overall (Romano *et al.* 2001). Mosses included *Anomodon* (Figure 24), *Leucodon* (Figure 25), and *Schwetschkeopsis* (Figure 26), all epiphytes.

Figure 26. *Schwetschkeopsis fabronia*, an epiphyte from Asia and North America, and home for tardigrades. Photo by Misha Ignatov, with permission.

As in the Alabama study, Jerez Jaimes (2002) found a low diversity of only seven species on the moss *Calymperes palisotii* (Figure 27) on six species of trees on the campus of the University of Puerto Rico at Mayagüez. The highest species richness was on *Mangifera indica* (mango) and *Swietenia macrophylla* (mahogany).

When collections came from trees and shrubs from all 67 counties in Florida, only 20 species of tardigrades were found (Meyer 2006, 2008). Meyer also found no specificity for a particular bryophyte (47 species included) or ecological region, but there was specificity for bryophytes as opposed to foliose lichens.

There seemed to be an avoidance of one moss species, *Aulacomnium heterostichum* (Figure 28), with no tardigrades occurring on it (Meyer 2008). Bartels and Nelson (2006), working in the Great Smoky Mountains National Park, USA, increased the number of known species in the park from three to 42 from multiple substrates, a further testimony to how little known these organisms are. Bartels and Nelson found that more tardigrades occurred in bryophytes at breast height on a tree than at the tree bases, perhaps again relating to longer or more frequent dry periods.

Diphascon [=Hypsibius] *scoticum* (Figure 29), a very common tardigrade, inhabits mosses on logs (Cushman, pers. comm. 1970). It would be interesting to compare the log-dwelling tardigrade taxa with those living on epiphytic bryophytes of the same species. Presumably, the log habitat would have longer moist periods. Based on the findings discussed above of Bartels and Nelson (2006) and Romano *et al.* (2001), one might expect more on the epiphytes, where alternating wet and dry periods might fit better with the apparent dormancy requirements of the tardigrades.

Aquatic

Few truly aquatic tardigrades seem to exist. Garey *et al.* (2008) reported that of the more than 900 species of tardigrades they reviewed, most live in the water film on the surface of bryophytes, lichens, algae, and other photosynthetic organisms. Of their 910 species of tardigrades, only 62 (in 13 genera) were truly aquatic. In New Zealand, tardigrades represented only 2.4% of the fauna among the bryophytes of an unshaded stream in the alpine zone on South Island (Suren 1991a). In a more extensive study there, they represented only 1.2% of the invertebrates collected among mosses in 103 streams in one study (Suren 1993). Similar small numbers were present among the moss *Fontinalis antipyretica* (Figure 34) in the Czech Republic, where one stream had 1541 per mL of moss (0.6% of the fauna in the moss) and another stream had only 545 per mL (0.1%) (Vlčková *et al.* 2001/2002). In the Colorado Rocky Mountains, Elgmork and Sæther (1970) found most of the tardigrades *Dactylobiotus* cf *macronyx* (formerly *Macrobiotus macronyx*) associated with algae, but they also reported them from *Fontinalis* beds (Figure 34) and other submerged mosses.

In streams, flow velocity may cause tardigrades to seek refuge among mosses. Suren (1992) reported high densities of tardigrades (*Dactylobiotus* [= *Macrobiotus*] *dispar*; Figure 30-Figure 31) associated with mosses in alpine streams of New Zealand. In an earlier study Suren (1991b) found that the colonization of this species on artificial mosses was at a reduced density compared to that on mosses [*Fissidens rigidulus* (Figure 32), *Cratoneuropsis relaxa*, *Bryum blandum* (Figure 33)].

Figure 30. *Dactylobiotus* [= *Macrobiotus*] *dispar*. Photo by Martin Mach, with permission.

Figure 33. *Bryum blandum* from New Zealand, where tardigrade density is greater than that on artificial mosses. Photo by Jan-Peter Frahm, with permission.

Suren (1992) reported densities of 3120 and 8160 per m² on the mosses in two trials, whereas they reached only 1760 and 1600 on the artificial substrata. He suggested that the high periphyton biomass among mosses provided a good food source that made this a good habitat for the tardigrades. This suggestion is supported by the largest percentage of variation (24.2%) being explained by the ultra-fine particulate matter (UFPOM). The abundance of tardigrades on bryophytes was 10 times that found on stream gravel.

Linhart *et al.* (2002) examined scattered clumps of the aquatic moss *Fontinalis antipyretica* (Figure 34) and found that whereas several groups of invertebrates were distributed among the clumps in relation to stream flow, this was not the case for tardigrades. Even though the researchers showed that fine organic matter trapped within the moss mat was determined by flow velocity, this did not seem to be a determining factor in tardigrade distribution.

Figure 34. *Fontinalis antipyretica* in flowing water. Photo by Michael Lüth, with permission.

In the Italian Alps *Borealibius zetlandicus* occurred on *Warnstorfia exannulata* (Figure 35; Rebecchi *et al.* 2009). This tardigrade species is known only from boreo-alpine areas, where it typically occurs in sediment, submerged aquatic mosses, or *Sphagnum* (Figure 5). But like many other tardigrades, this one has a wide habitat range, including the Barents Sea and terrestrial mosses and soil that rarely dry out. This boreal habitat distribution for this species is possible because this species is able to survive freezing. But the populations of the species studied are unable to survive desiccation.

Figure 35. *Warnstorfia exannulatus*, home for the tardigrade *Borealibius zetlandicus* in the Italian Alps. Photo by Michael Lüth, with permission.

Suren (1992) also considered the possibility that the mosses offered shelter from the rapid flow of water elsewhere. These tiny organisms are often in the leaf axils of the mosses, where they have almost no effect from the strong flow, yet the oxygen diffusion could be fairly rapid. But as yet, no data seem to support cause and effect of flow velocity and tardigrade distribution.

Living in a stream is challenging for a tardigrade. Using 22 animals, Shcherbako *et al.* (2010) found that *Milnesium tardigradum* (Figure 21) could manage in water with a mean velocity of 23.3 mm/h, moving at a mean speed of 19.8 mm/h in the light and 29 mm/h in the dark, making snails look like track stars! Bryophytes provide a safe refuge from fast-moving waters. Eles and Repas (2009) described the stream tardigrades as having faster motion and longer claws than their terrestrial counterparts.

In New Zealand, Suren (1992) found that the tardigrade *Dactylobiotus dispar* (Figure 31) represented about 6.6% of the fauna on mosses in unshaded streams compared to 0.6% on gravel. In shaded streams they occupied only 5.3% of the bryophyte fauna compared to 0.4% on gravel. But not all wet habitats seem to be very suitable for tardigrades.

Kaczmarek (pers. comm. 29 January 2010) has reminded me that most of the water-dwelling tardigrades are in fact marine. Those that are truly freshwater aquatic species live on algae or plants (including bryophytes), in the sand, or in sediments. The genus *Murrayon* (Figure 36) is unusual among the water-dwelling tardigrades in that some aquatic individuals lay their eggs in the shed shells of cladocerans (Bertolani *et al.* 2009).

Figure 36. *Murrayon dianeeae*, an aquatic tardigrade. Photo by Michael Collins, with permission.

Emergent bryophytes may be especially comfortable for some species of tardigrades. One of the more "friendly" environments is in association with *Barbula* [= *Didymodon*] *tophacea* (Figure 37-Figure 38), a well-known rock-forming moss, above the wet zone.

Figure 37. *Barbula* [= *Didymodon*] *tophacea*, an emergent moss known to house 84 tardigrades per gram. Photo by Barry Stewart, with permission.

The aquatic habitat is also sometimes hospitable to hygrophilous species that are more typical among moist mosses or species with a wide tolerance range for moisture conditions (Nelson & Marley 2000). On the other hand, *Hypsibius dujardini* (Figure 13) is known from moist mosses, but it is primarily aquatic (McFatter *et al.* 2007). *Parhexapodibius pilato* was found among mosses on a stream bank in central Georgia (McFatter *et al.* 2007), but otherwise is known only from Michigan (Bernard 1977).

Figure 38. *Barbula* [=*Didymodon*] *tophacea*, an emergent moss showing the numerous possibilities for resting in leaf axils. Photos by Michael Lüth, with permission.

Dry Habitats

Although collectors looking for a rich bryophyte flora would most likely ignore the desert, some bryophytes depend on its predominately dry nature. The cryptogamic crust of prairies and deserts has its own tardigrade fauna (Brantley & Shepherd 2002). In this habitat of bryophytes, lichens, Cyanobacteria, and algae, long dry periods are guaranteed. The occasional wet periods make it a suitable tardigrade habitat.

As already discussed, Meininger and Spatt (1988), working along Dalton Highway in the tundra adjacent to the trans-Alaska Pipeline, found that road dust had a major impact on both the mosses and the tardigrades. The mosses near the road represented xerophytic species tolerant of high calcium. Consequently, the tardigrades likewise were taxa tolerant of drier conditions. Because of the moisture limitations on other kinds of taxa, the tardigrades near the road were mostly fungivorous and algal feeders; those farther from the road, where *Sphagnum* (Figure 5) was able to grow, tended to be more omnivorous and carnivorous. These habitat differences caused differences in tardigrade fauna between roadside bryophytes and more distant *Sphagnum* species.

Vertical and Horizontal Distribution

It seems likely that some vertical distribution within the bryophyte mat should occur. These could be defined by light levels. The presence of eyespots (Figure 41) in at least some members of Tardigrada was reported by Grevén (2007), with responses to light varying from none to both positive and negative. Beasley (2001) reported negative photokinesis in the common tardigrade *Macrobiotus hufelandi* (Figure 19), a common moss dweller. Rather than being attracted to or from the light, they increased

their rate of movement. Since light indicates sun intensity, it also is an indicator of the likelihood of drying, making the response to move quickly away from light an adaptive one. Vertical differences in tardigrade distribution are known from soil (Leetham *et al.* 1982). Nevertheless, as noted elsewhere, there seems to be little evidence for vertical position differences or migration of tardigrades in mosses; only one tardigrade (*Echiniscus viridissimus*) seems more common near the upper portion of the moss (Nelson & Adkins 2001). Wright (1991) found that in xeric habitats this species does not migrate vertically to the C zone as the moss dehydrates, even though other species do at the same time.

Data from the Antarctic suggest that temperature may play a role in the vertical positioning of tardigrades there. On Signy Island, 80% of the tardigrades occurred in the upper 6 cm of moss, and usually 70% were in the top 3 cm (Jennings 1979). One factor that contributes to this limited distribution is that the turf below 7-8 cm is **anaerobic** (lacking oxygen), making it inhospitable for the tardigrades. In moss-dominated flushes near the Canada Glacier in southern Victoria Land, Antarctica, the invertebrates, including tardigrades, occurred at a mean depth ranging 5-10.83 mm (Schwarz *et al.* 1993). As discussed above, the relative number of organisms increased near the surface in post-melt mosses. This is not necessarily a direct temperature response; it could result from changes in light or humidity associated with the melt.

Schuster *et al.* (2009) examined the microclimate within a cushion of the moss *Rhytidiadelphus loreus* (Figure 39). They found that the deep layers had lower daytime and higher nighttime temperatures than **ambient** (in this case, air temperature). Oxygen was similar throughout the cushion, but CO₂ increased greatly with depth. The six species of tardigrades were concentrated in the green-brown layer of the moss. The authors suggested that light and oxygen had little impact on the distribution but that CO₂ kept the tardigrades from occupying lower positions and that temperature might cause migrations within the upper portion.

Figure 39. *Rhytidiadelphus loreus*. Photo by Michael Lüth, with permission.

Differences in horizontal distribution may be the result of microhabitat differences such as shade vs sun or distance from water. But they can also be a simple result of passive, random dispersal and the slow-moving nature of the animal. Degma *et al.* (2011) sampled *Hypnum cupressiforme* (25 samples; Figure 40) to try to determine

the causes of horizontal positioning of tardigrades on that species. They found 224 tardigrades in the species *Milnesium tardigradum* (Figure 41), *Hypsibius convergens* (Figure 42), *H. microps*, *Diphascon pingue* (Figure 17), *Astatumen trinacriae* (Figure 43), *Macrobiotus hufelandi* (Figure 7), and *Minibiotus* sp. (Figure 44). They found no significant moisture gradient among the moss plants. The distribution of the tardigrade species was aggregated, but the number of species (richness) was random. There was no relationship of tardigrade species distribution to moisture.

But even these species may not be able to tolerate desiccation. *Macrobiotus hufelandi* (Figure 7) and *Hypsibius dujardini* (Figure 13) are unable to live in habitats that desiccate quickly, perhaps explaining their association with the slow-drying bryophytes (Wright 1991). Other bryophyte dwellers [*Milnesium tardigradum* (Figure 41) and *Ramazzottius* (formerly *Hypsibius*) *oberhaeuseri* (Figure 3)] may not tolerate constant moisture, but these two species avoid high insolation and rapid desiccation, again making bryophytes a suitable habitat.

Figure 43. *Astatumen trinacriae*. Photo by Paul J. Bartels, with permission.

Figure 44. *Minibiotus intermedius*. Photo by William Miller, through Flickr.

Competition and food relations are often determinants of the species assemblages. For example, *Milnesium tardigradum* (Figure 41) may be found with two *Hypsibius* species that it can use for food (Wright 1991). Competition may account for the negative associations among *Macrobiotus hufelandi* (Figure 7), *Paramacrobiotus richtersi* (Figure 45), and *Isohypsibius prosostomus* (see Figure 46) in xeric habitats.

Summary

Tardigrades live on both terrestrial and aquatic bryophytes, with the lowest numbers in the tropics. Epiphytic mosses seem to be especially suitable for them. Altitude is influential on species and numbers in some cases, but in others researchers were unable to find any differences. There are indications that the greatest numbers on higher mountains occur at mid elevations. Latitude, scale, and moisture availability most likely play a role.

Numbers of species in most studies are modest. In forests, studies reported herein range 7-42 species. In one study, the number of species was greater in the pine forest, but the number of individuals differed little from that of clearcut areas. *Macrobiotus hufelandi* seems to be the most common species just about everywhere. The most common genera are *Echiniscus*, *Macrobiotus*, *Diphascon*, and *Hypsibius*, and the genera recently segregated from them. Tardigrades comprised only 1.2% of the invertebrates in an expansive New Zealand study and Hingley found only two taxa in peatlands. Dry habitats may pose food limitations; constantly wet ones may be unfavorable to their longevity.

Although mosses get wet and dry on top first, it appears that tardigrades have little ability to migrate and do not even seem to be arranged in vertical assemblages. But, they have eyespots, indicating that light may play some role in their locations.

Acknowledgments

Roberto Bertolani provided an invaluable update to the tardigrade taxonomic names and offered several suggestions on the text to provide clarification or correct errors. Łukasz Kaczmarek has provided me with references, images, contact information, and a critical read of an earlier version of the text. Martin Mach and Yuuji Tsukii have given permission to use images that illustrate the species and life cycle stages. And a big thank you goes to Michael Lüth for permission to use his many bryophyte

images, and my appreciation goes to all those who have contributed their images to Wikimedia Commons for all to use. Martin Mach was kind enough to send me corrections for typos in the previous online version. Thank you to my sister, Eileen Dumire, for providing the view of a novice on the readability of the text. Tardigrade nomenclature is based on Degma *et al.* 2010.

CHAPTER 5-4

TARDIGRADES: SPECIES RELATIONSHIPS

Figure 1. SEM of tardigrades on a leafy liverwort. Photo by Łukasz Kaczmarek and Łukasz Michalczyk, with permission.

Species Relationships

Tardigrades occur on both mosses and liverworts (Figure 1). Since bryophytes vary widely in structure, compactness, and moisture-holding nature, one would expect that some bryophytes would be more suitable for tardigrades than others, causing specificity. But is that really the case?

Although Hofmann and Eichelberg (1987), in Lahnau near Giessen, Germany, found a correlation between species of tardigrade and degree of moisture in their preferred mosses, there seemed to be no example of a single species of tardigrade preferring a single species of moss. It appeared that species of bryophyte was not an important factor for most tardigrades.

A number of studies name the bryophytes where the tardigrades have been found, but quantitative approaches

are limited. For example, Degma (2006) found *Echiniscus reticulatus* on the moss *Ctenidium molluscum* (Figure 2) and *Testechiniscus spitsbergensis* from the mosses *Tortella tortuosa* (Figure 3), *Ctenidium molluscum* (Figure 2), *Distichium capillaceum* (Figure 4), and *Ditrichum flexicaule* (Figure 5-Figure 6) in Slovakia.

Baxter (1979) did find differences in the tardigrades on several moss species in Ireland. These represented different life forms as well as habitats. Some of their more specific finds include stream bank mosses that had *Diphascion oculatum* (Figure 7). *Polytrichum* (Figure 8), with its more open structure, had *Diphascion scoticum* (Figure 9). *Hypsibius dujardini* (Figure 1) was abundant, accompanied by *Isohypsibius tuberculatus*, on the turfs of *Rhytidiadelphus squarrosus* (Figure 10).

Figure 10. *Rhytidiadelphus squarrosus*, where Baxter (1979) found *Isohypsibius tuberculatus* and *Diphascon scoticum*. Photo by Michael Lüth, with permission.

Figure 11. *Lembophyllum divulgum*, a home for 16 tardigrade species in New Zealand. Photo by Li Zhang, with permission.

Figure 12. *Hypnum cupressiforme*, the moss with the most tardigrade species in the New Zealand study by Horning *et al.* (1978), shown here on rock and as a pendant epiphyte. Photos by Michael Lüth, with permission.

Horning *et al.* (1978) examined the tardigrades on 21 species of mosses in New Zealand and listed the tardigrade species on each (Table 1). Some moss species clearly had more tardigrade species than others, ranging from 1 on *Syntrichia rubra* to 17 on *Hypnum cupressiforme* (Figure 12). *Lembophyllum divulgum* (Figure 11) had 16 species.

Hopefully lists like the one provided by Horning *et al.* (1978) will eventually permit us to determine the characteristics that foster tardigrade diversity and abundance. Perhaps the moss *Hypnum cupressiforme* (Figure 12) had the most tardigrade species among the mosses in New Zealand because of its own wide habitat range there. However, Degma *et al.* (2005) found that distribution of the number of tardigrade species on this moss in their Slovakia sites was random, as supported by a Chi-square goodness of fit test. But this still does not preclude the assertion that its ubiquitous nature on a wide range of habitats in New Zealand may account for the greater number of species of tardigrades on *Hypnum cupressiforme* in the New Zealand study.

A kind of vertical zonation occurs among tardigrades on trees that is the reverse of that sometimes found within a moss cushion. In the Great Smoky Mountains National Park, the number of tardigrade species among epiphytes at breast height was greater than the number of species found at the base (Bartels & Nelson 2006). This may relate to the

need for dry periods, but it could also relate to differences in predators and possibly even to dispersal patterns.

In their study of Chinese mosses Beasley and Miller (2007) found that **Heterotardigrada** (armored tardigrades) were better represented than were **Eutardigrada** (unarmored tardigrades), a factor the authors attribute to the **xerophilic** moss samples and the locality, which has hot, dry summers, very cold, dry winters, low summer rainfall, and high winds (Fullard 1968). The Heterotardigrada have armor, which may account for their ability to withstand the dry habitat. These tardigrades also have **cephalic** (head) appendages with a sensorial function, a character lacking in the Eutardigrada, but so far their function has not been related to a bryophyte habitat. Beasley and Miller found little specificity, but most of the mosses were xerophytic and exhibited similar moisture requirements. They did find that *Echiniscus testudo* (Figure 13) occurred on a wider variety of mosses than did other tardigrade species.

On Roan Mountain in Tennessee and North Carolina, Nelson (1973, 1975) found no specificity among 21 tardigrade species on 25 bryophyte species. Hunter (1977) in Montgomery County, Tennessee, and Romano *et al.* (2001) in Choccolocco Creek in Alabama, USA, again were unable to find any dependence of tardigrades upon a particular species of bryophyte in their collections.

Table 1. Tardigrade species found on the most common moss taxa in New Zealand. From Horning *et al.* 1978.

Hofmann developed a preference coefficient:

$$P_n = (T_n/S_n) \sum_{i=1}^n 100(T_i/S_i)$$

where P = preference index for category n of observed factor
n = index of observed category
T = number of tardigrade populations of a single species
S = number of samples in category
The preference indices will add up to 100%. The categories can be the five bryophyte habitat groups listed by Mihelčič 1954/55, 1963; Ramazzotti 1962, and Hofmann 1987 or other groupings defined for the purpose.

Table 2. Distribution of tardigrades on specific mosses in Xinjiang Uygur Region, China, based on herbarium specimens. From Beasley & Miller 2007.

tardigrade	numb/samples	moss
<i>Bryodelphax asiaticus</i>	1/1	<i>Pseudoleskeella catenulata</i>
<i>Cornechiniscus holmeni</i>	18/5	<i>Grimmia tergestina</i> <i>Mnium laevinerve</i> <i>Schistidium</i> sp.
<i>Echiniscus blumi</i>	4/4	<i>Abietinella abietina</i> <i>Schistidium</i> sp.
<i>Echiniscus canadensis</i>	82/7	<i>Grimmia laevigata</i> <i>Grimmia ovalis</i> <i>Grimmia tergestina</i>
<i>Echiniscus granulatus</i>	8/3	<i>Grimmia longirostris</i> <i>Schistidium trichodon</i> <i>Schistidium</i> sp.
<i>Echiniscus testudo</i>	11/4	<i>Grimmia anodon</i> <i>Grimmia longirostris</i> <i>Grimmia tergestina</i> <i>Lescuraea incurvata</i> <i>Pseudoleskeella catenulata</i> <i>Schistidium</i> sp.
<i>Echiniscus trisetosus</i>	33/5	<i>Abietinella abietina</i> <i>Grimmia ovalis</i> <i>Pseudoleskeella catenulata</i>
<i>Macrobiotus mauccii</i>	2/2	<i>Schistidium</i> sp.
<i>Milnesium asiaticum</i>	10/4	<i>Grimmia anodon</i> <i>Grimmia tergestina</i> <i>Grimmia ovalis</i> <i>Schistidium</i> sp.
<i>Milnesium longiungue</i>	4/2	<i>Grimmia laevigata</i> <i>Grimmia ovalis</i>
<i>Milnesium tardigradum</i>	5/4	<i>Grimmia tergestina</i> <i>Grimmia ovalis</i> <i>Orthotrichum</i> sp.
<i>Paramacrobiotus alekseevi</i>	5/4	<i>Brachythecium albicans</i> <i>Schistidium</i> sp.

Kathman and Cross (1991) found that species of bryophyte had no influence on the distribution or abundance of tardigrades from five mountains on Vancouver Island, British Columbia, Canada. In fact, Kathman and Cross (1991) were unable to find any correlation with altitude or aspect throughout a span from 150 to 1525 m. They concluded that it was the presence of bryophyte that determined tardigrade presence, not the species of bryophyte, altitude, or locality. Despite a lack of specificity among the tardigrades, 39 species inhabited these 37 species of mountain bryophytes, comprising 14,000 individuals. Several researchers contend that any terrestrial species of tardigrade can be found on any species of moss, given the "appropriate microhabitat conditions" (Bertrand 1975; Ramazzotti & Maucci 1983). If these tardigrade bryophyte specialists find no differences among the bryophytes, can we blame the ecologists for lumping all the bryophytes in their studies as well?

In collections from Giessen, Germany, the most common tardigrade species, the cosmopolitan *Macrobiotus hufelandi* (Figure 14), had no preference for any moss species (Hofmann 1987). But lack of influence of bryophyte species may not always be the case. Hofmann (1987) used a preference index to show that four out of sixteen tardigrades from Giessen had distinct preferences among five moss species and that they seemed to prefer cushion mosses over sheet mosses. Also contrasting with the above researchers, Bertolani (1983) found that there seemed to be a species relationship between tardigrades and coastal dune mosses. It is possible that this is again related to moisture. The moisture relationship might also explain why mosses on rotten logs seem to have few tardigrades. Could it be that they are too wet for too long?

Meyer (2006a, b, 2008) found 20 species of tardigrades among 47 species of mosses, liverworts, lichens, and ferns in Florida. There were some tardigrade species that were significantly associated with either mosses or lichens, but, as in most other studies, there was no convincing evidence for associations with any plant species substratum. Despite the lack of substrate specificity, there were three significant negative

associations and one positive association between species of tardigrades. Likewise, in Georgia and the Gulf Coast, USA, Hinton and Meyer (2007) found *Milnesium tardigradum* (Figure 16), *Minibiotus intermedius* (Figure 39), and *Minibiotus furcatus* among mosses, whereas *Echiniscus cavagnaroi*, *E. kofordi* (see Figure 15), and *Minibiotus fallax* were in both mosses and lichens.

Life Forms

There is some indication that species differences may exist, based on life form. The bryophyte form can affect the moisture-holding capacity and rate of loss of moisture. That foregoing evidence suggests that the moisture-holding capacity of cushion mosses was probably a desirable trait in that habitat. On the other hand, Beasley (1990) found that more samples of clubmosses (Lycopodiaceae – tracheophytes) (75%) had tardigrades than did mosses (46%) or liverworts (0%) in Gunnison County, Colorado.

There seems to be a preference for cushions among the most common species [*Macrobiotus hufelandi* (Figure 14), *Ramazzottius oberhaeuseri* (Figure 17), *Milnesium tardigradum* (Figure 16), and *Echiniscus testudo* (Figure 13)] (Hofmann 1987). But the less frequent species are commonly found among sheet mosses. The ubiquitous *Macrobiotus hufelandi* seems to have no preference for moss shape.

Figure 17. *Ramazzottius oberhaeuseri*. Photo by Martin Mach, with permission.

Jönsson (2003), working in the forests of Sweden, found that wefts had more tardigrades than other moss forms. Kathman and Cross (1991) likewise found that tardigrades from Vancouver Island were more common on weft-forming mosses than on turfs, suggesting that the thick carpets of the wefts were more favorable habitat than the thinly clustered turfs with their thick rhizoidal mats and

attached soil. Contrasting with some of these findings, and the preference for cushion mosses in the study by Hofmann (1987), Diane Nelson (East Tennessee State University, Johnson City, pers. comm. in Kathman & Cross 1991) found no preference for sheet or cushion mosses in her Roan Mountain, Virginia, USA study. Rather, those tardigrades were more common in thin, scraggly mosses or in small tufts than in thick cushion mosses.

Sayre and Brunson (1971) compared tardigrade fauna on mosses in 26 North American collections from a variety of habitats and substrata (Figure 18). They found that mosses of short stature in the **Thuidiaceae** (Figure 19) and **Hypnaceae** (Figure 20) had the highest frequencies of tardigrades. Other moss-dwellers were found in fewer numbers on members of the moss families **Orthotrichaceae** (epiphytic and rock-dwelling tufts; Figure 21), **Leucobryaceae** (cushions on soil and tree bases; Figure 22), **Polytrichaceae** (tall turfs on soil; Figure 23), **Plagiotheciaceae** (low mats on soil and tree bases; Figure 24), and **Mniaceae** (mats & wefts on soil; Figure 25).

Figure 18. Relative frequency of tardigrades on bryophytes of various North American substrata. Redrawn from Sayre & Brunson 1971.

Figure 20. *Hypnum revolutum* (Hypnaceae), representing a family that includes low-stature mosses that had among the highest frequencies of tardigrades in 26 North American collections (Sayre & Brunson 1971). Photo by Michael Lüth, with permission.

Figure 21. *Orthotrichum pulchellum*, an epiphytic moss in the **Orthotrichaceae**. This family is among those with lower numbers of tardigrades in the North American study of Sayre & Brunson (1971) compared to families of mat-forming species. Photo by Michael Lüth, with permission.

Figure 22. *Leucobryum glaucum*, a cushion moss in the **Leucobryaceae**. This family of mosses had lower numbers of tardigrades than those found in the mat-forming mosses in 26 North American collections (Sayre & Brunson 1971). Photo by Michael Lüth, with permission.

Figure 23. *Polytrichum juniperinum*, a moss in the Polytrichaceae. This family of mosses tends to have low numbers of tardigrades (Sayre & Brunson 1971). The tardigrades do live among them often nestle in the leaf bases where water evaporates more slowly. Photo by Michael Lüth, with permission.

Figure 24. *Plagiothecium denticulatum*, a low-growing soil moss in Plagiotheciaceae, a family with limited numbers of tardigrade dwellers (Sayre & Brunson 1971). The flattened growth habit provides few protective chambers, perhaps accounting for the lower numbers. Photo by Michael Lüth, with permission.

Figure 25. *Plagiomnium cuspidatum*, a soil moss in the Mniaceae, a family with limited numbers of tardigrade dwellers (Sayre & Brunson 1971). The spreading nature of the vertical shoots and the flattened nature of the horizontal shoots would most likely not provide many protective chambers for the tardigrades. Photo by Michael Lüth, with permission.

Collins and Bateman (2001), studying tardigrade fauna of bryophytes in Newfoundland, Canada, found that rate of desiccation of the mosses affected distribution of tardigrades, and this suggests that bryophyte species and life forms that dehydrate quickly should have fewer individuals and probably different or fewer species than those that retain water longer. In different climate regimes, that rate will differ. This may explain a preference for cushions in some locations and not in others. Data are needed on humidity within the various life forms of bryophytes, correlated with tardigrade densities, to try to explain why different life forms seem to be preferred in different locations.

Liverworts

I would expect liverworts, with their flat structure, to have at least some differences in tardigrade communities (Figure 1). But reports on liverwort inhabitants are limited, at least in part due to lack of knowledge about bryophytes on the part of the tardigrade specialists and an equal lack of knowledge of tardigrades by bryologists. Hinton and Meyer (2009) found two species of tardigrades [*Milnesium tardigradum* (Figure 16) and *Macrobiotus hibiscus*], both also common among mosses, in samples of the liverwort *Jungermannia* sp. (Figure 26). In the Gulf Coast states, USA, Hinton and Meyer (2007) found *Echiniscus virginicus* among liverworts.

Figure 26. The leafy liverwort *Jungermannia sphaerocarpa*, representing a genus from which tardigrades are known. Photo by Michael Lüth, with permission.

Liverworts may actually house some interesting differences as a result of their underleaves (Figure 27) and flattened life form (Figure 28). In their New Zealand study, Horning *et al.* (1978) found that among the liverworts (Table 4), *Porella elegantula* (Figure 27) had the most species (16). The folds and underleaves of this genus form tiny capillary areas where water is held, perhaps accounting for the large number of species. Interestingly, the tardigrade *Macrobiotus snaresensis* occurred on several liverwort species [4 *Lophocolea* species, *Plagiochila deltoidea* (Figure 29)], but did not appear in any moss collections. Of 150 liverwort samples (26 species), 27% had tardigrades, with a total of 16 species, mean of 2.8 species, range 1-9. In 107 samples of foliose lichens, 60.7% had tardigrades, mean 2.2 species, range 1-11.

Figure 29. *Plagiochila deltoidea*, a leafy liverwort that forms large patches in wet ground in New Zealand. This is a known habitat for tardigrades. Photo by Clive Shirley, Hidden Forest <<http://www.hiddenforest.co.nz>>, with permission.

It appears that at least some other researchers have paid attention to liverworts. Christenberry (1979) found *Echiniscus kofordi* and *E. cavagnaroi* on liverworts in Alabama, USA. Hinton and Meyer (2009) found *Milnesium tardigradum* (Figure 16) and *Macrobiotus hibiscus* in a liverwort sample from Georgia, USA. Michalczyk and Kaczmarek (2006) found a new species, *Paramacrobiotus magdalenae* (Figure 30, Figure 31), on liverworts in Costa Rica. Newsham *et al.* (2006) identified the tiny leafy liverwort *Cephaloziella varians* and used it to experiment on the effects of low temperature storage on tardigrades and other Antarctic invertebrates.

Just what do we mean by "appropriate habitat conditions"? The bryophytes only occur in conditions that are appropriate for them, hence defining the conditions for the tardigrades. And the bryophytes create habitat conditions of moisture due to their morphology and substrate preference. Lack of species preference in many studies may result from methods that were insensitive to subtle differences or that failed to control for microhabitat differences. Usually no statistical tests were employed, sample sizes were small, and enumeration was often simple presence/absence data.

Table 4. Species of tardigrades found on 13 liverwort species in New Zealand and surrounding islands. From Horning *et al.* 1978.

Substrate Comparisons

Meyer (2006b) extended the comparison of substrata in Florida, USA, to include not only liverworts, mosses, and foliose lichens, but also ferns. He found 20 species of tardigrades on 47 species of plants and lichens. They found that some species were positively associated with mosses or with foliose lichens, but as in most other studies, there was no association with any particular plant or lichen species.

Guil *et al.* (2009a) reviewed tardigrades and their habitats (altitude, habitat characteristics, local habitat structure or dominant leaf litter type, and two bioclimatic classifications), including bryophytes and leaf litter at various elevations. They were able to show some habitat preference. Species richness was most sensitive to bioclimatic classifications of macroenvironmental gradients (soil and climate), vegetation structure, and leaf litter type. A slight altitude effect was discernible. These relationships suggest that differences among bryophyte species should exist where bryophyte species occupy different environmental types or maintain different microenvironments within a habitat. But it also suggests that within the same habitat, bryophytes of various life forms should provide different moisture regimes, hence creating species relationship differences.

In a different study in the Iberian Peninsula (extreme southwestern Europe), Guil *et al.* (2009b) found that leaf litter habitats showed high species richness and low abundances compared to rock habitats (mosses and lichens), which had intermediate species richness and high abundances. Tree trunk habitats (mosses and lichens) showed low numbers of both richness and abundances. One might conclude that the moisture of these habitats is

the overall determining factor, and this should coincide with bryophyte species groups on the large scale.

Miller *et al.* (1996) found six species of tardigrades in lichen and bryophyte samples on ice-free areas at Windmill Islands, East Antarctica. The tardigrade species *Diphascon chilense* (see Figure 32), *Acutuncus antarcticus* (formerly *Hypsibius antarcticus*; see Figure 33), and *Pseudechiniscus juanitae* (= *Pseudechiniscus suillus*; Figure 34) showed a positive association with bryophytes and a negative association with algae and lichens.

Figure 32. *Diphascon* sp., member of one of the most common bryophyte-dwelling genera. Photo by Martin Mach, with permission.

Meyer and Hinton (2007) reviewed the Nearctic tardigrades (Greenland, Canada, Alaska, continental USA, northern Mexico). They found that one-third of the species occur in both cryptogams (lichens and bryophytes) and soil/leaf litter (Table 5). Few tardigrades occurred exclusively in soil/leaf litter habitats. Although many

occurred among both bryophytes and lichens, 18 species occurred only in bryophytes. It is likely that bryophytes offer a better moisture environment, but this has not been tested.

Figure 33. *Hypsibius*. Photo by Yuuji Tsukii, with permission.

Figure 34. *Pseudechiniscus juanita*. Photo by Paul J. Bartels, with permission.

Table 5. Comparison of tardigrades inhabiting their primary substrates in the Nearctic realm. Only species present on that substrate in at least three sites are included. From Meyer & Hinton 2007.

Substrate category	number of species
Cryptogams only	64
Both cryptogams and soil/leaf litter	27
Soil/leaf litter only	3
Both bryophyte and lichen	50
Bryophyte only	18
Lichen only	5

Beasley (1990) conducted a similar study in Colorado, USA. Out of 135 samples of liverworts, mosses, lichens, and club mosses (Lycopodiaceae), they found 20 species in 55 samples. There were no tardigrades on liverworts (!), but they were on 46% of mosses and 43% of lichens. The big surprise is that 75% of the clubmosses had tardigrades.

In the Great Smoky Mountains National Park, Bartels and Nelson (2006) found that the number of species differed little among the substrates they sampled (soil,

lichen, moss, & stream habitats). Whereas it is not unusual for the soil, lichens, and mosses to have similar fauna and richness, it seems a bit unusual for the stream habitat to be as rich. *Amphibolus* cf. *weglarskae* and *Diphascon* cf. *ramazzottii* were the only species found only on bryophytes among those four substrates.

Horning *et al.* (1978) collected from soil, fungi, algae, bryophytes, lichens, marine substrata, freshwater substrata, and litter in New Zealand and surrounding islands. From bryophyte and lichen habitats, they found that all 14 of the most abundant species occurred in at least three of the five "plant" categories (three lichen forms, liverworts, and mosses). Among these, the highest occurrence was among mosses. Although *Milnesium tardigradum* (Figure 16) was slightly more abundant on lichens than on mosses, the combined numbers on mosses and liverworts was still higher. Horning *et al.* identified the bryophytes and lichens and presented the species of tardigrades on each (Table 1, Table 4, Table 6). In 559 moss samples, 45.8% had tardigrades, mean of 1.8 species, range 1-8 (Table 1). Of 55 species of tardigrades known for New Zealand, 45 occurred on mosses.

Finding New Species

The common appearance of tardigrades among bryophytes causes those who seek to describe new taxa to go first to the mossy habitats. In this spirit, Kaczmarek and Michalczyk (2004a) found the new species of moss-dwelling *Doryphoribius quadrituberculatus* in Costa Rica. From mosses in China they described the new species *Bryodelphax brevidentatus* (Kaczmarek *et al.* 2005) and *B. asiaticus* (Figure 35; Kaczmarek & Michalczyk 2004b), as did Li and coworkers for *Echiniscus taibaiensis* (Wang & Li 2005), *Isohypsibius taibaiensis* (Li & Wang 2005), *Isohypsibius qinlingensis* (Li *et al.* 2005a), *Pseudechiniscus papillosus* (Li *et al.* 2005b), *Pseudechiniscus beasleyi*, *Echiniscus nelsonae*, and *E. shaanxiensis* (Li *et al.* 2007), and Tumanov (2005) for *Macrobiotus barabanovi* and *M. kirghizicus*. Pilato and Bertolani (2005) described *Diphascon dolomiticum* from Italy.

Figure 35. *Bryodelphax asiaticus*. Photo through Creative Commons.

Table 6. Comparison of numbers of individuals and percentage of individuals of each of 14 tardigrade species on liverworts, mosses, and lichens in collections from New Zealand and surrounding islands. The remaining ones were on other non-plant substrata. Number of samples is in parentheses. From Horning *et al.* 1978.

	n	liverworts % (150)	mosses % (559)	lichens % (239)
<i>Pseudechiniscus novaezeelandiae</i>	46	8.70	56.50	23.90
<i>Pseudechiniscus juanitae</i>	43	6.98	44.19	27.91
<i>Macrobiotus harmsworthi</i>	89	5.62	55.06	34.83
<i>Macrobiotus hibiscus</i>	90	7.78	60.00	17.78
<i>Minibiotus intermedius</i>	65	7.69	41.54	32.30
<i>Milnesium tardigradum</i>	143	7.69	35.66	37.06
<i>Hypsibius dujardini</i>	32	10.53	50.00	2.63
<i>Paramacrobiotus areolatus</i>	58	3.45	60.34	18.97
<i>Echiniscus bigranulatus</i>	18	5.56	38.89	38.89
<i>Hypechiniscus gladiator</i>	21	19.05	61.90	9.50
<i>Diphascon scoticum</i>	35	11.43	65.71	11.43
<i>Macrobiotus liviae</i>	72	8.33	56.94	18.06
<i>Macrobiotus anderssoni</i>	63	11.11	42.86	22.22
<i>Macrobiotus furciger</i>	89	12.36	50.56	22.47

New species from South Africa are no surprise, as enumeration of small organisms in that country is barely out of its infancy. Kaczmarek and Michalczyk (2004c) described the new species *Diphascon zaniewi* in the Dragon Mountains there. Other species found there were more cosmopolitan: *Hypsibius maculatus* (previously known only from Cameroon and England), *H. convergens* (Figure 36), *Paramacrobiotus cf. richtersi* (Figure 37), and *Minibiotus intermedius* (Figure 38-Figure 39).

Figure 36. *Hypsibius convergens*, a common moss-dweller. Photo by Björn Sohlenius, Swedish Museum of Natural History, with permission.

Figure 38. *Minibiotus intermedius*. Photo by William Miller through Flickr.

Figure 39. *Minibiotus intermedius* mouth. Photo by Łukasz Kaczmarek and Łukasz Michalczyk, with permission.

Likewise, in South America, Michalczyk and Kaczmarek (2005) described *Calohypsibius maliki* as a new species from Chile; Michalczyk and Kaczmarek (2006) described *Echiniscus madonnae* (Figure 40) from

Peru, all from bryophytes. In Argentina they described *Macrobiotus szepteykii* and *Macrobiotus kazmierskii* (Kaczmarek & Michalczyk 2009). In 2008 Degma *et al.* described another new species [*Paramacrobiotus derkai* (Figure 41)] from Chile, a country where only 29 species had previously been described.

Figure 40. *Echiniscus madonnae*, a moss dweller from Peru. Photo by Łukasz Kaczmarek & Łukasz Michalczyk, with permission.

Figure 41. *Paramacrobiotus derkai* emerging from egg. Photo by Łukasz Kaczmarek, with permission.

In Portugal, lichens and mosses provided the new species *Minibiotus xavieri* to Fontoura and coworkers (2009). In Cyprus, Kaczmarek and Michalczyk (2004d) described *Macrobiotus marlenae* (Figure 42). *Macrobiotus kovalevi* proved to be a new species from mosses in New Zealand (Tumanov 2004). Clearly, mosses have been a favorite sampling substrate for tardigrade seekers (Kaczmarek & Michalczyk 2009) and most likely hold many more undescribed species around the world.

Even when new species are collected, they are not always identified or diagnosed in a timely manner. This can result in their ultimate description from multiple locations. Such is the case for *Echiniscus viridianus* (Figure 43), a new species described by Pilato *et al.* (2007) from Alabama and New Mexico, USA, and from the Azores Islands, all from mosses.

Figure 42. *Macrobiotus marlenae*. Photo by Łukasz Kaczmarek and Łukasz Michalczyk, with permission.

Figure 43. *Echiniscus viridianus*. Photo by Paul J. Bartels, with permission.

Summary

Most studies indicate no correlation between bryophyte species and tardigrade species. There is limited indication that cushions may have more species, but in other studies thin mats have more than cushions. Other studies indicate they are more common on weft-forming mosses than on turfs. Open mosses like *Polytrichum* seem to be less suitable as homes. There may be some specificity for liverworts rather than mosses, as for example *Macrobiotus snaresensis* in New Zealand. Unfortunately, many researchers have not identified the bryophyte taxa in tardigrade faunistic studies. A common garden study including several bryophyte species and tardigrades of the same or different species could be revealing.

Acknowledgments

Roberto Bertolani provided an invaluable update to the tardigrade taxonomic names and offered several suggestions on the text to provide clarification or correct errors. Łukasz Kaczmarek has provided me with references, images, contact information, and a critical read of an earlier version of the text. Martin Mach and Yuuji Tsukii have given permission to use images that illustrate the species. Michael Lüth has given permission to use his many bryophyte images, and my appreciation goes to all

those who have contributed their images to Wikimedia Commons for all to use. Martin Mach was kind enough to send me corrections for typos in the previous online version. Thank you to my sister, Eileen Dumire, for providing the view of a novice on the readability of the original text (it has been much expanded since then). Tardigrade nomenclature is based on Degma *et al.* 2010.

CHAPTER 5-5

TARDIGRADE DENSITIES AND RICHNESS

Figure 1. *Echiniscus*, the genus with the most species among mosses. Photo by Martin Mach, with permission.

Densities and Richness

But just how common are these bryophyte-dwelling tardigrades (Figure 1)? I think the largest reported density I have found in the literature is 22,000 individuals per gram of dry moss (Mathews 1938), but that is an old number and may well have been replaced. These animals seem to be especially adapted for the bryophyte habitat (Jerez *et al.* 2002), achieving densities as great as 2,000,000 individuals per square meter of *Bryum argenteum* (Figure 2) (Brusca & Brusca 1990). (Is that greater than 22,000 per gram?) Nelson (2002) reminds us that densities of these animals are highly variable and conditions for optimum development of the population are unknown (see also Kinchin 1994). Factors such as temperature and moisture (Franceschi *et al.* 1962-1963; Morgan 1977; Briones *et al.* 1997), air pollution (Steiner 1994a, b, c, 1995), and food availability (Hallas & Yeates 1972) all influence population density. And it appears that random dispersal may be a major factor, since both population density and species diversity vary considerably between adjacent microhabitats that appear to be identical (Nelson 2002).

Figure 2. *Bryum argenteum* exhibiting the tight leaves that provide capillary spaces where tardigrades can enjoy prolonged water retention. Photo by Michael Lüth, with permission.

Among the more extensive studies is that of Kathman and Cross (1991) on Vancouver Island, British Columbia, Canada. They collected from mosses at six altitudes on five mountains and found 39 species among 37 moss species, with 13,696 individuals in all. However, as noted in Bertolani's (1983) study, the species of moss did not seem to be important.

Horning *et al.* (1978) collected from soil, fungi, algae, bryophytes, lichens, marine substrata, freshwater substrata, and litter in New Zealand and surrounding islands. They provide summaries of the tardigrade species from each bryophyte species. From their 1354 collections, they represented 577 terrestrial habitats. All 14 of the more abundant tardigrade species occurred in at least three of the five "plant" categories (three lichen forms, liverworts, and mosses). Among these, the highest occurrence was among mosses, except for *Milnesium tardigradum* (Figure 3), which occurred more often among lichens. They reported the number of species on each bryophyte, but not the density of individuals. As in other studies, moisture seemed to play a major role. They considered the "plant" categories, arranged from dry to moist, to be crustose lichen > fruticose lichen > foliose lichen > liverworts & mosses. The foliose lichens and mosses served as habitat for more tardigrade species than did the liverworts, crustose lichens, or fruticose lichens. Liverworts housed 30 tardigrade species on 26 liverwort species.

Figure 3. *Milnesium tardigradum*, a moss dweller that seems to have a slight preference for lichens. Photo by Martin Mach, with permission.

Roof mosses (Figure 4) have their share of tardigrade fauna; Morgan (1977) recorded densities of four tardigrade species [*Macrobiotus hufelandi* (Figure 15), *Milnesium tardigradum* (Figure 3), *Ramazzottius oberhaeuseri* (Figure 5), *Echiniscus testudo* (Figure 6)] of up to 823 individuals per gram of the mosses *Ceratodon purpureus* (Figure 7) and *Bryum argenteum* (Figure 8) on roofs in Swansea, Wales. In total, Morgan collected 32,552 tardigrades from these two mosses on just three roof locations at the University College of Swansea.

Even new species might be abundant in many parts of the world. This is an under-collected group, as suggested by finding very common species for the first time in some countries. Kristensen *et al.* (2009) found more than 200 individuals of a new species of *Bryodelphax* (see Figure 9) in a "very small moss sample." And these were cohabiting with *Macrobiotus hufelandi* (Figure 15) and *Milnesium tardigradum* (Figure 3).

Europe

One might expect the knowledge of European tardigrades to be the most complete, partly because the taxonomy of the bryophytes has been known longer than in many other countries, including North America, and partly because of the interest of Europeans in natural history.

Some European mosses have abundant tardigrades: *Hypnum cupressiforme* (Figure 10), *Hylocomium splendens* (= *Hypnum parietinum*) (Figure 11), and *Sanionia uncinata* (Figure 12), as well as *Grimmia* (might include *Schistidium*; Figure 13) and *Tortula* (Marcus 1928a; probably includes *Syntrichia*; Figure 14) and may contain up to 20,000 individuals per 1 g of air-dried moss (Marcus 1928b).

Figure 13. *Grimmia elongata* cushions. Photo by Michael Lüth, with permission.

Figure 14. *Tortula intermedia* cushion. Photo by Michael Lüth, with permission.

In a boreal forest in Sweden, Jönsson (2003) found sixteen species of tardigrades on mosses, including the widespread *Macrobiotus hufelandi* (Figure 15) as the most common. Among these, five were new to Sweden. They also found that the forest tended to have more tardigrade species than did a clear-cut area, but overall abundance within a species differed little between these two habitats.

Figure 15. *Macrobiotus hufelandi*, a dominant species on *Rhytidiadelphus squarrosus* (Figure 19) in the Black Forest, Germany. Photo by Martin Mach, with permission.

In the Tihany Peninsula, Hungary, Felföldy and Iharos (1947) found modest numbers, with 38 individuals per gram of the moss *Eurhynchium swartzii* (Figure 16) and 84 per gram among clones of *Barbula* [formerly in *Didymodon*] *tophacea* (Figure 17).

Hofmann and Eichelberg (1987) found sixteen species, including two undescribed, among mosses at Lahnu, near Giessen, Germany. Maucci (1980) collected 2686 samples of bryophytes and found 23 species of tardigrades.

In Sardinia, Pilato and Sperlinga (1975) likewise found sixteen species of tardigrades among the bryophytes. These included *Macrobiotus nuragicus* and *M. arguei* as new species. *Isohypsibius pappi*, *I. sattleri* (formerly *I. bakonyiensis*), and *Hypsibius convergens* (Figure 18) were new for Sardinia. It seems that finding new species within tardigrade communities is a fairly common occurrence.

Figure 18. *Hypsibius convergens*, one of the most common of bryophyte dwellers. Photo by Łukasz Kaczmarek and Łukasz Michalczyk, with permission.

Schuster and Greven (2007) followed the inhabitants of the moss *Rhytidiadelphus squarrosus* (Figure 19) in the Black Forest in Germany for 54 months (Table 1). They uncovered 19,909 individuals comprising 24 species. The dominant species were *Macrobiotus hufelandi* (Figure 15; 56%), *Paramacrobiotus richtersi* (Figure 20; 18%), and *Diphascon pingue* (Figure 21; 12%). In contrast to the Oregon study, the highest diversity occurred in winter, whereas the number of individuals declined in winter, then increased from spring until autumn, as in Oregon. On the other hand, *D. rugosum* (Figure 22), *Hypsibius dujardini* (Figure 23), and *H. cf. convergens* (Figure 18) exhibited peaks in winter. Water-loving species were most numerous in the moist season, whereas *euryhydric* species increased when it was relatively dry and sunny. During the course of the 54 months, 14 of the 24 species remained, whereas species succession/change occurred among the others.

Species such as *Diphascon oculatum* (Figure 24) that had reasonable numbers on *Rhytidiadelphus squarrosus* (Figure 19), but for which no eggs were found (Schuster & Greven 2007), might deposit eggs at a different season than those sampled. It is unlikely that they would deposit eggs in a different habitat/location from that of the adults because of their limited mobility. On the other hand, rare species occurring only once, e.g. *Mesocrista spitzbergensis* (Figure 25) [note – this is a name change from *M. spitzbergense*, required to make the gender agree with that of the genus (Degma *et al.* 2010)], may have been an accidental arrival on *Rhytidiadelphus squarrosus*, or generally rare. It would be interesting to know the longevity and life cycle of rare species.

Figure 25. *Mesocrista spitzbergensis*, an inhabitant of *Rhytidiadelphus squarrosus*. Photo by Björn Sohlenius, Swedish Museum of Natural History, with permission.

In Scotland, Morgan (1976) found that bryophyte and lichen dwellers represented the highest number of tardigrades as well as having the greatest species diversity. In Wales, Morgan (1974) found tardigrades numbering $2287 \times 10^3 \text{ m}^{-2}$ among mosses. By contrast, Hallas and Yeates (1972) found only $12 \times 10^3 \text{ m}^{-2}$ in soil and litter in Danish forests.

Studies on abundance reveal a wide range of densities. Degma and coworkers (2003, 2006; & Pecalková 2003; *et al.* 2004, 2005) have provided us with records of tardigrades on named species of mosses in Slovakia. On *Hypnum cupressiforme* (Figure 10) in Central European

oak-hornbeam forests of Slovakia, Degma *et al.* (2005) found 3050 tardigrades [21 species in two families (*Hypsibiidae* & *Macrobiotidae*)] from 79 moss samples. As in many other studies they were unable to demonstrate any of 12 environmental variables that accounted for the distribution of the tardigrades. Rather, they found that the distribution of species was random.

Nevertheless, in his 2003 study, Degma found particular tardigrades on particular bryophytes (Figure 26-Figure 43): *Eremobiotus alicatai* on mosses *Brachythecium rutabulum* (Figure 26) and *Eurhynchium hians* (Figure 27); *Isohypsibius pappi* on these two as well as on *B. reflexum* (Figure 28), *Homalothecium sericeum* (Figure 29), *Hypnum cupressiforme* (Figure 10), *Mnium stellare* (Figure 31), and *Rhynchostegium megapolitanum* (Figure 32); *Isohypsibius josephi* on *Amblystegium serpens* (Figure 33) and *Brachythecium starkei* (Figure 34); *Diphascon iltisi* on *Campylium halleri* (Figure 35); *Astatumen trinacriae* (Figure 36) on *Brachythecium rutabulum* (Figure 26), *Homalothecium sericeum* (Figure 29), *Hypnum cupressiforme* (Figure 10), *Isothecium alopecuroides* (Figure 30), *Leskeella nervosa* (Figure 37), *Paraleucobryum longifolium* (Figure 38), and *Pterigynandrum filiforme* (Figure 39); *Isohypsibius dasychi* in unidentified moss. Degma and Pecalková (2003) reported *Diphascon belgicae* in *Brachythecium reflexum* (Figure 28); *Calohypsibius schusteri* and *Itaواسcon pawlowskii* in *Hypnum cupressiforme* (Figure 10). In 2006 Degma reported *Echiniscus* cf. *reticulatus* on *Ctenidium molluscum* (Figure 40); *Testechiniscus*

spitsbergensis on *Ctenidium molluscum* (Figure 40), *Distichium capillaceum* (Figure 41), *Ditrichum flexicaule* (Figure 42), and *Tortella tortuosa* (Figure 43). But are these just chance findings, or is there a preference? It is interesting that all but the last three and *Paraleucobryum longifolium* (Figure 38) are mat-forming mosses. Was this a preference of the tardigrade or the collector? Or simply a consequence of the habitat?

North America

The neglect of tardigrades has not escaped North America. Meyer (2006a) lamented that only one species of tardigrade had been reported from Florida. By sampling 47 species of mosses, liverworts, lichens, and ferns from trees and shrubs in all 67 counties of Florida, he found 20 species of tardigrades. Like other studies discussed here, he could find no association between tardigrade species and any particular bryophyte or lichen species. He did, however, find differences between species occurring on lichens and mosses in general.

It is clear that neglect of the bryophyte habitat is neglect of tardigrades in general. Based on species-area curves, Bartels and Nelson (2007) estimated the greatest species richness among bryophytes in their comparison of habitats in the Great Smoky Mountains, USA, although their actual numbers showed about equal numbers of species among the terrestrial habitats:

Aquatic	29
Soil	39
Lichen	35
Moss	37
Total	140

Among the additional species most likely to contribute to the predicted number of bryophyte dwellers are a number of species found there on other substrata, that are known from bryophytes elsewhere but not found in the necessarily limited sampling in this study.

Meyer *et al.* (2003) examined populations among a variety of habitats in central Florida and Ouichita Mountains, Arkansas, USA. They found the tardigrades to be both diverse and abundant, varying greatly within the same species among mosses on different rocks and trees. For example, in an extreme case a tree exhibited three species with numerous individuals while the adjacent tree had none. Four adjacent cores yielded from 0 to 86 individuals, totalling 5 species. This type of distribution is consistent with the patchiness discussed below and supports the hypothesis of random dispersal followed by aggregation resulting from reproduction without migration.

Paul Davison (pers. comm. 21 June 2006), working in Alabama, USA, contends that tardigrades are best found on "scrappy mosses" that occur in harsh environments. These include those on the face of concrete steps or rock and concrete walls, rooftops, or bark of city trees. In fact, some researchers have suggested that the tardigrades might require a dry period during their lives to survive. Using such mosses, drying, and crumbling them through a 0.5 cm screen over a dish pan can yield as many as 70 tardigrades in just 5 mL of processed extract.

A more modest flora was in evidence in the collections from Southwestern Virginia, USA (Riggin 1962). In 434 collections of mosses and lichens, Riggin found only 694 individual tardigrades – hardly a story of high densities on a broad scale. These were represented by 26 species. *Macrobiotus* seems to be among the most common genera on bryophytes, including North American collections where Riggin found 63% of the Virginia bryophyte (moss?) and lichen collections housing members of this genus.

In a study of both the Upper and Lower Peninsulas of Michigan, USA, Meyer *et al.* (2011) revealed 28 species of tardigrades from mosses, liverworts, lichens, and leaf litter, of which 19 were from bryophytes [*Echiniscus blumi*, *E. merokensis*, *E. virginicus*, *E. wendti*, *Pseudechiniscus facettalis*, *P. suillus* (Figure 44), *Milnesium tardigradum* (Figure 3), *Hypsibius arcticus* (Figure 45), *Ramazzottius baumanni*, *R. oberhaeuseri* (Figure 5), *Diphascion alpinum*, *D. nodulosum* (Figure 46), *Astatumen trinacriae* (Figure 36), *Macrobiotus echinogenitus*, *M. hufelandi* (Figure 15), *Minibiotus intermedius* (Figure 47), *Fractonotus caelatus*, *Paramacrobiotus areolatus* (Figure 48), *P. tonollii* (Figure 49)]. Of the 28, 18 species were considered to be cosmopolitan. They found only one new

species, and it was not a bryophyte dweller. Although Ramazzotti and Maucci (1983) reported that more than ten taxa of tardigrades can often occur in a single bryophyte sample, and the range is generally 2-6, Meyer *et al.* found diversity on Michigan bryophytes to usually be at the lower end of this range.

Nelson and Hauser (2012) collected epiphytic mosses and liverworts in a natural area in Oregon, USA. Out of 1102 invertebrates collected, the tardigrades ranked second, exceeded only by the mites (*Acari*). They pointed out the need for water sampling (washing samples) to find tardigrades. These animals did not show up in the Berlese

extraction used by many collectors. Their collections reveal at least six or seven different taxa of tardigrades from each epiphytic moss water sample, a number that brings the patchy distribution of tardigrades into question. They considered the tardigrades to be well represented for a group with approximately 1000 species, compared to mites with approximately 50,000 species.

South America and Neotropics

Numbers of species and density varies widely among tardigrade collections. Claps *et al.* (2009) found 28 species in 10 genera in a sub-Antarctic *Nothofagus* forest (18) and plateau (13) in the Rio Negro province of Argentina. In Costa Rica, Kaczmarek *et al.* (2009, 2011) found more than 7000 tardigrade individuals in 700 samples of lichens, mosses, and liverworts. These comprised 64 species in 18 genera, but the average number of species per sample was not more than three. They found altitude to be an important factor in distribution, with the highest diversity in the range of 1400-2000 m asl (35 species, 55% frequency). Only 18 species (28% frequency) occurred in the range of 2400-2800 m asl. In the range of 2000-2400 m asl the number of individuals was high. Then at 3200 m asl the frequency (70%) and abundance increased again. Surprisingly, they found a significantly higher presence in the urban and agricultural habitats than they did in natural habitats. Although 24 species had very defined habitat preferences, with the highest frequency in humid habitats, substrate and plant type were not important in their habitat choice.

Asia

Unfortunately, much of the Asian literature is lost to the western world because of our lack of skill in reading the languages. But according to Beasley *et al.* (2006), the knowledge of tardigrades in China is meager. And ecological studies seem to be totally wanting. Many of the studies are simply reports of collections made by outsiders (*e.g.* Mathews 1937a, b; Bartos 1963; Pilato 1974; Beasley *et al.* 2006). Pilato (1974) found six species of tardigrades in Chinese bryophyte communities and identified three new species: *Bryodelphax* [= *Echiniscus*] *sinensis*, *Macrobiotus mandalae*, and *Macrobiotus mauccii*. Yang (2002) reported on tardigrades from bryophytes in Yunnan Province. Beasley *et al.* (2006) reported only 18 species from a wide geographic range (3 provinces) in China, with 12 of these species occurring on mosses [*Echiniscus nepalensis*, *Pseudechiniscus jiroveci*, *Murrayon hibernicus*, *Hypsibius pallidus*, *Isohypsibius sattleri*, *Doryphoribius flavus*, *Diphascon pingue* (Figure 21), *Diphascon scoticum* (Figure 50), *Diphascon prorsirostre*, *Mesocrista spitsbergensis* (Figure 51), *Platicrista angustata* (Figure 52), *Milnesium tardigradum* (Figure 3)] and 1 on a liverwort [*Cornechiniscus lobatus* (see Figure 53)]. Of the 18 species reported, 8 were new to China! It is likely that a much larger fauna exists but has not been explored – or translated.

In 2007, Beasley and Miller published a list of tardigrades from Xinjiang Uygur Autonomous Region, China, based on bryophyte specimens from the Missouri Botanical Garden. They found only 78 tardigrades among the 270 specimens of bryophytes, comprising 12 species. Of these 12, 7 were new to China. Several additional

species could not be identified. The best known bryophyte dweller among these was *Milnesium tardigradum* (Figure 54). *Echiniscus testudo* (Figure 6) was found among the greatest number of bryophyte species. The majority of species were in the *Heterotardigrada*, possibly due to the higher elevation of the samples and the arid nature of the habitats.

Figure 51. *Mesocrista spitsbergensis*. Photo by Björn Söhlenius Swedish Museum of Natural History, with permission.

Figure 52. *Platicrista angustata*, a species that occurs on mosses in China. Photo by Michael Sullivan, with permission.

International knowledge of the Japanese tardigrade fauna suffers from the same language barrier. Mathews, who also named a number of Chinese taxa, reported on the Japanese tardigrades in 1936/37. More recently, Ito (1999) made an ecological study on the north slope of Mt. Fuji,

sampling soil, mosses, and lichens. The number of soil tardigrades ranged 8,050 m⁻² to 75,500 m⁻². Their density was as high as the density of soil arthropods such as mites (Acari) and springtails (Collembola). A few of these showed a relationship with altitude (950-2380 m asl), but typically the dominant species for a habitat did not change much among locations. On the other hand, they changed considerably between habitats at a single location.

Figure 53. *Cornechiniscus cornutus*. Photo by Martin Mach, with permission.

The Japanese certainly have not ignored the tardigrades. They have made important contributions to the physiology (Horikawa & Higashi 2004; Horikawa *et al.* 2006) and space biology (Horikawa 2008; Ono *et al.* 2008) of these organisms. There are also good studies on the ecology of soil species. But ecological studies on bryophyte-dwelling taxa are hard to find.

Africa

Although little is known about them, Africa sports its share of moss-dwelling tardigrades. Pilato and Pennisi (1976) reported 21 species of tardigrades among the mosses in their collections from Cyrenaica (eastern coast of Libya), two of which represented the first members of their genera in Africa. A third, *Isohypsibius brulloi*, was a new species. Binda (1984) found thirteen species of moss-dwelling tardigrades in South Africa and Mozambique.

Meyer and Hinton (2009) found only nine species of tardigrades among mosses and lichens in KwaZulu-Natal, South Africa, bringing the total number of species from soil, mosses, and lichens to 61 in southern Africa. But aside from species records, tardigrade-bryophyte ecological studies seem to be rare or non-existent for Africa.

Antarctic and Arctic

Unlike Asia, Africa, and South America (McInnes 1994), tardigrades are fairly well studied in polar climates, especially in the Antarctic. In the Antarctic, bryophytes, as well as lichens and algae, provide important habitats for tardigrades, rotifers, and nematodes (Utsugi & Ohyama 1991; Sohlenius *et al.* 2004). Most invertebrates decrease in abundance as one approaches the poles, but Jennings (1979) found that tardigrades actually increase in abundance in the Antarctic tundra. Peters and Dumjahn (1999) found 15 species in ten genera in their 249 cushion moss samples from Disko Island, West Greenland. On the other hand, in his moss studies on the Antarctic

Schirmacher Oasis, Mitra (1999) examined 36 sites and found only two tardigrade species.

Here they are also patchily distributed, nevertheless usually having the highest densities among these three groups of organisms. The ubiquitous and very common moss inhabitant, *Macrobiotus* sp., is present there, on the sub-Antarctic Marion Island (McInnes *et al.* 2001). Other tardigrades present include *Milnesium* cf. *tardigradum* (Figure 54) and *Echiniscus* sp. (Figure 55). Gut analysis of *M. tardigradum* revealed the presence of bdelloid rotifers and even other tardigrades (*Diphascon* sp.). Sohlenius and Boström (2006) also noted predation by tardigrades on rotifers in East Antarctica.

On the **nunataks** (mountain peaks that penetrate the ice sheet) in continental Antarctica, distribution of tardigrades is patchy, with the greatest abundance occurring within moss cushions and **guano** (accumulated excrement of seabirds and bats) from bird colonies (Swedish Museum of Natural History 2009). Nine tardigrade taxa have been identified in the Swedish studies.

Figure 54. *Milnesium tardigradum*, a cosmopolitan moss inhabitant. Photo by Yuuji Tsukii, with permission.

Figure 55. *Echiniscus*, a ubiquitous genus that occurs on mosses in the Antarctic. Photo by Martin Mach, with permission.

On Signy Island off the coast of Antarctica, Jennings (1979) found five species of tardigrades that occurred at both of the sampling sites: *Echiniscus capillatus*, *E. meridionalis*, *Hypsibius dujardini* (Figure 23), *Diphascon alpinum*, *Diphascon pingue sensu lato* (Figure 21; or may be *Diphascon polare*, *D. dastychi*, or *D. victoriae*), and *Macrobiotus furciger* (Figure 56). Other less common taxa were *Diphascon scoticum* (Figure 50), *Isohypsibius renaudi* (Figure 57), and *Isohypsibius asper* (Figure 58). Jennings conducted sampling for two years and found maximum populations of 309x10³ m⁻² in moss communities of *Polytrichum strictum* - *Chorisodontium aciphyllum* (Figure 59-Figure 61). In the *Calliergidium austro-*

stramineum – *Calliergon sarmentosum* – *Sanionia uncinata* communities (Figure 12; Figure 62; Figure 63) they found a maximum of $71 \times 10^3 \text{ m}^{-2}$. Reproductive potential is high, with increases of 3- to 4-fold in a single year. Hallas and Yeates (1972) found they could reach as high as 10- to 20-fold increases. *Echiniscus* increased 100-fold at one Signy Island site (Jennings 1979).

Figure 57. *Isohypsibius renaudi*. Photo through EOL Creative Commons.

Figure 58. *Isohypsibius asper*. Photo by Smithsonian Institution through EOL Creative Commons.

In their Antarctic study, Utsugi and Ohyama (1989) found five species of tardigrades in 15 out of 31 samples from Ongul Island, Langhovde, Skarvsnes, Einstoingen, and Rundvagshetta, including algae, lichens, and mosses. *Hypsibius arcticus* (Figure 45) was common in all their samples. The other four species were rare.

Figure 59. *Polytrichum strictum* and *Chorisodontium aciphyllum* in the Antarctic, where Jennings (1979) found 309×10^3 tardigrades per m^2 . Photo by Tim Hooker, with permission.

In a different study on Wilkes Land, East Antarctica, Petz (1997) found tardigrades in more than 74% of the collections of fellfield mosses. These were the most abundant of the invertebrates, with 4,607 in just one gram of moss. Rotifers were the most abundant in other habitats. Ottesen and Meier (1990) likewise found that tardigrades were more abundant among mosses on South Georgia, compared to other habitats.

Seasonal Variation

Densities may vary with seasons (Figure 66). *Hypsibius convergens* (Figure 18) exhibits temporal variation in pool and meadow moss habitats (Marcus 1929). In city mosses, the numbers of individuals of *Macrobiotus hufelandii* (Figure 15) and *Pseudechiniscus pseudoconifer* correlated with meteorological factors during a 3-month winter/early spring study (Franceschi *et al.* 1962-63). It appears that *Echiniscus* (Figure 55) and its segregate genera may commonly have seasonal variations. Jennings (1979) found that *Echiniscus* (possibly considered a segregate genus now) was the only tardigrade with seasonal variation among the eight species in his Signy Island study.

This is at least in part a reflection of changes in moisture. As already seen for *Diphascon rugosum* (Figure 22), *Hypsibius dujardini* (Figure 23), and *Hypsibius cf. convergens* (Figure 18), there were clear population peaks in winter in a carpet of the soil moss *Rhytidiadelphus squarrosus* (Figure 19) in the Black Forest, Germany (Schuster & Greven 2007). Species diversity and evenness was generally higher for the tardigrade communities in winter and least in summer (Figure 64). On the other hand, *Macrobiotus hufelandii* (Figure 15), *Diphascon pingue* (Figure 21), and to a lesser degree *Paramacrobiotus richtersi* (Figure 20), declined in winter, increasing in spring through fall (Figure 65). *Macrobiotus hufelandii* had its peaks in summer and lows in January (Schuster & Greven 2007), as shown for total tardigrades by Merrifield and Ingham (1998), but the other major species did not follow that pattern (Schuster & Greven 2007).

Figure 64. Seasonal changes in number of species of tardigrades found in *Rhytidiadelphus squarrosus* (Figure 19) clumps. (n = 108). Redrawn from Schuster & Greven 2007.

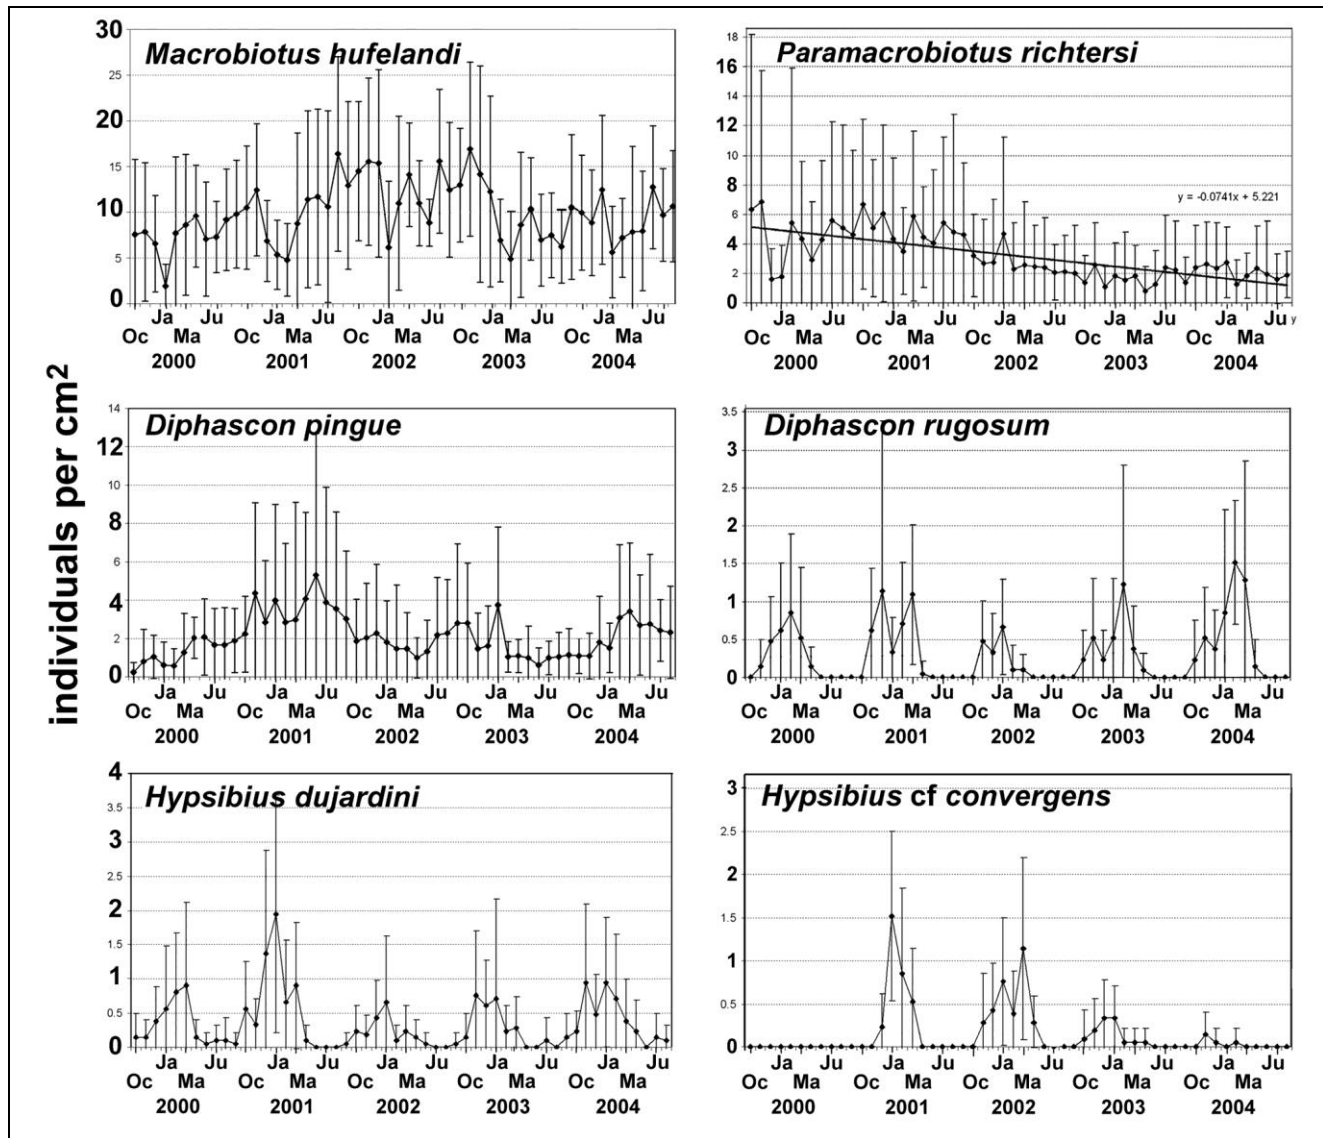

Figure 65. Seasonal changes in number of individuals of the dominant tardigrades found in *Rhytidiadelphus squarrosus* (Figure 19). *Paramacrobotus richtersi* shows a trend of decline during the sampling years, as shown by the regression line. Modified from Schuster and Greven 2007.

Using a Baermann funnel (Merrifield & Ingham 1998), Merrifield (1992) reported 5 tardigrades per gram on *Eurhynchium oregonum* (Figure 67) in Oregon, USA, from April to August, with an increase to 15 in September and October, then a crash to 1 for winter months of November through March (Figure 66). Were the bears hibernating elsewhere, or were numbers crashing in the damp Oregon winter?

Figure 66. Seasonal changes in numbers of tardigrades on mosses at Mary's Peak, Oregon, USA. Redrawn from Merrifield & Ingham 1998.

Figure 67. *Eurhynchium oregonum*, a non-winter habitat for tardigrades. Photo from University of British Columbia bryophyte website, with permission.

Romano *et al.* (2001) attempted to determine the seasonal effects on tardigrades among mosses along Choccolocco Creek, Alabama, USA. They surveyed mosses on three trees each in six sites for 18 months and found no correlation between occurrence and season. However, they did find seasonal differences in the number of species and abundance when they pooled samples.

Patchiness

A number of studies suggest that the distribution of tardigrades within a given area or on a particular type of substrate is patchy. Degma *et al.* (2005) actually did both cluster analysis and CCA, demonstrating that most of the differences in species diversity were the result of randomly found species and that colonization of any given substrate is a random process. It would appear that the greatest determining factor in their specific location and species composition is their dispersal to that location, a process that is as random as it is for the mosses and liverworts they sit on. Further support for this randomness is their random distribution among populations of the moss *Hypnum cupressiforme* (Figure 68), supported by a Chi-square goodness of fit test.

Figure 68. *Hypnum cupressiforme*, a ubiquitous moss that seems suitable for many taxa of tardigrades. Photo by Michael Lüth, with permission.

Degma *et al.* (2009, 2011) found that the horizontal distribution of the tardigrades on a moss clump is aggregated, but that aggregation is not related to moisture in the moss cushion. They hypothesized that once a tardigrade arrives through random recruitment it is able to establish a micro-population. From that beginning slow radiation occurs. The result is that large substrates have more tardigrades but some parts of these larger patches will lack tardigrades while other parts will house aggregations. They continued their study (Degma *et al.* 2011) using *Hypnum cupressiforme* (Figure 68) with a 5x5 matrix of circular plots and determined that there was no significant moisture gradient along that moss slope. Nevertheless, the tardigrades existed in clumps or patches. With a large number of individuals (224) in seven species [*Milnesium tardigradum* (Figure 3), *Hypsibius convergens* (Figure 18), *H. microps*, *Diphascon pingue* (Figure 21), *Astatumen trinacriae* (Figure 36), *Macrobiotus hufelandi* (Figure 15), *Minibiotus* sp. (Figure 47)], they found that species number was random, but that species distribution

was aggregated. That aggregated distribution was NOT related to moisture in the moss mat. They concluded, therefore, that the best hypothesis to explain the patchy distribution of the tardigrades within the moss cushion was that recruitment of eggs and specimens on the moss was random and that these recruits subsequently reproduced, creating micro-populations where density gradually increased over time. This hypothesis makes the assumption that tardigrades migrate little from the location of their birth. Following this reasoning on a larger scale would account for the patchy distribution observed on larger moss clumps. Larger patches of mosses are more likely to be the recipients of dispersed tardigrades or their eggs and hence are more likely to have tardigrades than would small patches. This would also account for the high degree of variation encountered in random sampling from various moss cushions in the same location. While the individuals are aggregated, the aggregations are random.

Meyer (2006b) did a careful study on the spatial variability of tardigrade populations among moss patches on trees and rocks at three locations in the USA. He examined the fauna on patches ranging 0.1 to >5 cm². He found very high variation among the patches. One interesting discovery was that very small patches rarely had tardigrades. Could it be that they did not retain moisture long enough, or was it a matter of dispersal, with small patches having endured too short a time for colonization to be common?

Perhaps it is predictable that patchiness would characterize Antarctic moss dwellers. In the Antarctic, bryophytes, as well as lichens and algae, provide an important habitat for tardigrades, rotifers, and nematodes (Utsugi & Ohyama 1991; Sohlenius *et al.* 2004). Here tardigrades are also patchily distributed, nevertheless having the highest densities among these three groups of organisms. One might assume that bryophytes must arrive first, or that the tardigrades arrive with their bryophyte home. Hence, dispersal to the continent and its remote islands most likely plays a major role in their location.

Studies by the Swedish Museum of Natural History (2009) likewise found patchy distribution of tardigrades on the nunataks of the Antarctic. These windswept peaks emerge above the ice sheets and provide the substrate needed for bryophytes, lichens, and inhabiting tardigrades. Moss cushions and humus enriched by bird colonies provided the greatest numbers of tardigrades, with 400 samples yielding only nine tardigrade taxa. Nevertheless, 32% of the samples had tardigrades (Sohlenius & Boström 2006). The importance of the stochastic process of colonization is supported by the presence of different developmental stages in various samples, suggesting that dispersal may be a dynamic, albeit random, process occurring constantly on the windy peaks. Further population control may exist through competition with the co-occurring nematodes, whereas it appears that the poor rotifers serve as dinner for at least some of these tardigrades.

Bettis (2008) tested differences in tardigrade distribution on *Grimmia* (Figure 69) on exposed granitic outcrops vs protected seasonally riparian forms in California, USA. Again, the distribution was "very patchy" and did not support the hypothesis that more tardigrades would be on the more protected, more moist mosses.

Figure 69. *Grimmia laevigata* in Europe. Photo by Michael Lüth, with permission.

Both Meyer (2006b) (in the terrestrial system) and Romano *et al.* (2001) (in the aquatic system), emphasized the importance of accounting for this patchiness in designing a sampling strategy. Meyer suggested that the variability of a given location should be understood before determining the number of samples to take. Romano emphasized the need for a greater sampling effort.

In short, it appears that the major factor accounting for tardigrade distribution and patchiness is dispersal. If the tardigrade lands in an appropriate habitat, it is able to withstand considerable environmental variation there, and the habitat itself seems to offer little to discriminate against any tardigrade species. Rather, factors like reproductive potential may play the greater role in determining the abundance, and possibly even the diversity, once the tardigrades arrive.

I was excited to make new friends among newcomers to the bryophyte-tardigrade relationship. I hope this chapter has inspired more young researchers to include the bryophyte microcosm in their studies. Jaime Jiménez, a vertebrate zoologist, summarizes his conversion to tardigrade study in the box below:

Statement by Jaime Jiménez

While working on the seedsnipe and geese feces with Nick [Nick Russo] and Mike [Robertson] on Navarino Island, examining for bryophytes fragments to cultivate, they found a few small water bears. Nick and Mike were my first cohort students from my IRES-NSF grant (Bernard [Goffinet] was the US co-mentor). We were all captivated to see these creature for the first time. It happened that Peter Convey (BAS that used to examine tardigrades from Antarctica) was at the lab during these days and he offered to bring these samples to Cambridge to the tardigrade world expert Sandra McInnes. She put me in contact with William Miller (KS, one of the US tardigrade experts), as she recently reviewed a paper of him on tardigrades found in bird nests. Simultaneously, with Mike, Nick and Sandra we presented a poster in Copenhagen and then in British Columbia (American Ornithological Societies conference). I invited William to

UNT, and since then we have been collaborating. As a result, I “rearranged my lab” to add microscopes, dissecting scopes and cameras to mammal traps, camera traps, mist nests and binoculars. This triggered my enthusiasm to collect many bryophytes/moss samples throughout southern Chile from which I am “hunting” tardigrades to study their biogeography and habitat associations. I also have one graduate student working on tardigrade biotic homogenization.

Summary

Tardigrades can range in numbers from none to 22,000 individuals per gram of dry moss. More than 2 million are known from a single square meter. On Vancouver Island in Canada, 39 species have been found among bryophytes. They do not seem to prefer any particular moss, and they often occur equally as frequently on lichens and liverworts as they do on mosses. In New Zealand, 30 species are known from liverworts.

Macrobiotus and *Echiniscus* (and their more recent segregates) are among the most abundant tardigrades in the bryophyte fauna. Although most invertebrates decrease in numbers toward the poles, tardigrades actually increase. However, their numbers are highly variable from one place to another. Here, even more so than elsewhere, distribution of the tardigrades is patchy. Even adjacent trees in some localities are known to differ greatly in their tardigrade fauna. Yet, on Wilkes Land in the Antarctic, 74% of the fellfield mosses had tardigrades.

They are known to increase up to 100-fold, but it appears that 3- to 4-fold is more typical. Their abundance can be seasonal, with some peaking in winter and others in summer or spring/fall. Some respond to the rainy season. Others don't seem to respond to season.

Dispersal plays a large role in both geographic distribution and local patchiness. Within the cushions the tardigrades are often aggregated, but there appears to be no relationship with moisture. On the other hand, small patches seem to lack tardigrades, suggesting that moisture is important. But arrival is a major factor, and from that arrival of one tardigrade, a population develops. Since their movement is slow, they accumulate. But small patches of mosses indicate a short time in which arrival could have occurred.

Acknowledgments

Like all of my chapters, this one is really the product of the efforts of many biologists. Roberto Bertolani provided an invaluable update to the tardigrade taxonomic names and offered several suggestions on the text to provide clarification or correct errors. Bryonettors have been wonderful in making their photographs available to me and seeking photographs from others. Paul Davison and Des Callahan have been helpful in providing suggestions and offering images. Bob Goldstein, Bjorn Sohlenius, Martin Mach, and Yuuji Tsukii have given permission to use images that illustrate the species and life

cycle stages. Łukasz Kaczmarek has provided me with references and contact information. As always, a big thank you goes to Michael Lüth for permission to use his many images and to all those who have contributed their images to Wikimedia Commons and other public domain sources for all to use. I must admit that this chapter would have been far less interesting without the help of Google to locate the tardigrade stories. I fear I have forgotten some who have helped – I have worked on this chapter for too many years. Nomenclature follows Degma *et al.* (2010).

CHAPTER 5-6

TARDIGRADE ECOLOGY

Figure 1. *Echiniscus*, the genus with the most species among mosses. Photo by Łukasz Kaczmarek and Łukasz Michalczyk, with permission.

Dispersal

As already discussed, one suggested reason for patchy distribution of tardigrades is the difficulty of dispersal for this small organism. Miller *et al.* (1994) concluded that tardigrade distribution in the Antarctic is influenced more strongly by dispersal limitations than it is by climate or habitat interactions. McInnes and Convey (2005) found a low species richness of tardigrades (6 taxa) in the South Sandwich Islands in the sub-Antarctic. They found indications that the tardigrades originated from both sub-Antarctic and maritime Antarctic populations.

Wind dispersal is considered the major means by which tardigrades move to new locations (Christenberry & Higgins 1979; Bertolani *et al.* 2009). The anhydrobiotic state is very light weight and can easily survive the various dangers of space (see below).

Faurby *et al.* (2008) suggested dispersal rate may be coupled with survival in the anhydrobiotic state. Based on these assumptions, Bromley (2009) has considered the possibilities that habitats such as rooftops with mosses serve as islands for tardigrades.

Sudzuki (1972) experimented with wind dispersal to moss mats and found that smaller micro-organisms (<10x30x50 µm) were easily blown from their location to reach the mosses 100-500 cm away. Tardigrades, on the other hand, almost never reached the mosses during two

months of experimentation with the fan-generated wind operating alternate days.

Although wind is probably the most common means, other means of dispersal may be afforded by water, insects, and other invertebrates. Resting eggs offer another dispersible propagule. Eggs of tardigrades are about the same size as a pollen grain and may similarly be dispersed by wind (Ramazzotti 1972). Many species have eggs with decorations on them (Figure 2) reminiscent of allergenic pollen grains, *i.e.*, those adapted for wind pollination.

Figure 2. Egg of *Dactylobiotus* sp. showing decorated wall similar to that of a pollen grain. Photo by Yuuji Tsukii, with permission.

Whereas tardigrades don't seem to be dispersed very easily by themselves, their dispersal as hitch-hikers on bryophytes is a more feasible means (Janiec 1996). Not only live animals, but also tuns, cysts, and eggs can be dispersed when their bryological home is dispersed. Storms, animals, wind, and water are all means by which the substrate and fauna could travel together.

Most recently, we find that a combination of seedsnipes, bryophytes, and tardigrades may contribute to their dispersal (Robertson *et al.* 2020). Robertson and coworkers demonstrated that tardigrades can live in the feces of the White-bellied Seedsnipe (*Attagis malouinus*, Figure 3). These included the tardigrades *Adropion* (Figure 4), *Isohypsibius* (Figure 26), and *Macrobiotus* (Figure 11, Figure 17, Figure 25). Since at least some of these genera are known to live among bryophytes, and *Attagis malouinus*, as well as two species of the geese *Chloephaga picta* (Figure 5) and *C. poliocephala* (Figure 6) are known to ingest bryophytes (Russo *et al.* 2020), dispersal of mosses and their adherent tardigrades might very well be dispersed by **endozoochory** – that is, dispersal by passing through the gut of the birds.

Peninsula Effect

The **peninsula effect** postulates that the number of species will decrease as one approaches the tip of a peninsula. This presumably is the case because of the lack of opportunity for invasion of new species from the more seaward positions. Simpson (1964) suggested that there is a peninsular effect in animal distribution similar to that seen in island biogeography. Jenkins and Rinne (2008) defined the peninsula effect as "the prediction that the number of species declines from a peninsula's base to its tip." They considered whether this concept might be a "red herring" and expressed concern that most studies had not controlled for other possible explanations or from unequal sampling effort. In the Florida, USA, peninsula, they found that 82.5% of variation in freshwater microcrustacean species richness was attributed to habitat and sampling effort, and there was no peninsular effect. In fact, they suggest that the evidence previously published only supported the concept for mammals.

Taylor and Regal (1978) tested the concept of extinction and recolonization, a tenet of the peninsular effect, for rodents in Baja California and concluded that for an effective peninsular effect the habitable sites "are few and widely spaced." Brown (1987) examined the effect on butterflies (Lepidoptera) in the Baja peninsula and determined that there was no peninsular effect for that group. Likewise, Busack and Hedges (1984) found no peninsular effect for lizards and snakes on the Baja peninsula.

Taylor and Regal (1978) suggest that changes in vegetation in Florida that are due to rising water levels and climate change may account for the decline in species richness southward on that peninsula. They argue that other large peninsulas where Simpson demonstrated a peninsular effect represent major topographic changes or harsh climate gradients that could account for changes in species number.

Nevertheless, Meyer (2008) found a peninsular effect in tardigrades when bryophyte and lichen epiphytes in all 67 Florida counties were sampled, with species richness diminishing from north to south. If we combine the information gained from the above studies, it appears that Taylor and Regal (1978) may have been correct in suggesting that the peninsular effect required few and

widely spaced habitable sites. And widely spaced for one species may be a lazy day's walk for another. To put this into the perspective of bryophyte-dwelling tardigrades, isolation and difficulty of dispersal are typical, *i.e.*, widely spaced habitable sites (see dispersal discussion above), and would make tardigrades more likely to have the extinction-recolonization limits required for the peninsular shape to have a "peninsular effect." The apparent need for wind dispersal of tardigrades is further complicated by their residence within the bryophyte mat, and it seems they would most likely be dispersed only when they and their bryophyte substrate are dry and fragments to which they adhere become airborne. This dispersal limitation has been discussed earlier (Chapter 5-5 of this volume) in relation to the patchiness of populations within a given small area.

There is a possible caveat to this discussion. The definition of a peninsular effect seems to have drifted from that of Simpson (1964). He considered peninsulas to have fewer species (lower richness) than continental areas and did not treat them as having fewer species toward the tip. However, he did consider that spread of species could occur in one direction only (*i.e.*, no new mammal species were likely to arrive from the tip in the short term). He suggested that this would make them more liable to local extinctions (*i.e.*, reducing the density of species richness).

Distribution

Tardigrades, like the protozoa, have many taxa with worldwide distributions (McInnes 1994; McInnes & Pugh 1998). With so little attention paid to this group, relative to that for the protozoa, it is difficult to draw distributional conclusions. There are hints of the "**everything is everywhere**" principle (in Wit & Bouvier 2006) for these small, lightweight creatures. (See Chapter 2-6 on Protozoa Ecology.) Their ability to become anhydrobiotic for long periods of time increases their chances for successful dispersal over great distances.

Among the moss dwellers, we find that *Doryphoribius flavus* has been found in Europe, Asia, Africa, and Central America (McInnes 1994). It is now known from Tennessee, USA (Bartels *et al.* 2007). Its original discovery was in moss subjected to desiccation (Iharos 1966). On the other hand, *Doryphoribius polynetae* had been found only in Russia in a small lake and in mosses [*Sphagnum* sp. (Figure 7), *Polytrichum juniperinum* (Figure 8)] near the lake, but was likewise recently found in Tennessee (Bartels *et al.* 2007).

Figure 7. *Sphagnum warnstorffii*. Photo by Michael Lüth, with permission.

Meyer (2008) found *Minibiotus fallax*, previously known only from Australia (Pilato *et al.* 1989), in moss and lichen collections from Florida, USA. Other surprising disjunctions are likely to appear because the group is poorly known and sampling is spotty.

Jørgensen *et al.* (2007) explored the microspecies concept in *Echiniscus testudo* (Figure 9), using DNA sequences. Their study included 13 localities on three continents. They found high haplotype diversity and low sequence diversity, suggesting that this species had haplotype evolution with distinct asexual lineages and a high dispersal, as suggested by lack of isolation by distance. Although there were geographic differences, there was low genetic diversity. *Echiniscus* (Figure 10) is the largest genus, and the authors suggest that the high number of species may result from the combination of large potential for dispersal coupled with the lack of need of a partner for reproduction. Bryologists might benefit from understanding the distribution of these organisms as bryophytes and tardigrades seem to have similar dispersal advantages and disadvantages and both are capable of asexual reproduction.

Although it does not appear that *E. testudo* (Figure 9) has a large number of microspecies, it is likely that some of the more common species may actually be species complexes, further complicating our understanding of species distributions and diversity. These include taxa such as *Macrobiotus hufelandi* (Figure 11), *Minibiotus intermedius* (Figure 12), *Diphascon scoticum* (Figure 13), and *Milnesium tardigradum* (Figure 14) (Bertolani & Rebecchi 1993; Claxton 1998, 1999; Pilato 1987).

Blaxter *et al.* (2004) examined the Scottish tardigrade fauna for genetic differences. They found that some **Molecular Operational Taxonomic Units (MOTU)** were shared between the two rural collections in the study, but that none were found in both the one urban and two rural sites. This lack of commonality conflicts with the generally accepted concept of ubiquity of this faunal group. They described the high variability among the specimens as representing "**taxon flocks.**" It suggests to me that once arriving at a new site, the tardigrades are likely to reproduce asexually and eventually diverge from their ancestors, creating **cryptic species**. **Genetic drift**, **Founder Principle**, and **microselection** factors could all contribute to enhancing this noted variability. I suspect we will find many similar examples among bryophytes.

Such possibilities of genetic variation without obvious morphological indicators demonstrate the folly of attempting to present a reasonable distribution pattern for the moss-dwelling tardigrades at this stage. Look for them. You will probably find a new species, or at least a new cryptic species, and certainly expand our understanding of their distributions and their ecology.

Distribution is the product of many factors, including dispersal, climate, niches available, microclimate, and attending factors such as altitude, rainfall, temperature range, and severity and length of winter or summer. Guil *et al.* (2009) sampled mosses and other vegetation to determine the effects of micro- and macro-environmental factors on the distribution of tardigrades in those habitats in the central Iberian mountain areas of Spain. They found that bioclimatic classification was the best predictor for

species richness. Altitude had a relationship, but its effects could not be separated from the macro-environmental gradients of soil, climate, vegetation type, and litter type. Within the micro-scale plots, the micro- and macro-environmental variables could explain ca 60% of the species richness, particularly litter type and vegetation type. On the other hand, abundance was not explained by the macro-environment, but rather was explained by soil composition and litter type. I have to wonder if soil composition affected the availability of bryophytes and their growth forms.

Common Species

Among the many collections of bryophytes, species of *Echiniscus* (Figure 15), *Hypsibius* (Figure 16), *Macrobiotus* (and segregate genera; Figure 17), *Milnesium* (Figure 14), and *Ramazzottius* (Figure 18) seem particularly common.

Table 1 lists some of the taxa known from the literature, but many more exist and would be an endless task to include here. A complete list of all tardigrade names with updated nomenclature (used here) is in Degma *et al.* 2010.

Figure 17. *Macrobiotus blocki*, an Antarctic member of one of the most common moss-dwelling genera. Photo by Martin Mach, with permission.

In Sweden, Jönsson (2003) found that *Macrobiotus hufelandi* (Figure 11) is far more common among mosses than are other tardigrade species. This species seems to be abundant in most bryophyte studies. It seems remarkable that as late as 2003, the common bryophyte dwellers *Murrayon diana*, *Isohypsibius sattleri*, *Platicrista angustata* (Figure 22), *Diphascon belgicæ*, and *Diphascon pingue* (Figure 19) were recorded from Sweden for the first time (Jönsson 2003).

Figure 18. *Ramazzottius* sp., member of a common moss-dwelling genus. Photo by Martin Mach, with permission.

Figure 19. *Diphascon pingue*. Photo by Michael Collins, with permission.

A major problem in trying to define tardigrade distributions and habitats is the lack of sufficient study of this entire group of organisms. Guil and Cabrero-Sañudo (2000) stated that the "tardigrade species description process fails to show an asymptotic tendency." Meyer and Hinton (2007) reported that "30% of the Nearctic species have been reported from a single site!" In other words, it will be a long time before we even know most of the species in existence or even make reasonable estimates of

how many species there are. And ecological descriptions necessarily lag behind the descriptions of the species.

Beasley *et al.* (2006) lamented the difficulty of assessing diversity of tardigrades in China because of the limited data available. In their report on 18 tardigrades of Sichuan, Yunnan, and Xizang Provinces, eight were new records for China. Among the 86 species known from China, 82 are terrestrial. Among these, *Echiniscus nepalensis*, *Pseudechiniscus jiroveci*, *Murrayon hibernicus*, *Hypsibius pallidus*, *Isohypsibius sattleri*, *Doryphoribius flavus*, *Diphascon pingue* (Figure 19), *D. scoticum* (Figure 13), *D. prorsirostre* (Figure 20), *Mesocrista spitsbergensis* (Figure 21), *Platicrista angustata* (Figure 22), *Milnesium tardigradum* (Figure 14) were from mosses. Only *Cornechiniscus lobatus* (see Figure 23) was found on liverworts.

Communities

Séméria (1982) found that a typical bryophyte-dwelling (and lichen-dwelling) tardigrade had one predator and several detritivorous or herbivorous species in its community. Typical communities of bryophyte-dwellers have 2-6 tardigrade species, and sometimes even more than ten (Ramazzotti & Maucci 1983).

Specific bryophyte communities have rarely been identified, but Miller *et al.* (1996) identified significant positive associations between the three most common of the tardigrade species and certain bryophyte species in the Antarctic. On the other hand, these same three species had a strong negative association with algae and lichens. In Britain, Wright (1991) suggested that *Milnesium tardigradum* (Figure 14) might have a selective predatory association with *Hypsibius dujardini* (Figure 16) and *Ramazzottius oberhaeuseri* (Figure 28).

Among the Florida epiphytes, Meyer (2008) typically found one predatory species [*Milnesium tardigradum* (Figure 14, Figure 50), *Paramacrobiotus richtersi* (Figure 24)], *Macrobiotus* cf. *harmsworthi* (Figure 25), or one other *Macrobiotus* species, one *Minibiotus* species, and one echiniscid species. One or more of these niches is frequently unoccupied, but when occupied the species followed this trophic hierarchy. In only one sample were there two predatory species.

Figure 24. SEM of *Paramacrobiotus richtersi*. Photo through Creative Commons.

Figure 25. *Macrobiotus harmsworthi*, a common tardigrade on bryophytes and elsewhere. Photo by Paul J. Bartels, with permission.

Collins and Bateman (2001) found that *Isohypsibius prosostomus* (Figure 26) did not occur with *Diphascon scoticum* or *Minibiotus intermedius* (Figure 12) and only rarely occurred with *Diphascon pingue* (Figure 19) or *Hypsibius convergens* (Figure 27), attributing these negative associations to trophic overlap.

Figure 26. *Isohypsibius prosostomus*. Photo by Michael Collins, with permission.

Figure 27. *Hypsibius convergens*. Photo by Łukasz Kaczmarek and Łukasz Michalczyk, with permission.

Competitive exclusion, most likely for food, also drives community associations. Wright (1991) found that *Macrobiotus hufelandi* (Figure 11), *Paramacrobiotus richtersi* (Figure 24), and *Isohypsibius prosostomus* (Figure 26) avoid each other's company.

But food webs are not the only controlling factors. Bryophytes can play a major role through the climate they create. For example, *Macrobiotus hufelandi* (Figure 11) and *Hypsibius dujardini* (Figure 16) are absent when the habitat desiccates rapidly, making some bryophytes ideal for them (Wright 1991). *Milnesium tardigradum* (Figure 14, Figure 50) and *Ramazzottius* (formerly *Hypsibius*) *oberhaeuseri* (Figure 28) likewise avoid areas with a high rate of desiccation, as well as locations with high insolation, but also avoid poorly drained sites, excluding them from bryophytes in low-lying, wet areas. These limitations can result in predictable associations. Among these is a significant association among *Milnesium tardigradum* (Figure 14, Figure 50) – a predator – and two *Hypsibius* species among the British fauna. Further temporary community differences can be driven by the behavior of some species to migrate vertically in the moss cushion to a position of greater moisture, while other species such as *Echiniscus testudo* (Figure 9) remain behind. And of course this inability to migrate may limit the mosses it occupies in the first place.

But despite the importance of moisture in the continuing life cycle of the tardigrades, there is not always agreement on the moisture level needed. In Newfoundland, only *Hypsibius dujardini* (Figure 16) seems to follow a consistent relationship to a moisture category (Collins & Bateman 2001). It appears that rate of desiccation must be considered along with moisture level in determining the community structure.

Even on the same moss species or growth form, macrohabitat makes a difference. Jönsson (2003) found that tardigrade abundance of the same species differed between a forest and a clearcut area, with greater numbers of species in the forest. Nevertheless, abundances were similar.

Unique Partnerships?

Despite the tiny size of this moss community, its relationships can be complex. The tardigrades *Ramazzottius oberhaeuseri* (Figure 28) and *Milnesium tardigradum* (Figure 14) both can carry the protozoan *Pxyidium tardigradum* (Figure 29) on their surface, a relationship known as that of a **symphoriont** (Morgan 1976). Morgan found both of these tardigrades with their passengers living among mosses. Van der Land (1964), who first discovered these protozoa on lichens, revived the dried tardigrades there, only to discover these protozoa that also were dormant became active after being placed in water. The accompanying rotifers and oribatid mites had no protozoan passengers, but Van der Land (1964) could not determine if these companions were alive at the time he rehydrated them. As noted earlier, this protozoan can at times be so abundant (up to 35 on a single water bear) that they slow down the tardigrade and might more appropriately be considered a parasite (Vicente *et al.* 2008). Although such symphoriont/parasitic(?) relationships have rarely been observed among the moss dwellers, we simply have not spent much time looking for them.

Figure 28. *Ramazzottius oberhaeuseri*. Photo by Martin Mach, with permission.

Bryophyte Dangers – Fungal Parasites

This wonderful bryophyte home is not without its dangers to the moss-dwelling tardigrades. The phycomycetous fungus *Catenaria anguillulae* (Figure 30) is a widespread parasite on living, senescent, and dead microscopic animals (Barron 2009). The motile zoospores are attracted to exudations from openings on the bodies of nematodes and rotifers (Jansson & Thiman 1992), and it is likely that this opportunist also occurs on tardigrades (George Barron, pers. comm. 2010). The zoospores encyst on the cuticular covering near the opening or a wound. Hence, it is typical for them to colonize around the mouth or other opening. They subsequently germinate and penetrate through the orifice or wound to attack the animal on the inside.

Figure 30. Tardigrade with fungus on its side. It is likely that this fungus is *Catenaria anguillulae* and that the attack location is a wound. Photo by Martin Mach, with permission.

Two fungi in the Ascomycota, *Lecophagus* [= *Cephalophora*] *muscicola* (Figure 31-Figure 32) and *Lecophagus* [= *Cephalophora*] *longispora* (Figure 33-Figure 34), capture rotifers and possibly tardigrades within the bryophytes and bryophyte-covered soil (Barron *et al.* 1990). This rather strange pair of fungi is endowed with elongate, hyaline, multiseptate, canoe-shaped conidia produced in small clusters at the apex of the conidiophores. When rotifers are present, the conidia germinate and produce one or several adhesive pegs that capture rotifers and tardigrades. Such fungal predators have been identified from moss-covered soil and forest debris in New Zealand and mosses in Canada, as well as from leaf mold in Japan, but their actual attack on tardigrades dwelling in mosses lacks documentation.

McInnes (2003) reports that the predatory fungus *Lecophagus antarcticus* attacks tardigrades that occur on cyanobacterial mats in lake sediments. Since *Lecophagus muscicola* (Figure 31-Figure 32) and *L. longispora* (Figure 33) are in the same genus and occur in wet or mossy soil (Barron *et al.* 1990; George Barron, pers. comm. 25 January 2010), it is reasonable to suggest that they might attack tardigrades in the same habitat, but can they? In fact, rotifers are attracted to the adhesive pegs of the fungus and then attach to the tip of the peg. That is their downfall, as the predator becomes the prey when the host (rotifer, nematode, or tardigrade) adheres to these adhesive pegs, possibly by lectin/carbohydrate bonding. But instead of providing a meal for the invertebrate, the fungus penetrates and parasitizes it, making it a host. Barron considers this "a stretch" to consider that the tardigrades would attack the fungi just as readily as would the rotifers. But tardigrades are known to consume other filaments such as those of algae, so it is at least a possibility.

Figure 31. *Lecophagus muscicola* with two captured rotifers and two adhesive pegs. Photo by George Barron, with permission.

Figure 32. Conidia (X600) of *Lecophagus muscicola*. Photo by George Barron, with permission.

Figure 33. *Lecophagus longispora* infecting rotifers. Note also the elongate branch with terminal conidiogenous cell bearing a cluster of developing conidia. (X450). Photo by George Barron, with permission.

Several species of fungi in the genus *Ballocephala* (Zygomycota) (Figure 35-Figure 37) are known to attack tardigrades (Pohlad & Bernard 1978; Barron 2007). *Ballocephala pedicellata* was first described from individuals attacking the tardigrades *Hypsibius dujardini* (Figure 16) and the *Diphascon pingue* (Figure 19) complex living among mosses (Pohlad & Bernard 1978).

Adhesive conidia of *Ballocephala* species (Figure 35) attach to the cuticle surrounding the mouth of the tardigrade (Figure 35). These adhesive spores then encyst on the outside of their host. The spores extend long, narrow penetration pegs that are used to "snake" their way into the host, bypassing the defense mechanisms of the animal (Barron 2007). As the hyphae grow they penetrate the host and fill it with hyphae (Figure 36) that secrete extracellular enzymes to digest the tardigrade and assimilate its tissue.

Figure 34. Hypha of *Lecophagus longispora* with a cluster of conidia and adhesive pegs, a fungus that traps rotifers and that may be a threat to some tardigrades living in mosses. Inset shows the adhesive pegs. Photos by George Barron, with permission.

Eventually the fungus breaks from the inside to the outside where it produces asexual spores (**conidiospores**) (Figure 38) that attack additional hosts. The fungus even has its own means to survive when the environment dries up and the tardigrade with it. Like many algae faced with

declining conditions, this fungus undergoes sexual reproduction and produces zygotes that in turn form a thick wall and become **zygospores** (Figure 37). These resting spores permit the fungus to survive long periods of time (weeks to years) until favorable growing conditions return. Upon germination the zygospores presumably will divide to produce conidiophores and conidia that infect later generations of the tardigrade, but so far, this event has not been witnessed.

Figure 38. Conidiospores of the fungus *Ballocephala sphaerospora* on a tardigrade. Photo by George Barron, with permission.

The parasitic fungus *Haptoglossa mirabilis* (Figure 39) attacks tardigrades using the most complicated cellular mechanism known among the fungi (Robb & Barron 1982). It uses a gun-shaped attack cell that "shoots" into the host (Figure 40-Figure 41). At the anterior end of its cell is an elongated, barrel-shaped form. It is invaginated deeply into the cell, forming a bore. At the base of the bore is a walled chamber to house a missile-like attack apparatus. Robb and Barron hypothesize its mechanism:

This apparatus is able to fire the projectile at a high speed like a hypodermic needle, penetrating and injecting the host with the sporidium that infects the host. To accomplish this it has a basal vacuole with very high osmotic power. Water enters it rapidly and pumps the protoplasm and nucleus from the gun cell, through the hypodermic tube, and into the body of the host. If rotifers touch this fungus, they are hit within 0.1 second! But the proficiency of this apparatus doesn't end there. The head of this "harpoon" projectile is laminated, making it compressible. Thus, once it penetrates its host, it expands to seal the wound.

Once within the tardigrade, the fungus forms a cylindrical thallus (Figure 39) that consumes the poor tardigrade in a matter of days (Robb & Barron 1982). The hyphae eventually form zoospores. These exit through tubes and swim away to encyst. When the cysts germinate they form new clusters of gun cells. Some species can attack rotifers and nematodes as well.

George Barron (personal communication 1 March 2010) has commented to me that parasitic and predatory fungi are likely if both stylet-feeding and ingestion-feeding tardigrades coexist among mosses. But he finds it surprising that they have not yet been discovered.

Figure 39. Fungus *Haptoglossa mirabilis* in a tardigrade, where it has formed a single thallus. Photo by George Barron, with permission.

The parasitic fungal genus *Harposporium* (Figure 42) has members that attack tardigrades (Saikawa *et al.* 1991), but the fungus must be ingested to function (George Barron, pers. comm. 25 January 2010). Barron (2008) suggests, as a hypothesis, that the spore is pumped down the oesophagus, where "it spirals and screws into the muscle fibres, thus lodging in the oesophagus."

Role of Bryophytes in Fungal Interactions

Milnesium tardigradum (Figure 14) can be parasitized by a chytridiomycetous fungus, a zoosporic fungus that is common in soil (Dewel & Dewel 1987). Letcher and Powell (2002) attempted to determine the role that mosses play in the establishment of **Chytridiomycota** in four sites in the Blue Ridge and Allegheny Mountains of Virginia, USA. They first determined that frequency of **Chytridiomycota** was greatest in soil under and surrounding the rhizoids of two moss species [*Polytrichastrum* (formerly in *Polytrichum*) *ohioense* (Figure 43), *Dicranum polysetum* (Figure 44)]. They also found that random point sampling suggested differences existed in zoosporic fungal frequency between the moss-covered soil and the exposed soil adjacent to these mosses, as well as between the two taxa. Similar differences were demonstrated using linear transect sampling. But, at last, the statistical analysis of the random point samples failed to demonstrate that the differences were significant for frequency of zoosporic fungi between the exposed soil and the moss-covered soil. However, they did find a significant difference between different moss/soil complexes for the frequency of the 15 common zoosporic fungal species they identified.

Figure 43. *Polytrichastrum ohioense* males with new growth. Photo by Janice Glime.

Figure 44. *Dicranum polysetum*. Photo by Robert Klips, with permission.

One reason to suspect fungal differences under mosses compared to exposed soil is moisture. Using a scale of 0-10 (dry to saturated), Letcher and Powell found that the 48 moss-covered soil samples had a mean soil moisture content of 1.89, whereas the 24 exposed soil samples had a mean of 1.33.

Pollution

In addition to fungal dangers, the bryophytes also become dangerous to tardigrades when they become polluted (Steiner 1994b). Vargha *et al.* (2002) found that the concentrations of metals in tardigrades bore a relationship to the concentrations in the mosses. Elevated concentrations of heavy metals correlated with a decrease in tardigrade fauna. Meininger *et al.* (1985) found that poor air quality (SO₂) could reduce the number of tardigrades in otherwise suitable moisture regimes among epiphytic mosses in the area of Cincinnati, Ohio, USA (Figure 45).

Figure 45. Effects of relative humidity and sulfur deposits from SO_2 on the frequency of tardigrades inhabiting lichens and mosses on red oak (*Quercus rubra*) in the Cincinnati area of Ohio, USA. $n=20$. Redrawn from Meininger *et al.* 1985.

Just as bryophytes and lichens have often been used as indicators of clean air or biomonitors of air pollution, so have their tardigrade inhabitants in both aquatic (Steiner 1994a) and terrestrial (Steiner 1995) conditions. And their responses are much the same. In a study in the Cincinnati, Ohio, USA area, Meininger *et al.* (1985) found that both epiphytic (tree-dwelling) bryophytes and their tardigrade fauna had the greatest species richness in areas with high humidity and clean air. Humidity is typically depressed in urban areas, and depression is likewise more rapid there, resulting from the more open environment (fewer trees) and reradiation of heat trapped by buildings and asphalt. Two moss-dwelling tardigrades provided good indicators. *Diphascon scoticum* (Figure 13) was dominant in urban park sites with low air quality and reduced humidity. They feed on protococcal algae on the tree bark, and the low pH tolerance of this species may have played a role in its prevalence there. *Minibiotus intermedius* (Figure 12), on the other hand, occurs more often in the more humid rural sites and is apparently unable to tolerate the rapid evaporation rates that may characterize more urban environments.

Hohl *et al.* (2001) investigated tardigrades upwind and downwind of a coal-burning power plant in Missouri, USA. They found that the tardigrade density was greater upwind, but *Echiniscus* sp. was found only downwind. The more sensitive *Ramazzottius* sp. occurred only upwind. *Macrobiotus* sp., *Minibiotus* sp., and *Milnesium*

tardigradum occurred in both locations, but in different numbers. Although these species were mostly named only to genus, all were in genera or species known from bryophytes.

Acid Rain, SO_2 , and NO_2

Acid rain poses a threat to at least some tardigrades. *Hypsibius dujardini* (Figure 16) has reduced activity at pH 4.0 (Bartels 2005). Even at pH 5, activity is reduced compared to controls at pH 7 (Thompson 2008). At pH 2.8 they are killed (Bartels 2005). Acevedo (2008) examined one of the most common bryophyte dwellers, *Milnesium tardigradum* (Figure 14), for its tolerance to pH, as measured by activity. Although *M. tardigradum* could survive from pH 1.54 to 12.5 for 1 minute, this species, like *Hypsibius dujardini* (Figure 16), had increased survival time as the pH approached 7. This species proved to be more sensitive at the higher pH levels.

Nevertheless, Steiner (1994a) found that neither tardigrades nor rotifers seemed to vary in abundance in response to SO_2 or NO_2 . But in 1995, Steiner reported that the community composition did change in response to SO_2 .

In the aquatic environment, using both experiments and air quality at 12 sites, Steiner (1995) showed that changes to the tardigrade and other aquatic fauna composition correlated negatively with the SO_2 concentrations. They used untreated control mosses and those subjected to concentrations of 0.025, 0.075, and 0.225 ppm SO_2 for 18 months and found that the highest level caused significant decreases in the numbers of several tardigrade species. SO_2 caused a significant decrease in pH in the moss cushions. The populations of *Macrobiotus persimilis* actually increased as pollution increased. Steiner (1994a) suggested that the tardigrade (and other invertebrate) fauna of epilithic moss cushions could be appropriate biomonitors for air quality.

Urban Environment

Even if the urban habitat is not always polluted in the usual sense, it is a drastic contrast in environment to that of more natural rural areas. Cities themselves both create and hold heat. That makes them susceptible to rapid drying, a condition lethal to many tardigrades.

Johansson *et al.* (2011) compared tardigrades from 73 urban and 24 rural locations in Fresno County, California. Only 22% of the urban samples had tardigrades, whereas 74% of the rural samples had tardigrade inhabitants. The urban samples likewise had fewer species, but the densities of these species differed little from that of the rural sites. Of the 26 species found, 7 were found only in the urban samples, 16 only in rural samples, and 3 in both. The rural communities differed more among themselves than did the urban samples. Interestingly, tardigrades seemed to prefer lower pH levels in both community types. Hence, the researchers excluded acid rain as the cause of differences. It is likely that the microclimate of the city is less favorable due to greater exposure and heat, leading to more rapid drying.

Moly de Peluffo *et al.* (2006) conducted a more controlled study of urban conditions by using samples from the same tree species from the city of General Pico in Central Argentina. They included paved areas with different traffic intensities, non-paved areas, an industrial area, and a bus station. They examined 11 mm diameter

samples of lichens and mosses from the trees. Only 5 tardigrade species were collected in total [*Echiniscus rufoviridis*, *Milnesium cf. tardigradum* (Figure 14), *Ramazzottius oberhaeuseri* (Figure 28), *Paramacrobiotus areolatus* (Figure 46), *Macrobiotus* sp.]. *Milnesium cf. tardigradum* and *Ramazzottius oberhaeuseri* were the most abundant. Mean density of tardigrades was 10, but the maximum reached 50 per cm². *Milnesium cf. tardigradum* dominated along paved streets where there was intense traffic, suggesting that it was the most tolerant species. In periurban areas, *Ramazzottius oberhaeuseri* dominated despite the high suspension dust and high sun exposure. In the Neotropical region of Santa Rosa, Argentina, Peluffo *et al.* (2006) found the same five species. Again, only *Milnesium cf. tardigradum* occurred in areas with high levels of vehicle traffic.

Figure 46. *Paramacrobiotus areolatus* head region. Photo by Martin Mach, with permission.

Dust can be a factor in tardigrade distribution. Meininger and Spatt (1988) found that both tardigrades and their bryophyte environment are affected by road dust such as that created by the trans-Alaska Pipeline haul road (Dalton Highway). In this case, the dust is calcium-rich. *Sphagnum* (Figure 7) is absent within 10 m of the road. Instead, calcium-tolerant moss species such as *Aulacomnium turgidum* (Figure 47) and *Dicranum angustum* (Figure 48) occupy these alkaline areas. The tardigrades that survive here are xeric species such as *Diphascon scoticum* (Figure 13) and *Hypsibius dujardini* (Figure 16). Farther from the road, these fungal and algal feeding species are replaced by omnivores and carnivores [*Macrobiotus hufelandi* (Figure 11) and *M. harmsworthi* (Figure 25), respectively].

Tardigrades in Space

Imagine living through conditions of 151°C, -273°C, the vacuum of space, radiation 500 times that humans can tolerate, 2000X normal atmospheric pressure, and ten years with no water! (Ramløv & Westh 2001; Jönsson *et al.* 2008; ZAMP Wiki 2009). Tardigrades are sometimes considered to be **extremophiles**, and their ability to survive these conditions would seemingly put them among the champions. But extremophiles are organisms that *live* at extremes; tardigrades must become dormant to survive these, and the longer they are in this condition, the lower their chances of survival (Mullen 2002). These abilities to

become dormant - enter **cryptobiosis** - have made them popular animals for space travel, surviving and carrying back the evidence of the effects of space on subcellular components. And they were the first space travellers without space suits to survive.

Figure 47. *Aulacomnium turgidum*, a calcium-tolerant species, in Norway. Photo by Michael Lüth, with permission.

Figure 48. *Dicranum angustum*, a calcium-tolerant species. Photo by Jan-Peter Frahm, with permission.

The ability to shut down makes tardigrades ideally suited for space travel (Jönsson *et al.* 2008; Rebecchi *et al.* 2009a). They can survive a vacuum (Gavaret 1859) and its resulting extreme dehydration (Jönsson *et al.* 2008). They also survive both solar and cosmic radiation. They survive extreme ionizing radiation (570,000 roentgens kills only 50%; humans can be killed by 500) (May *et al.* 1964) and can return from space travel under these extremes and become active again with no reduction in survival (Jönsson *et al.* 2008; Rebecchi *et al.* 2009a). They have even survived temperature extremes from -200°C to 151°C (Doyère 1842; Rahm 1923, 1937; Becquerel 1950; Keilin 1959; Seki & Toyoshima 1998; Lindahl & Balser 1999).

Richtersius coronifer (Figure 49), *Milnesium tardigradum* (Figure 50) (Jönsson 2008), and *Paramacrobiotus richtersi* (Figure 24) (Rebecchi *et al.* 2009a, b) began their space adventure on 17 September 2007. They arrived back from their adventure in space on 26 September, and not only were they alive, but they could

also reproduce! *Milnesium tardigradum* did better than *R. coronifer*. About 12% of those exposed to UV-A and UV-B managed to recover, although they exhibited reduced egg production compared to the control animals that stayed on Earth. Those exposed to the full range of UV radiation only partially recovered, then died. Jönsson *et al.* (2005) suggested that during anhydrobiosis there are no biochemical protectants to protect against radiation. Rather, it appears that survival of tardigrades may be due to efficient DNA repair.

Figure 49. *Richtersius coronifer* and its close relatives have a beautiful deep yellow color. This species has been a successful space traveller. Photo by Martin Mach, with permission.

Paramacrobiotus richtersi (Figure 24) and *Ramazzottius oberhaeuseri* (Figure 28) were able to withstand high doses of ultraviolet radiation in both active and anhydrobiotic states (Altiero *et al.* 2011). Nevertheless, the survival rate of hydrated or desiccated specimens was inversely related to the UV doses, with *P. richtersi* tolerating the increase of UV dose better than *R. oberhaeuseri*.

The survival of *Richtersius coronifer* (Figure 49) in the adventure beginning 17 September 2007 (Jönsson 2008) was at least somewhat predictable. In the lab, this species survived instant freezing to -195.8°C and vacuum conditions with 96-100% survival (Persson *et al.* 2009). In low Earth orbit it experienced little effect from cosmic radiation or microgravity (68, 89, 82% survival). On the other hand, when Persson *et al.* (2009) subjected *R. coronifer*, *Ramazzottius oberhaeuseri* (Figure 28), and *Echiniscus testudo* (Figure 9) to desiccation on moss, the survival rate was very low (0-22.5%). They emphasized that the protocol for desiccation is important and may not have been appropriate for survival.

Another moss-dweller (among other substrata), *Hypsibius dujardini* (Figure 16), was scheduled to be travelling in space on a Russian spacecraft as I write (Milstein 2009). Following its liftoff in October 2009, it was scheduled to reside there for three years! Its habitat is a bit of polymer microcosm with conditions mimicking those of a bit of meteor rock. But, alas, technical and safety issues have caused a two-year delay before lift off (Madrigal 2009). The objective is to determine if life can survive interplanetary space travel, a test of the **Transpermian Theory**. The Transpermian Theory suggests that life might have travelled on a bit of meteoric rock from Mars or other planet and landed on Earth billions of years ago. The tough part, both for the real meteoric

rock traveller and the spacecraft test subjects may be the landing event on Earth.

Figure 50. *Milnesium tardigradum*, a space traveller. Photo by Martin Mach, with permission.

Most tardigrades have gone on their space adventure in an anhydrobiotic state. Rebecchi *et al.* (2011) used *Paramacrobiotus richtersi* (Figure 24) to determine the effects of the anhydrobiotic state on survivorship in space. They flew these animals for twelve days in a low-earth orbit (250-290 km altitude). The desiccated animals had high survival rate (79-95%), similar to that of non-desiccated ground controls. There was no visible damage to their double-stranded DNA, but their heat shock proteins (HSP expression at 70 and 90 kDa) increased compared to ground controls.

Persson *et al.* (2011) assessed the effects of cosmic radiation on tardigrades, as well as rotifers. The tardigrades spent time in a low Earth orbit where they were exposed to cosmic radiation and microgravity. *Richtersius coronifer* (Figure 49) was dried for two years on Whatman-3 filters during its space travel. However, none of the members of this species could be revived. In a different microcosmos experiment, Persson *et al.* desiccated *R. coronifer*, *Ramazzottius oberhaeuseri* (Figure 28), and *Echiniscus testudo* (Figure 9) as well as rotifers and nematodes on a moss substrate. Species in this experiment had some, but very low, survival. Embryos of *Milnesium tardigradum* (Figure 14), on the other hand, all survived cosmic radiation from space flight. *Richtersius coronifer* also survived extreme cold and vacuum while in anhydrobiosis.

Evolutionary Similarities to Bryophytes

What could tardigrades and bryophytes possibly have in common? Their habitat requirements, for one thing. Hence, both do well with asexual reproduction (Pilato 1979). And both do well under circumstances requiring dormancy. Pilato points out that there is marked

uniformity in both size and morphology in the four invertebrate groups of rotifers, gastrotrichs, nematodes, and tardigrades. That character does not seem to fit so well with bryophytes, but if one compares them to tracheophytes, perhaps it does. Both groups have "a less common pattern of geographic distribution than usually believed" for organisms having only passive transport. They furthermore have maintained their antiquity and have given rise to entire orders. But there are also some strong differences. Compared to tardigrades, bryophytes do not have a constant cell number, have no marine members, and are capable of regeneration. Pilato suggests that parthenogenesis would have significantly delayed evolution, a concept that has come into question for bryophytes. He furthermore suggests that by entering cryptobiosis, these invertebrate organisms escape the variability of the environment and thus escape many of the selection pressures that drive evolution.

Sampling and Extraction

Sampling from mosses is not a very standardized procedure. The moss must first be collected from its substrate. What works for a flat mat does not work for a thick mat, wet, or tall turf. Sayre and Brunson (1971) suggested using a metal test-tube cap 2.5 cm in diameter to cut a core from the moss (see also Guil *et al.* 2009) – a technique that should work well for thin mats with stems that are not tough, but many growth forms would not sample well by this method. Since tardigrades are slow-moving, one need not worry about their escaping during the cutting procedure. However, I prefer the hand removal, followed by a dry weight of bryophyte for quantification. Fortunately, both bryophytes and tardigrades can survive such drying. A large clump could later be cut down the middle and still permit sampling of all the sub-habitats.

Fortunately, mosses need little care once collected and can easily be kept in small paper bags – the kind that was once used in the candy store (~10 x 20 cm when folded). If it is not too hot or severely dry, these will permit the mosses to dry slowly, provided they are not in the path of a fan or other drying agent. Using plastic bags can foster growth of fungi if the bag is kept for more than a day or two, and it will not permit the drying needed for both kinds of organisms. Morgan and King (1976 in Clifford 2005) suggested using an open plastic bag that would permit air drying.

Obtaining tardigrades from mosses may be a bit tedious. One method is to immerse the bryophytes in water (Claxton 1998; Guidetti *et al.* 2008) in something like a finger bowl or Petri dish. Tap water may be okay, depending on chlorine levels; if pond water is used, it should be boiled and filtered to avoid contamination. Distilled water should NOT be used because it will cause the tardigrade to take on water by osmosis and it is likely to become too extended to move. Placing the bryophyte upside down with the soil portion above the water will give the best results; muddy water makes it difficult to spot the bears (Sayre & Brunson 1971). If you are interested in vertical positioning, place aluminum foil or other cover over the container to keep it dark.

Sayre and Brunson (1971) recommend keeping the moss submerged for 24 hours at room temperature. The moss should then be removed and the absorbed water

squeezed into the dish. The water in the dish should then be stirred and poured into a counting dish. After the tardigrades have settled they can be counted with a dissecting microscope. They recommend 60X, but most dissecting microscopes don't go that high, so one might need a pair of 20X oculars. If there is too much water, they suggest decanting off the excess, but for quantitative purposes, I suspect that will lead to inaccuracies for these light-weight animals.

Nelson (1991) considered this to be a common method. She recommended letting the collected bryophytes dry in paper bags for at least several days, then placing them in water for several hours to awaken the tardigrades. The wet bryophytes are then squeezed to remove water with water bears into a Petri dish or other container. As in the Sayre and Brunson method, excess water can be decanted off and the sediment examined.

Guidetti *et al.* (2008) recommend that after immersing the bryophytes, the water should be sifted repeatedly to collect the tardigrades. From there, the animals can be extracted while observing them with a dissecting microscope.

Schuster *et al.* (1977) used a similar method. Collection material (bryophytes, soil, detritus) was swirled in water and once the dense particles settled, the water was decanted and poured through a US Standard #325 filter, pore size ~44 µm. These were then washed from the filter into a preservation jar or onto a glass slide. Specimens can be preserved by adding 5% formalin or glutaraldehyde, or alcohol, as discussed later.

Other researchers choose to use the Baermann funnel to extract the animals (Hohberg 2006) as already described for invertebrates (Chapter 4-1 of this volume).

A slight modification of these methods is to clean a bryophyte clump of its loose soil and place it into a Petri plate upside down (Deep Data 2009). Fill the plate with water. When the bryophyte absorbs all the water, add more. Maintain a few mm of water in the plate after the bryophyte is fully hydrated. The bryophyte should be kept hydrated for several hours or overnight before examination. Remove the bryophyte from the water and examine it with a dissecting microscope at 20X or higher. Alternatively, this website also recommends squeezing out the water and examining the liquid. Look for yellow, red, or whitish animals that move "like puppies."

Nelson and Bartels (2007) used a different method when working with samples from soil, lichens, mosses, and leaf litter from the Smoky Mountains. They extracted the tardigrades using centrifugation with Ludox AM™ and mounted them on microscope slides in Hoyer's medium.

Tardigrades can be put to sleep with MgCl₂ or shocked with freshwater, then decanted into a fine mesh (20-40 µm) net (Nelson 2002). An intriguing method is to use an aquarium air stone to bubble the tardigrades that can then be collected with a piece of paper towel laid on the surface of the water. (If that works, I doubt that decanting is good for quantitative studies.) The towel should then be rinsed through a 30-40 µm net. For aquatic samples, water can be used from the habitat.

Clifford (2005) draws heavily on the experience of Morgan and King (1976) in his Tardigrada website. He suggests narcotizing the water bears with 20% alcohol in a volume equal to that of the bryophyte plus water. The

bears will no longer be able to cling to the bryophytes and can be more easily dislodged into the alcohol/water solution. The bryophyte and associated organisms can be removed after about 10 minutes and wrung into a Petri dish to remove the adhering water and bears. This immersion and wringing should be repeated several times, with immersion up to 15 minutes. The extracted water can be examined at about 50X magnification. (As you can see, recommendations for magnification vary from 20X to 60X. You will have to see what works for you.)

Clifford (2005) suggests that a somewhat simpler method is to flood the bryophyte with enough water to cover it for 48-72 hours. Then remove the moss to a new dish and start with the alcohol at 70%. Force the alcohol through the bryophyte clump with a pipette that has a strong bulb. A baster might work for larger mosses, but I haven't tried it. This alcohol method seems a bit cruel to the bears.

Nelson and Hauser (2012) complain that extraction from the limnoterrestrial habitats, those habitats of water adhering in spaces such as the ones among bryophytes, is often done with the Berlese funnel. They contend that this method has a strong bias toward arthropod diversity and

does not work well for relatively slow-moving or immobile animals such as tardigrades. Rather, they found much more diversity among the microscopic invertebrates such as tardigrades when they used water flooding for extraction. In fact, they found almost no taxa overlaps when comparing these two methods!

Tardigrades can be preserved in 70% alcohol, but they can be difficult to locate again, and one must check periodically to be sure the alcohol isn't about ready to dry up. A few drops of glycerine in the vial of alcohol helps when the alcohol does dry out. The preferable method seems to be to mount them in one of the standard mounting media used for bryophytes and other things. Pennak (1953) gives instructions for various media. Unfortunately (or fortunately) a number of these media have been declared carcinogenic or toxic and are no longer available.

Checklist of Bryophyte Dwellers

I won't even pretend that I can provide a complete list of these taxa. I have not covered all the literature, and certainly many have yet to be discovered, but at least Table 1 is a start.

Table 1. Partial list of tardigrades known to inhabit bryophytes, based on literature.

Summary

The patchy distribution of tardigrades may be due to dispersal. The tardigrades (unlike their mossy habitats) are not easily blown 100 cm by typical winds. Nevertheless, they easily survive space travel during those uncommon events of dispersal. Highly resistant eggs may be a common means of dispersal. Bryophytes and feces of bryophyte consumers may provide means of dispersal.

The most common genera are *Echiniscus*, *Hypsibius*, *Macrobiotus* and segregate genera, *Milnesium*, and *Ramazzottius*. Many taxa are widespread, and many more are likely to be discovered. Cryptic species are likely.

Despite their cosmopolitan distribution and widespread occurrence in moss, lichen, and certain soil habitats, it is relatively easy to find new species anywhere in the world. Whole states in the USA (16!) lack any tardigrade records.

Acknowledgments

Like all of my chapters, this one is really the product of the efforts of many biologists. Roberto Bertolani provided an invaluable update to the tardigrade taxonomic names and offered several suggestions on the text to provide clarification or correct errors. Bryonettors have been wonderful in making their photographs available to me and seeking photographs from others. Paul Davison and Des Callaghan have been helpful in providing suggestions and offering images. Bob Goldstein, Bjorn Sohlenius, Martin Mach, and Yuuji Tsukii have given permission to use images that illustrate the species and life cycle stages. Łukasz Kaczmarek has provided me with references and contact information. George Barron was invaluable in helping me to update the fungal nomenclature, craft the fungal stories, locate illustrations, and provide many valuable email discussions. As always, a big thank you goes to Michael Lüth for permission to use his many images and to all those who have contributed their images to Wikimedia Commons and other public domain sources for all to use. I must admit that this chapter would have been far less interesting without the help of Google to locate the tardigrade stories. I fear I have missed some who have helped – I have worked on this chapter for too many years.

CHAPTER 6-1

ONYCHOPHORA

Figure 1. *Euperipatus rowelli*, a velvet worm that is being cultured on *Sphagnum*. Photo by Andras Keszei, with permission.

Phylum Onychophora (Velvet Worms)

Onyches is the Greek word for claws and *pherein* means to carry, *i.e.*, claw bearers. The phylum Onychophora (Figure 1) derives its name from the pair of retractable, chitinous claws on each foot (Figure 2-Figure 3). It is interesting that the mandibles (jaws), deep within the throat, resemble these claws. This is a phylum of wormlike creatures, 0.5-20 cm long, closely related to the arthropods and tardigrades, classified into a super group known as the Panarthropoda (Wikipedia 2010). These functionally segmented animals have antennae (Figure 4), tiny eyes (Figure 4), many paired legs (Figure 2; Figure 6), and slime glands, but they lack the chitinous exoskeleton of the arthropods. Because of their legs, they more closely resemble caterpillars, but the fleshy antennae distinctly set them apart. And they are not jointed in the same way as arthropods. Their slow movements are not unlike those of caterpillars.

Figure 2. *Euperipatus rowelli*, revealing the feet with chitinous claws. Note the two bluish slime glands beneath the antennae and the barely visible mouth in the center of the head.. Photo by Andras Keszei, with permission.

Figure 3. Close view of foot and claws of *Euperipatus rowelli*. Photo by Andras Keszei, with permission.

Figure 4. *Euperipatoides rowelli* showing antennae with tiny eyes near their bases. Photo by Andras Keszei, with permission.

The phylum is rare. This is in part due to the restricted ranges of the species and their very narrow and restricted habitat needs. But part is due to industrialization and the loss of suitable habitat. Only eleven species have been studied in detail, and three of those are critically endangered or in one case possibly extinct (Wikipedia 2010).

They are circumtropical, but are most common in the Southern Hemisphere tropics, where they prey on small insects. Because of their sensitivity to drying out, they are most common in humid forests such as the tropical rainforests, where mosses seem to be an important part of their habitat (Figure 5) (Onychophora 2005). On the other hand, Brues (1948) reported that Dr. P. J. Darlington collected a specimen of *Paraperipatus* in the Bismarck range of New Guinea in moss at 10,000 ft. (3048 m), which is above timberline. *Epiperipatus biolleyi* (Figure 6) is often associated with mosses, especially in the early stages of succession (Brinck 1956; Ruhberg 1985; Mayer 2006). Mayer and Harzsch (2007) collected this species from mosses in Costa Rica for their study of the nervous system. The onychophorans use the moss as cover to protect them from the radiation.

Feeding Habits

These are slow walkers (1 cm s^{-1}) (Monge-Nájera *et al.* 1993) and thus cannot realistically use aggression for protection or capture. They sense their prey by air movements caused by the movement of the prey; they are nearly blind. To catch their prey, they squirt a sticky slime, generally about 1 cm, but up to 30 cm from the onychophoran (Read & Hughes 1987; Wikipedia 2010; BBC 2010). The glue dries very quickly and immobilizes the prey. For larger prey, they may target the limbs, immobilizing them with the glue-like slime. This slime comprises up to 11% of the dry weight of the velvet worm and is 90% water. Its constituents include mostly collagen proteins. It also includes sugars, lipids, and nonylphenol, a surfactant known only in the Onychophora. This makes a super glue, and the nature of the lipid and nonylphenol suggests that these two substances may be used to prevent the organism from being glued by its own secretions by stopping or slowing the drying process. Haritos *et al.* (2010) examined the mechanism in *Euperipatoides rowelli* (Figure 4) and proposed that when the slime is expelled from the gland, evaporative water loss triggers a "glass transition change in the protein solution, resulting in adhesive and enmeshing thread formation, assisted by cross-linking of the complementary charged and hydrophobic regions of the protein." That is, this species, and probably other onychophorans, uses disordered proteins rather than the structured silk-like proteins used by some other kinds of invertebrate predators. The large percentage of body mass accounted for by this substance is

somewhat balanced by the organism's behavior of eating and reusing the dried slime of its prey (Read & Hughes 1987; Wikipedia 2010; BBC 2010). It requires 24 days to replenish the supply provided by the repository (Read & Hughes 1987). This glue also seems to be their only form of defense.

Moisture and Light Relations

The Onychophora have a covering of α chitin that seems to do little to prevent desiccation, forcing them to live in areas with high humidity – mosses and leaf litter of rainforests (Wikipedia 2010). Their sensitivity to desiccation is counteracted by having their activity primarily at night or in rainy weather (Monge-Nájera *et al.* 1993). And at least some also prefer soil that has been covered by moss, most likely because that soil has a higher moisture content. When suddenly exposed to light and its drying effects, they may roll into a ball like some isopods, forming a position that conserves moisture (Figure 7).

Figure 7. *Euperipatoides rowelli* enrolled after being exposed from its log habitat. Photo by Andras Keszei, with permission.

It appears that desiccation is not the only problem for exposed onychophorans. *Epiperipatus biolleyi* (Figure 6) is phototactic and hides from direct sunlight, avoiding light in the range of 470-600 nm (Monge-Nájera *et al.* (1993).

Monge-Nájera *et al.* (1993) reported that the field preference of the onychophoran *Epiperipatus biolleyi* (Figure 6) was either the moss-substrate interface or in burrows in the soil. Using a series of experiments, Monge-Nájera *et al.* demonstrated the preference of the *E. biolleyi* for bryophytes over grass (Figure 10). The researchers covered half a Petri dish with the thallose liverwort *Marchantia polymorpha* (Figure 8) and half with blades of grass. When subjected to light, nearly 80% of the animals curled up under the bryophytes within a mean time of 189 seconds ($n=9$). The ones on soil continued searching by inserting their antennae and head among soil particles, but they never came to rest or made any burrow (Figure 10). The researchers suggested that in nature these animals may be limited to areas where there are suitable burrows or cover such as bryophytes that provide cover similar to that in a burrow. It appears that *Macroperipatus torquatus* (Figure 9) has a similar restriction (Read 1985) to such habitats.

Figure 8. *Marchantia polymorpha*. James K. Lindsey, with permission.

Figure 9. *Macroperipatus torquatus*, shown here crossing young bryophytes, used the liverwort *Marchantia polymorpha* as cover from light in the lab. Photo by Mr. Spanky, through Creative Commons.

Moisture, as well as light, were most likely driving forces in these experiments. Monge-Nájera *et al.* (1993) measured the humidity in the two vegetation choices (Figure 10) by drying them to a constant weight. Moisture was significantly higher in the bryophyte portions (bryophytes: 84.2 ± 3.4 , 76.5 - 87.9% ; grass: 71.1 ± 4.4 , 66.8 - 80.0%) using Mann-Whitney U with $p < 0.001$ and 10 replicates.

Figure 10. Comparison of percentage of *Epiperipatus biolleyi* in bryophyte cover vs grass blade cover (left) and on soil from under bryophytes vs soil from under grass (right) in 8 cm diameter Petri plates. These onychophorans were 5 cm long, so some straddled the two areas, having no clear choice. Modified from Monge-Nájera *et al.* 1993.

The onychophorans most likely also use the mosses as cover to avoid predators, which include the Clay-colored Robin (*Turdus grayi*; Figure 11) and Hemprich's Coral Snake (*Micrurus hemprichii*; Figure 12) (Monge-Nájera *et al.* 1993).

Mating and Reproduction

Finding suitable habitat or finding a mate requires considerable time for such slow-moving creatures and puts them at risk of desiccation. Thus, an efficient system for locating their habitat increases their chances for survival. Elliott *et al.* (1993) demonstrated for the first time in onychophorans, using *Cephalofovea tomahmontis*, that the crural glands at the bases of the legs in males produce a pheromone that attracts females of the same species. It appears that pheromone-producing glands not only help in locating males, but may also prevent desiccation in females seeking new locations.

Peat moss is a typical substrate for culturing *Euperipatus rowelli* (Figure 13) (Barclay *et al.* 2000; Reinhard & Rowell 2005; Haritos *et al.* 2010; Andras Keszei, pers. comm. 7 March 2013). Keszei finds that

Sphagnum (Figure 15) is the only suitable substrate he has found for culturing these onychophorans because it prevents mold while keeping them moist. This is perhaps due to the antibiotic properties of *Sphagnum*. He says that this species does not normally live among the *Sphagnum* [they live in decaying logs, including *Eucalyptus* (Figure 14)], but that he has collected them from less than 100 m away and considers *Sphagnum* as a possible hunting ground for them.

Figure 15. *Sphagnum cristatum*, a suitable substrate for culturing onychophorans. Photo by Janice Glime.

Eggs of at least some species are laid under mosses (Mayer & Tait 2009). On Mt. Macedon, Victoria, Australia, Mayer and Tait found *Ooperipatellus insignis* (see Figure 16) in leaf litter and under moss.

Figure 16. *Ooperipatellus viridimaculatus* on moss. Photo by Chris Morse, through Creative Commons.

Barclay *et al.* (2000) demonstrated that in *Euperipatoides rowelli* (Figure 13-Figure 19), males are the first dispersers. They secrete a pheromone that attracts both males and females of the same species. Thus, when these males disperse to decomposing logs, the females are able to locate this suitable habitat with a much lower water loss and expenditure of energy. It would be interesting to know if such a pheromone signal is equally used and effective among those onychophorans dwelling among bryophytes.

Like most of the onychophorans, *Euperipatoides rowelli* (Figure 1-Figure 2, Figure 7) is secretive. However, Reinhard and Rowell (2005) suggest that their behavior is nevertheless complex. They form aggregations as large as 15, comprised of females, males, and young. The female is dominant, and despite collective hunting, the dominant female eats first – alone. Behavior of aggressive dominant and passive-subordinate establishes a hierarchy. This structured group will defend its log aggressively against any invasion by onychophorans from another location.

Monge-Nájera and Alfaro (1995) hypothesized that onychophorans might find mosses because of some odor contributed by the mosses. However, when they provided them with filter paper with water on one end and macerated moss on the other end, the onychophorans showed no preference. Furthermore, while the preference of this species for moist habitats was greater than for dry habitats in Costa Rica, more specific preferences were not clear. Habitats included sandy soil, under moss, in and under logs, under stones, and in soil of crevices.

Reproduction is sexual in all but *Epiperipatus imthurmi*, a species lacking males and using **parthenogenesis** (reproduction from an unfertilized egg) instead (Wikipedia 2010). Interestingly, the females are typically fertilized only once during their lives. If they are fertilized before the egg cells are mature, the sperm will be stored in a special reservoir. Sperm are released from their packets when amoebocytes from the female's blood collect inside the deposition site and decompose the packets. The young may be born live or laid as eggs, depending on the species.

Birds and rodents prey on the velvet worms. Their foraging activities may account for some of the disturbances to the mossy habitat.

Peripatoides novaezelandiae (Figure 21-Figure 23) is the most common peripatus species in New Zealand (Ryan 2012). I have not been able to verify that it lives among mosses, but it is commonly cultured on *Sphagnum* (Figure 15). However, a discussion on YouTube indicated that one of the posters photographed this species on *Sphagnum*, and

he stated that he photographed it in a culture that used the moss where it had been found.

Mimics?

In the cloud forests of Ecuador, an onychophoran and a lepidopteran mimic live in the arboreal bryosphere (Zitani *et al.* 2018). The onychophorans are unable to close their many tracheal spiracles and thus lose water easily. Therefore, bryophytes may serve as a moist habitat to maintain the moisture of the onychophorans. They are nocturnal and have limited dispersal, further conserving their moisture. In these arboreal moss cushions, they cohabit with annelids, molluscs, crustaceans, millipedes, centipedes, arachnids, and insects. But in one of the mosses samples there was a caterpillar that resembled the onychophoran in size, shape, and coloration. Is it really a mimic, or are both adapted by cryptic coloration to the same habitat? Is one of them unfit for would-be predators?

Summary

Among the bryophyte inhabitants are members of the relatively rare phylum Onychophora. Little is known about their behavior, but it appears that bryophytes are important in maintaining moisture in the soil beneath them where onychophorans may live. It is likely that we will discover that many more species make use of the bryophytes in some capacity.

Sphagnum is an important culture medium for onychophorans because they do not develop fungal infections when it is used.

Acknowledgments

I appreciate the helpful comments and images of Andras Keszei that have greatly enhanced the clarity of this chapter. Bernard Goffinet kindly sent me the article on the Onychophoran by Zitani *et al.*

CHAPTER 7-1

ARTHROPODS: HABITAT RELATIONS

Figure 1. The epiphytic moss *Orthotrichum lyellii* that has been chewed, most likely by an arthropod, partially stripping the stems. Photo by C. Robin Stevenson, with permission.

Arthropods (Phylum Arthropoda)

The most conspicuous group of organisms living in the shelter of bryophytes are the arthropods (Bonnet *et al.* 1975; Kinchin 1990, 1992). McKenzie-Smith (1987) contended that animal densities among bryophytes often were greater than those we might expect simply on the basis of the greater surface area, implying that they provided more than just space. Yet, as Gerson (1969) so aptly pointed out, ecologists, both botanical and zoological, had dismissed the bryophyte habitat, as Cloudsley-Thompson (1962) put it, because "it is clear that moss does not form a biotope with a stable microclimate." Humph! To what were the ecologists comparing it?

Not only do the bryophytes modify their internal climate relative to the ambient conditions, they also modify the soil conditions, permitting some of the arthropod species to survive there when the ambient atmospheric conditions are extreme and uninhabitable (Gerson 1969). Acting like a spongy insulator, they buffer soil temperatures and reduce water evaporation from the soil. But they also can interfere with water reaching the soil in short spates or very light rainfall. They provide a humid

environment when the sun dries the atmosphere. And some species act like a black box, absorbing heat with dark-colored leaves and reaching temperatures higher than those in the atmosphere. With these varying conditions, we might hypothesize that bryophytes can serve as a refuge at times while being inhospitable at others, and for some, provide a source of food (Figure 1).

The abundance of arthropods among bryophytes may in part relate to their concurrent venture onto land in the early Ordovician (Anissimov 2010). Once on land, they have invaded the three main strata: subterranean, forest floor debris, and arboreal (Grimmett 1926). Among these, we will generally not be concerned with the subterranean stratum as it is rarely a habitat for bryophytes. The stratum of forest floor debris reminds us that soil scientists often consider the moss layer as part of the soil, and most certainly Grimmett included it with the forest floor debris.

Yanoviak *et al.* (2004) considered such habitats as epiphytic mosses to enhance species richness of the arboreal arthropods by increasing the available types of niches. The bryophytes provide a structural component to

the arboreal habitat and function to buffer the moisture and protect against the wind. They furthermore provide a foraging location and a place to deposit eggs (Gerson 1982; André 1983; Nadkarni 1994; Kitching *et al.* 1997; Drozd *et al.* 2009).

The bryophytes can serve as food for a wide range of arthropods and at the same time they provide excellent camouflage. Fischer (2005) estimated that 300 species of animals, many of which are arthropods, live among mosses in the Pacific Northwest and Appalachian Mountains, North America. These arthropods, in turn, can serve as food for a wide range of larger animals.

In their *Science* article, "The Forgotten Megafauna," Hansen and Galetti (2009) state that "In any given ecosystem, the largest vertebrates have ecosystem impacts that are similar on a relative scale to those of the largest vertebrates in another ecosystem: One ecosystem's mesofauna is another ecosystem's megafauna." This concept can be extended to comparing the bryophyte habitats. In this case, it would usually be the arthropods that occupy this position of megafauna. Although most of these top predators are insects, other arthropods are likewise important. As will become evident, we know almost nothing about these relationships in the bryophyte habitat.

Arthropods were so-named because they have jointed legs (Hingley 1993). Some arthropods are small enough to inhabit the water film in a leaf concavity, and small crustaceans and mites are able to live in that film between the leaves. Larger arthropods such as spiders and insects can run across the surface or navigate among the stems and leaves.

Bryophytes in all sorts of habitats house a varied arthropod fauna. Smrž (1992) studied the microarthropods inhabiting mosses on roofs. Block (1985) described arthropods in a terrestrial community on Signy Island in the maritime Antarctic. In the Antarctic, mosses modify soil moisture and temperature, permitting arthropods to live there (Gerson 1969). Curry *et al.* (1989) studied the invertebrate fauna of reclaimed peatlands in Ireland. De Graaf (1957) examined both the macrofauna such as arthropods and the microflora of a quaking bog in the Netherlands. Varga (1992) examined the communities associated with two protected moss species [*Plagiobryum zierii* (Figure 2) & *Saelania glaucescens* (Figure 3)] in Hungary and found that mosses with high lead concentrations near roads were associated with poorer bryofauna than mosses from unpolluted control sites, as already noted for micro-organisms. Protozoa, small metazoa, bacteria, organic debris, and plant material serve as food for the inhabiting arthropods, permitting the arthropods to sustain life within the protection of a bryophyte clump.

Insects, the largest group of arthropods and the largest single group of animals on the planet, have many members small enough to navigate within the moss clumps, and are therefore a major component of the fauna. They can be so numerous as to require special extraction methods (Andrew & Rodgers 1999). Their abundance and diversity have earned them separate chapters in this book.

Figure 3. *Saelania glaucescens*, a lead accumulator that becomes unsuitable for many invertebrates. Photo by Michael Lüth, with permission.

Habitat Relations

Since I first began, early in my career, studying arthropods associated with aquatic bryophytes, numerous studies have addressed the fauna of the protective bryophyte habitat (see Borges *et al.* 2005). Yet, the relationships of the bryological fauna to the bryophytes remains poorly known (Drozd *et al.* 2008). Drozd and coworkers (2009) were able to demonstrate that significant relationships exist between the microhabitat conditions within the bryophyte cushions and the patterns of abundance of the invertebrate community (Figure 4).

In comparison to litter habitats, Drozd *et al.* (2009) were surprised to find that nearly all arthropod groups were in greater abundance in the litter than in moss cushions ($p = 0.0003$; *e.g.* Figure 5). But as they identify species, we may find this relates to available space for larger organisms that cannot navigate well among the bryophytes. Drozd *et al.* (2009) found that moss presence, moss species, and moisture were very important in determining arthropod abundance.

Much remains for us to understand about the arthropod fauna of these unique habitats.

Figure 4. Abundance of arthropod taxonomic groups in pitfall traps in the mountains of the Czech Republic. Ants (Formicoidea) from Podolánky were drawn separately because of their high numbers. Control = litter; moisture categories are wet (high), middle, and dry (low). Redrawn from Drozd *et al.* 2009.

Figure 5. Abundance of arthropod taxonomic groups in pitfall traps at Pražmo in the mountains of the Czech Republic. Moisture categories are wet (high), middle, and dry (low). Redrawn from Drozd *et al.* 2009.

Epiphytes

The importance of bryophytes to the arthropod community is suggested by a positive correlation between bryophyte abundance and arthropod morphospecies in a study in Maine, USA (Miller *et al.* 2007). Epiphytes, especially in the tropics, are a habitat for a number of arthropod inhabitants (Nadkarni & Longino 1990). Nadkarni and Longino found that canopy "soils" in Costa Rica included Coleoptera, Collembola, Acari, insect larvae, ants, Amphipoda, and Isopoda. And disturbance that removes bryophytes typically results in a decrease in arthropods, at least temporarily.

Zytyńska *et al.* (2011) found that genetic variation in species of tropical trees could affect associated epiphytes and invertebrates. They found that greater genetic diversity

among the trees led to greater diversity among epiphyte and invertebrate communities. The very limited specificity of bryophytes for host trees suggests there may not be a strong influence on bryophyte diversity, but we must ask how much influence the genetic differences in the trees may have on the invertebrate communities living among those bryophytes. Peck and Moldenke (2010) found that there were no significant differences among arthropods between the two tree species they sampled, but rather arthropod communities related more to location of the mats.

Pettersson *et al.* (1995) found that the number of larger invertebrates, important food sources for birds, was greatest among arboreal lichens in the boreal forest of Sweden, compared to habitats in managed forests that lacked

abundant lichens. The predominant invertebrates were spiders (**Araneae**), **Lepidoptera**, and **Diptera** larvae. Thus, decline in bird populations have been linked to loss of food organisms that depend on lichens in that habitat. Similar studies for bryophytes (Nadkarni 1994), indicate that it is likely that loss of spiders from disturbed habitats that previously had more bryophytes might likewise be a cause for bird decline.

Secondary forests developed after deforestation are recolonized slowly by bryophytic epiphytes (Pettersson *et al.* 1995). Hence, the arthropods and other invertebrates are necessarily delayed in their arrival. Absence of suitable habitat nearby will further delay colonization of new growth. Pettersson *et al.* (1995) demonstrated that natural boreal forests (i.e., those without harvesting) supported five times as many invertebrates per tree branch as the mature secondary forests as well as a greater diversity. Spiders were among the dominant organisms. Non-migrating birds often depend on these invertebrates during the winter when small differences in food abundance can be critical to sustaining their lives. Furthermore, only the invertebrates larger than 2.5 mm form suitable prey for overwintering passerine birds, a size that was consistently higher in unlogged forest. Although most epiphytes in this case were lichens, bryophytes are likely to present a similar story.

Typical tropical sampling methods, including fogging, tend to miss many of the bryophyte-dwelling arthropods (Yanoviak *et al.* 2003). Nevertheless, tropical studies indicate the importance of epiphytic bryophytes as habitat for numerous arthropods (Yanoviak *et al.* 2007). In Monteverde, Costa Rica, secondary forests had thinner mats that were less structurally diverse than those in primary forests. Although species richness differed little between the two forest types, abundance of arthropods was significantly higher in the secondary forest, primarily because of the presence of ants. During the dry season (February – May), the number of taxa was lower, with arthropods becoming dormant or seeking places with greater moisture, including deep in mats. Nadkarni and Longino (1990) demonstrated the invertebrates that were dominant in the Costa Rican canopy as well as the forest floor: adult beetles (**Coleoptera**), **amphipods**, ants (**Hymenoptera**), springtails (**Collembola**), insect larvae, **isopods**, and mites (**Acari**). The ground fauna exhibited 2.6 times the density of that found in the canopy, but this does not diminish their importance for canopy-dwelling birds. Temperate bryophytic epiphytes can be suitable habitats for arthropods as well (Voegtlin 1982).

Forest Floor

It is likely that bryophytes, like litter, influence the kinds of spiders and other arthropods on the forest floor. Willett (2001) demonstrated in the Santa Cruz Mountains of California, USA, that forest floor spiders indicated such characters as old growth vs logged forest. Both diversity and abundance of spiders decreased with herb cover. Those spiders that live in association with moss mats are likely to decrease as well in disturbed (logged) forests, often due to a decrease in prey abundance.

Rock Zonation

Bonnet *et al.* (1975) examined the ecology of 26 bryophyte-dwelling species of springtails (**Collembola**) and 45 species of mites (**Acari**, Figure 6). These

arthropods exhibited a population gradation from soil to aerial mosses. Likewise, there was a gradation from drier mosses on the south face of the forest rock to the deep soil communities on the north face. This study pointed to the importance of humidity and temperature in determining the distribution of these two arthropod groups.

Figure 6. Mite (**Acari**). Photo by Alan R. Walker, through Creative Commons.

Cryptogamic Crusts

The cryptogamic crust is a mix of lichens, algae, Cyanobacteria, and bryophytes that form a crust on dry soil. In prairies and semidesert lands they may occupy as much as 70% of the soil (Brantley & Shepherd 2004) and provide a means of conserving moisture, providing a suitable habitat for arthropods. In the piñon-juniper woodland of central New Mexico, mosses provided a better habitat (greater faunal abundance) than did lichens or mixed lichen crusts (Brantley & Shepherd 2004). Likewise, mosses housed the most taxa (29 species, then mixed lichens and mosses (27), then lichens (21). Fifteen taxa occurred on all three of these substrata, suggesting possible specificity, but with a greater degree of generalists than specialists among cryptogamic taxa. Shepherd *et al.* (2002) found that the fauna of crust mosses were active following winter precipitation, exhibiting significant increases in both richness and abundance. This period may introduce arthropods when other fauna are absent, thus having an important impact on soil nutrient cycling.

In the Little Desert National Park, northwest Victoria, Australia, the soil crusts (nine mosses and nine liverworts) housed only the phylum Arthropoda among the invertebrates (Milne *et al.* 2006). Diversity was low; diversity was greater in the wetter periods.

Streams

Bryophytes in streams greatly increase substrate available to arthropods (Suren 1988; Figure 7). Sometimes they house communities that mimic those of riffles, but in other cases they harbor very different communities. And the pH conditions can affect the faunal composition. In the River Liffey, Ireland, Frost (1942) compared 23 bryophyte samples each between an acid and alkaline stream and found that the numbers of organisms differed little between them (acid ca 282,000; alkaline ca 306,900 organisms), but the composition of the organisms differed. In a mountain

stream in Nara Prefecture in Japan, Tsuda and Nakagawa (1959) likewise found that communities of moss-covered rocks differed from those of bare rock.

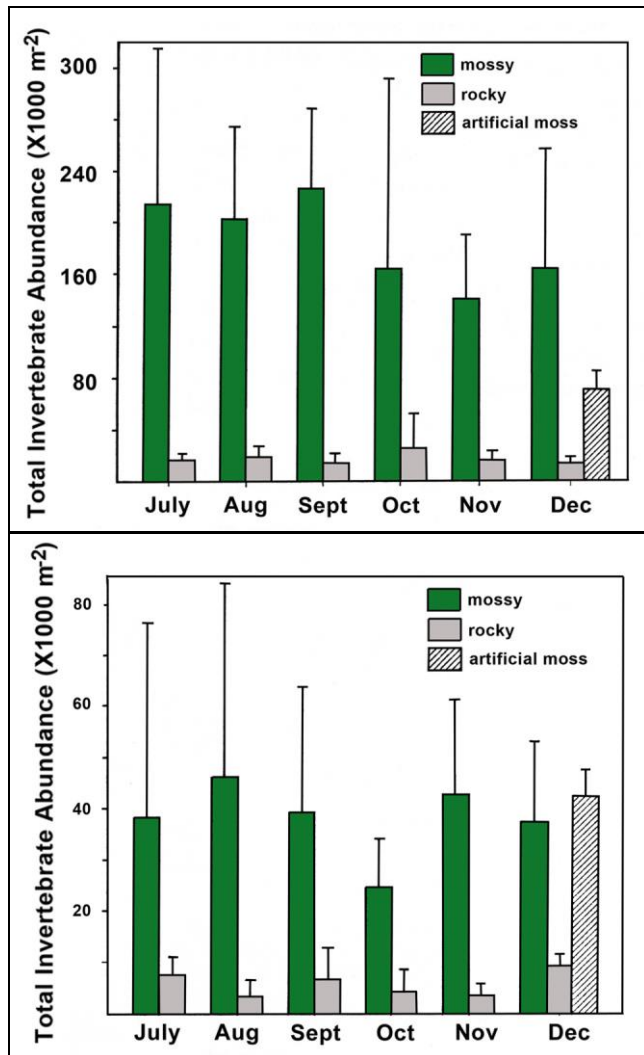

Figure 7. Comparison of invertebrate abundance in mossy habitats, rocky habitats, and artificial mosses made of nylon twine in two streams in New Zealand. Redrawn from Suren 1988.

In streams, bryophytes house not only numerous aquatic insects, but also amphipods like *Gammarus* (Figure 8, Figure 11) (Badcock 1949). And this invertebrate eats its own home. *Gammarus* lives among *Fissidens* (Figure 9) and eats its leaves (Minckley & Cole 1963).

Figure 8. *Gammarus* sp., a scud that is often found among aquatic bryophytes. Photo by Janice Glime.

Bryophytes in streams serve as a perennial refuge for many arthropods in a habitat where other plants usually disappear for the winter or are absent altogether because the flow rate is too rapid for them to survive at some times during the growing season. Such ephemeral plants prevent the establishment therein of such arthropods as *Asellus* (Figure 10) and *Gammarus* (Figure 11) (Fontaine & Nigh 1983), but the more permanent bryophytes often house these taxa.

Figure 9. *Fissidens fontanus*, a moss that serves as both home and food for *Gammarus*. Photo by Michael Lüth, with permission.

Even in raging water of snowmelt, chambers within the bryophyte mat tend to be quiet (Dorier & Vaillant 1954; Kamler & Riedel 1960). This depends in part on the form and depth of the moss. The heavy flow often relegates the bryophytes to the downstream sides of rocks. The flow dynamics cause the water to arch over the bryophytes, creating the negligible flow within the moss mat (Kamler & Riedel 1960). These factors determine the quantity and composition of the fauna (Kamler & Riedel 1960).

Figure 10. *Asellus aquaticus*, a common inhabitant of aquatic bryophytes. Photo by Jacob LaCroix, with permission.

Referring to the stream bryophyte fauna, Suren (1992a) stated that "these invertebrates are traditionally neglected in stream surveys and their ecological roles poorly understood." He found that densities of meiofauna were greater than those in stream gravel habitats. Faunal communities among bryophytes were different from those in gravel. As in many other cases, the availability of periphyton as food seems to be an important factor in the distribution of these fauna (Glime & Clemons 1972;

Johnson 1978; Devantray 1987; Suren 1988, 1990; Suren & Winterbourn 1992b). But shelter from fast current among stems and in leaf axils is most likely important for many species (Suren 1992a; Suren & Winterbourn 1992a, b).

Figure 11. The scud *Gammarus* sp., sometimes an abundant inhabitant of aquatic bryophytes. Photo by Janice Glime.

Organic matter (FPOM and UFPO) fractions in bryophyte samples differ between shaded and unshaded sites (Suren 1992a, b; Suren & Winterbourn 1992b). At the unshaded site the food source was primarily periphyton, but at the shaded site it was primarily fine amorphous detritus (Figure 12). This greater detritus accumulation was largely due to the position of this portion of the stream below timberline (Suren 1992b).

Figure 12. *Hygroamblystegium fluviatile* showing detritus (grey areas) trapped among the branches. Photo by Michael Lüth, with permission.

There have been many discussions about the importance of bryophytes as a food source. Until relatively recently, ecologists considered bryophytes to be unfit food, hence rendering them unimportant in many ecosystem studies. More recent studies suggest that at least some organisms use them as food, but it is likely that their role as a substrate for epiphytic algae might be more important than their direct use, at least in aquatic systems. McWilliam-Hughes *et al.* (2009) examined the role of various components as carbon sources in two temperate rivers. Epilithic algae were primary food sources. They found that 98% of the scrapers (primarily insects) exhibited enriched $\delta^{13}\text{C}$ values relative to those of bryophytes, and that values in these two components were correlated. This relationship was not so obvious in slow-water habitats. In headwater streams, the brook moss *Fontinalis* (Figure 36)

was abundant. In low order streams (a first-order stream is a headwater stream), *Drepanocladus* (*sensu lato*?; Figure 13-Figure 14) was abundant. McWilliam-Hughes and coworkers suggested that when rivers had low productivity and were nutrient limited, scrapers compensated for the limited food availability by switching to "marginal" foods, including bryophytes. They based this suggestion on the scrapers in low-order streams that depended more on *Fontinalis* than did the scrapers in high-order streams depend on *Drepanocladus*.

Linhart *et al.* (2002) support yet another means by which bryophytes support the food pyramid in streams. *Fontinalis antipyretica* on rock rip-rap in a channel of the Morava River, Czech Republic, trapped particulate matter that provided a food source for arthropods. Seasonal variation in the arthropod groups of **Hydrachnidia** (=Hydracarina – mites), **Cladocera** (Figure 15), **Copepoda**, and **Chironomidae** (midges) correlated significantly with trapped matter and specifically with organic matter. Linhart and coworkers concluded that aquatic bryophytes on rip-rap increase spatial diversity that supports considerably greater numbers of **meiofauna** (component of fauna of sea or lake bed comprising small, but not microscopic, animals; defined by size based on standard mesh width of sieves with 500-1000 μm as upper and 32-63 μm as lower limit; all animal life of any particular region or time) than the gravel bed.

Abundance of various types of arthropods varies widely among stream locations. Table 1 demonstrates a few of these differences from a wide range of studies. Unfortunately, the methods of reporting abundance vary as widely as the invertebrates, but relative numbers are useful. Those not reported often mean the investigators did not include them in the study.

Table 1. Comparison of arthropod abundance (exclusive of Insecta) in various locations around the world. NR = not reported.

Heino and Korsu (2008) reminded us that there are few studies that address the species-area concept of stream bryophyte fauna (macroinvertebrates). Contrary to 2-d substrates, only one significant species-area relationship existed among the six that they tested. They found two significant individuals-area relationships, but both were nevertheless weak. Rather, they found strong significant relationships between both species richness and the number of individuals with bryophyte biomass in all six sampling locations. Furthermore, disturbance by a bulldozer resulted in a stronger species-bryophyte biomass relationships. The species-area relationships on stones were weak. Heino and Korsu suggest that bryophyte biomass has a "pivotal role" both species richness and number of individuals among stream macroinvertebrates. They recommended experimental testing to determine the importance of passive sampling, provision of more food, more niche space, and flood disturbance refugia in these bryological-faunal relationships.

Peatlands

Be careful when you pull that handful of *Sphagnum* from the crimson mat in the peatland. It might bite! And

you might be crushing hundreds of lives – rotifers, ants, mites, spiders, and more, not to mention the numerous protozoa (Chacharonis 1956; de Graaf 1957; Heal 1962, 1964; Corbet 1973; Bninska *et al.* 1976; Bateman & Davis 1980; Clymo & Hayward 1982; Borcard 1986, 1993; Schönborn & Peschke 1990; Hingley 1993).

The bog provides a wide range of niches. The surface layer can experience a 30°C temperature variation in a single day, with humidity ranging 40-100% (Gerson 1969). But down in the layer of stems the temperature variation drops to only 5°C per day and the humidity is stable at 100%.

One *Sphagnum* site housed 145 species of invertebrates, whereas a nearby forested site housed only 65 (Schofield 1985). Chiba and Kato (1969) suggested that the testacean (protozoan) community in the Mt. Kurikoma district of Japan is related to the habitat of the bryophytes there.

Since *Sphagnum* is a habitat of large scale, it is not surprising that Biström and Pajunen (1989) found some of the larger invertebrates – the multipedes (animals with many feet, mostly used for millipedes, centipedes, and symphylans, but also sometimes applied to spiders and insects), including *Araneae* (mites; also Gerson 1972; Seyd 1988), *Pseudoscorpionida*, *Opiliones* (harvestmen), *Diplopoda* (millipedes), *Chilopoda* (centipedes), and *Symphyla* (blind, white multipedes; Figure 20) among both the *Sphagnum* and *Polytrichum commune* in the Finnish peatlands. *Sphagnum* and *Polytrichum commune* (Figure 16) habitats housed numerous spiders (1368 individuals/77 species), as well as *pseudoscorpions* (35/1) (Figure 17), *harvestmen* (157/5), *centipedes* (43/3) (Figure 18), *millipedes* (39/4) (Figure 19), and *Symphylans* (multipedes; 9/1) (Figure 20) (Biström & Pajunen 1989). It is interesting that despite high variability overall, *Sphagnum girgensohnii* (Figure 21) has its own characteristic species, with a high proportional similarity among samples, indicating that the faunal communities of this species are fairly consistent and suggesting the possibility of some characteristic favoring this species group (Biström & Pajunen 1989).

Figure 16. *Polytrichum commune*, a habitat for a wide range of arthropods. Photo by Michael Lüth, with permission.

Spiders can actually characterize the various biotopes within a peatland (Villepoux 1990). Lycosid spiders (wolf spiders) such as *Lycosa pullata* (Figure 22) and *Pirata piraticus* (Figure 23) seem to be common in peatlands (Nørgaard 1951), no doubt benefitting from the abundant invertebrates clambering about among the mosses. In poor pine fens, one can find the wolf spider *Pardosa maisa* in the *Sphagnum* layer (Itaemies & Jarva 1983). At the Massif Central, France, spiders in the *Sphagnum* bog were so diverse and common that they could be used to characterize the different biotopes making up the bog (Villepoux 1990). And not surprisingly, at least in Sweden, there is a rare spider wasp, *Anoplius caviventris* (Hymenoptera: Pompilidae), there to take advantage of the situation (Berglind 1993).

Arthropods can encounter difficulty in the base-poor environment of peatlands. Normally, calcite (CaCO_3) is used to harden the cuticle, but this compound is generally not available in the acid environment of the peatland. Norton and Behan-Pelletier (1991) found that the *Sphagnum*-dwelling mites *Eniochthonius minutissimus*, *Archoplophora rostralis*, and *Prototritia major* deposit whewellite, a form of calcium oxalate that may originate as precipitation from the fungal food eaten by the mites, using the whewellite as a cuticular hardening agent.

Removing invertebrates from *Sphagnum* can be a laborious task. While sifting may be viable for tiny beetles, it is impractical for many taxa. Providing a vertical gradient of temperature and O_2 (Fairchild *et al.* 1987) can drive the invertebrates to a common location at the top or bottom of the moss column for easy removal, suggesting to us that these organisms in the peatlands must balance the heat near the surface with the diminished oxygen but cooler temperatures further down in the *Sphagnum* mat.

Antarctic

Even the Antarctic and sub-Antarctic have their share of arthropod moss-dwellers (Goddard 1979; West 1984; Block 1985). Booth and Usher (1986) examined the life history of mites living among moss turfs. They (Booth & Usher 1984) found that *Polytrichum* (s.l.?) cover was somewhat important, but percentage water content was consistently important, a factor discussed already for other invertebrates. Calcium and potassium were likewise important in the arthropod distribution. It is also likely that the warmer temperatures in the bryophytes encouraged arthropod colonization (Gerson 1969). Gerson (1969) suggested that, particularly in the Antarctic, the moss-arthropod associations were the result of modifications of the soil. The mites sometimes feed on mosses as well.

The bryophyte habitat is very important for diversity of Antarctic arthropods (Gerson 1969; Block 1985; Kennedy

1994), although diversity can be somewhat low (Block 1985). Mats of *Polytrichum-Dicranum* harbor more arthropods than do *Pohlia* mats. They are less wet and cold in summer had have more open texture. *Ceratodon purpureus* (Figure 24) and *Distichium capillaceum* (Figure 25) have larger numbers of microarthropods compared to communities of *Andreaea* (Figure 26). Kennedy suggests that the paucity of invertebrates in *Andreaea* may relate to its lack of convolutions or internal spaces compared to the other aforementioned species.

Figure 26. *Andreaea rupestris*, a compact moss possessing less chambering than that found among *Distichium capillaceum* stems. Photo by Michael Lüth, with permission.

Altitude

On four mountains in New Zealand, Andrew *et al.* (2003) found that although diversity varied with altitude, there was no trend along the altitudinal gradient. For example, Otira had the highest diversity among both invertebrates and bryophytes at low altitudes, whereas Kaikoura had its highest invertebrate diversity coupled with the lowest bryophyte diversity at the highest altitudes. However, on Mt. Field, Andrew and Rodgers (1999) found a mid-altitudinal peak in abundance of invertebrates living among bryophytes. On Mt. Rufus they found an altitudinal abundance gradient but no differences in species richness with altitude. They determined that scale variation was a greater contributor to richness than altitude on Tasmanian mountains.

Temperature Protection for Arthropods

Bryophyte mounds and turfs provide an insulating layer that is important for a number of organisms. Some insects, like the Mecopterans *Boreus westwoodi* (Figure 27) and *B. hyemalis* in southeast Norway, are active on the snow in the winter (Hagvar 2001). These insects lay their eggs among mosses in **subnivean** (under snow) air space, thus protecting the larvae from exposure. **Collembola** (springtails) are likewise winter active and are common both on the surface and in the moss mats (Hagvar 2001).

Figure 27. *Boreus westwoodi* on mosses. Photo by Barbara Thaler-Knoflach, with permission.

In peatlands, *Sphagnum* hummocks may maintain a nearly constant temperature just below freezing (-2.5 to -8.5°C) while the air temperature drops to as low as -20°C (Longton 1979a). Nevertheless, in the cold Antarctic, Booth and Usher (1984) found that the cover of *Polytrichum* was usually less important than percentage water content and calcium content for the inhabiting arthropods.

In summer, bryophytes in some locations provide a cool haven from the summer heat (Gold *et al.* 2001). Under the moss-dominated crusts in the Olympic Mountains of Washington, USA, soil surface and near-surface temperatures are 5-8°C cooler at midday than in bare soil. Lichens cool the soil surface even more, by 10-11°C. *Sphagnum*, on the other hand, can reach temperatures as much as 10°C above ambient (Longton

1979a), forcing its inhabitants to move further down into the mat. And in the boreal forest at Pinawa, Canada, temperatures in *Bryum argenteum* (Figure 28) reached as high as 55°C! (Longton 1979b). It is likely that dark pigments contribute to the warming of bryophyte habitats, even under light snow cover.

Disturbance

Disturbance of bryophyte habitats creates islands that may limit faunal dispersion. Using experiments, Lawton (1999) found that bryophyte islands support all the predictions for isolated micro-arthropod communities. That is, Lawton found that fragmentation would lead to species extinctions, corridors will reduce extinctions, and abundance will decrease in those species that survive.

Hoyle and Gilbert (2004) examined the effects of fragmentation on the microarthropod microcosms in a temperate ecosystem. Earlier evidence had suggested that the species richness and abundance are maintained if moss patches are connected by corridors. While this may be true, Hoyle and Gilbert found that species richness (including microarthropods) actually varies little between landscapes of various sizes and connectivity with other moss landscapes. Furthermore, there seemed to be no differences in responses between predators and non-predators. However, they suggested that corridors might be more important in more extreme environments, such as the Antarctic.

Figure 28. *Bryum argenteum*. Photo by Michael Lüth, with permission.

But not all small patches are doomed to extinction of their arthropod fauna. As exhibited by many studies on Antarctic mosses (discussed in a later chapter), new fauna will arrive. This is typically achieved by passive transport (**aerobiology**) for both the bryophytes and their microfauna (Mandrioli & Ariatti 2001). And the smaller arthropods might just hitch a ride on bryophyte fragments.

Role of Life Form

Kinchin (1992) found that acrocarpous cushions house a richer fauna than the more open pleurocarpous mosses. This suggests that moisture-holding capacity of the habitat is an important attribute. For example, at 100% relative humidity, the acrocarpous *Bryum argenteum* had a water

content equaling 277% of its dry weight. This contrasted with the pleurocarpous *Hypnum cupressiforme*, which held 1496% of its weight as water. Whereas *B. argenteum* held 85% of its dry weight as soil among its rhizoids, *Hypnum cupressiforme* held less than 1%. This soil difference could have contributed to the differences in fauna, but it is more likely that rate of water loss played a more important role. *Hypnum cupressiforme* reached steady dryness in 132 hours, whereas *B. argenteum* required 180 hours, despite starting at a much lower moisture content. Further support for the moisture hypothesis is provided by *Tortula muralis* and *Grimmia pulvinata*. These mosses have long hair points, most likely contributing to slow drying, and are inhabited by an especially rich fauna. But greater protection from UV light and heat of the sun could also play a role in accounting for the greater number of species within acrocarpous cushions.

Chemical Refuge

More recently, researchers have investigated the role of bryophytes as a chemically defended refuge. Because the bryophytes are well defended by secondary compounds, larger generalist feeders do not consume them. This results in an avoidance of the bryophytes so that they likewise do not consume the smaller invertebrates that live among them. Parker *et al.* (2007) demonstrated that crayfish (*Procambarus spiculifer*, Figure 29) and Canada geese (*Branta canadensis*, Figure 30) selectively consumed *Podostemum ceratophyllum* (riverweed, a tracheophyte; Figure 31) in preference over the brook moss *Fontinalis novae-angliae* (Figure 36), despite the fact that the moss made up 89% of the total plant biomass. Extracts of the moss demonstrated the presence of a **C18acetylenic acid**, octadeca-9,12-dien-6-ynoic acid, that discouraged feeding by crayfish. Experiments with pellets demonstrated that it was not plant structure that determined which plant was eaten. On the other hand, the moss supported a community of macroinvertebrates twice the size of that on riverweed. By being unpalatable to large carnivores, the moss could provide a refuge for smaller animals, especially arthropods.

Figure 29. *Procambarus spiculifer*, a crayfish that won't eat *Fontinalis novae-angliae*. Photo by Josh Geyer through Creative Commons.

The deterrents, as in this case, may not be general deterrents. While crayfish rejected it, the amphipod *Crangonyx gracilis* (Figure 32) and isopod *Asellus aquaticus* (Figure 33) consumed the moss but not the riverweed. Such chemical defenses thus create enemy-free space for these smaller invertebrates and can influence the community structure.

Figure 30. Canada geese (*Branta canadensis*), a species that avoids eating invertebrates from among *Fontinalis antipyretica*. Photo by Janice Glime.

Figure 31. *Podostemum ceratophyllum* (riverweed), a flowering plant that looks like an overgrown liverwort when it does not have flowers, and that is not avoided by Canada geese as a source for invertebrate food. Photo by Alan Cressler, with permission.

Figure 32. *Crangonyx gracilis* (amphipod). Photo from Discover Life through Creative Commons.

Figure 33. *Asellus aquaticus* (isopod). Photo by Morten D. Hansen, with permission.

The study by Parker *et al.* (2007) supported a further advantage of the bryophyte habitat (Figure 34 & Figure 35). The geese were often swept downstream by the rapid water where the bryophytes grew. The smaller invertebrates, however, were able to navigate safely within the protection of the moss, taking advantage of the reduced flow there.

Figure 34. Mean loss or gain (\pm SE) of plant mass in the moss *Fontinalis novae-angliae* vs tracheophyte *Podostemum ceratophyllum* due to grazing by amphipods (*Crangonyx gracilis*) and isopods (*Asellus aquaticus*). Probability level indicates whether change in biomass is significantly different from zero when the two plant species were offered individually to amphipods and isopods. Redrawn from Parker *et al.* 2007.

Figure 35. Comparison of feeding by geese on control pellets (freeze-dried, powdered broccoli & lettuce) vs pellets enhanced with crude extracts of the brook moss *Fontinalis novae-angliae*. Squares refer to number of window screen squares from which pellets were eaten. Redrawn from Parker *et al.* 2007.

Food Value

Despite traditional thinking, terrestrial bryophytes can serve as food for some arthropods (Lawrey 1987). Catching them in the act can be difficult as many of these herbivores are nocturnal (Hribljan 2009). A common pattern of eating seems to be to strip all but the border and costa (Wyatt & Stoneburner 1989, Davidson *et al.* 1990), not unlike insects that skeletonize tree leaves.

Contrary to many statements in the literature about poor nutritional value of mosses (*e.g.* Pakarinen & Vitt 1974; Suren & Winterbourn 1991), Parker *et al.* (2007)

found that *Fontinalis novae-angliae* (Figure 36) had the highest dry mass, ash-free dry mass, and protein content among the available plants in their study stream at Chattahoochee River National Recreation Area near Atlanta, Georgia, USA.

Figure 36. *Fontinalis novae-angliae*. Photo by Janice Glime.

It is not just aquatic mosses that provide nutrition. Lawrey (1987) provided us with a review of moss and lichen nutritional value for arthropods. He contends that the nutritional composition is similar to that of the tracheophytes, containing the same sugars (Lawrey 1987), but with the addition of some unknown ones in at least some mosses (Maass & Craigie 1964). The caloric content is likewise similar to that of higher plants (Bliss 1962; Forman 1968; Pakarinen & Vitt 1974; Rastorfer 1976). Elemental concentrations are similar (and vary among species), with only potassium and magnesium being at lower levels than in tracheophytes (Prins 1981). Spores have the highest lipid concentrations, resulting in their consumption by some arthropods such as ants (Plitt 1907) and other animals.

Thus, we must ask why there is so little evidence of consumption of bryophytes by arthropods. Lawrey (1987) suggests several explanations. Low digestibility has been suggested several times, in part based on the high ratio of cell wall to cell contents. Furthermore, liverworts are well known for their secondary compounds (Adam & Becker 1994; Adio & König 2005; Veljić *et al.* 2008), and recent studies likewise indicate that other bryophytes, including mosses, are highly endowed with antifeedant secondary compounds as well (Davidson 1988; Mueller & Wolf-Mueller 1991; Frahm & Kirchoff 2002; Asakawa 2005). But it is not just the high ratio of cell walls or the antifeedants that make the bryophytes less digestible. They have lower concentrations of easily digested soluble carbohydrates and hemicelluloses than do tree leaves, and, supporting the cell wall to contents ratio hypothesis, they have higher concentrations of structural components such as cellulose and lignin-like polyphenolic compounds that are not easily digested than do their tracheophyte counterparts (Table 2) (Skre *et al.* 1975; Lawrey 1987).

Lawrey actually compared these components in the moss *Polytrichastrum* (= *Polytrichum*) *ohioense* (Figure 37-Figure 39) with those of a conifer and angiosperm. My concern with using this study as a basis for understanding bryophyte herbivory is that Polytrichaceae has a more highly structured body plan than most bryophytes and I

suspect its content of lignin-like polyphenolic compounds is greater than that of many kinds of moss. Furthermore, the cuticle, at least in *Polytrichum commune* (Figure 40), seems likewise to be more developed than that of many other moss taxa (Proctor 1979), so it may not be representative of the edibility of mosses.

Table 2. Comparison of percentage of structural components of tree leaves and of plants of the moss *Polytrichastrum* (= *Polytrichum*) *ohioense*. From Lawrey 1987.

Litter type	soluble carb	hemi-cellulose	cellulose	"lignin"	ash
<i>Pinus resinosa</i> leaves	35.41	13.44	19.37	23.56	3.68
angiosperm tree leaves	43.89	11.59	20.43	11.04	6.97
<i>Polytrichastrum ohioense</i>	16.51	14.07	24.37	12.90	4.24

Not only are the polyphenolic compounds difficult to digest, but they typically have antibiotic activity (e.g. Madsen & Pates 1952; Pates & Madsen 1955; Ramaut 1959; McCleary *et al.* 1960; Wolters 1964; McCleary & Walkington 1966; Gupta & Singh 1971; Banerjee & Sen 1979; Asakawa 1990, 2007; Basile *et al.* 1995; Verhoeven & Liefveld 1997; Frahm & Kirchoff 2002). Lawrey (1987) suggests that these antibiotics could affect both palatability and digestion for the arthropods. Since the microflora of the gut aids digestion in a number of arthropods (not many have been examined carefully), antibiotics could kill these important digestive components, to the detriment of the host. Hence, not only would the bryophytes be difficult to digest, but so would other food eaten with them.

But bryophytes can serve as food sources for arthropods indirectly. Their many invertebrate inhabitants (Yanoviak *et al.* 2003, 2006) provide food for birds, especially in the tropics (Nadkarni & Matelson 1989). In discussing the role of lichens in boreal forests, Pettersson *et al.* (1995) suggested that this habitat could be critical for passerine birds in winter, citing the loss of spiders and insects in managed forests compared to natural forests. It is likely that bryophyte communities in many forests serve as a similar refuge of importance during seasons of limited access to arthropods as food.

Bryophytes most likely play a major role in the locations and activity of soil organisms, hence facilitating movement of nutrients through that ecosystem, although little definitive study seems to exist. Organisms such as pillbugs migrate downward in the daytime and back up at night, feeding on the mosses, then returning downward where their feces ultimately rest (Hribljan 2009). This results in cycling of nutrients from one location to another, undoubtedly causing these recycled nutrients to reach the soil more easily. It is likely that insects and other invertebrates actually retreat into the soil to escape predation, desiccation, and UV light, then venture upward into moss mats at night to forage. In some cases, mosses may be essential as part of the habitat. They therefore contribute, through these migrant invertebrates, to aeration, nutrient movement, biodiversity, and water movement in the soil. While this role is an intriguing notion for soil properties and nutrients, its importance needs to be tested.

Collection and Extraction Techniques

When I first tried to publish my doctoral work on insects associated with stream mosses, I listed numbers like 12,064 Chironomidae per gram of moss. The reviewer wanted to know how I had developed these numbers because I "obviously had not counted them." But I did!

The variety of invertebrates makes a single technique impractical – and biased. The 6 or more legs of arthropods easily get caught on the stems and leaves. Mine were necessarily preserved because I would have a collecting day and come back with 30-40 collections of mosses that needed to have arthropods removed. I had no way to provide the cold, oxygenated water they required to stay alive, and many of them would disintegrate quickly once dead. In fact, many insects release enzymes when their cells die that cause the cells to break down quickly, a process known as **autolysis**.

Collection

One problem one must face during collection is the loss of organisms during the collection. Borcard (1986) used a cylindrical sampler mounted on a hand drill to make a core of *Sphagnum* for collecting mites. These samples were not deformed or compressed and thus provided uniform samples suitable for statistical comparisons.

For epiphyte dwellers, particularly in the tropics, insecticide fogging (**Pyrethrin** insecticide) is commonly used for arthropods (Yanoviak *et al.* 2003), but this method is often not effective for arthropods that hide in crevices, tree holes, humus pockets, and epiphytes, including bryophytes. Instead, most of the bryophyte inhabitants are trapped within the mats. The smaller of these arthropods are the least likely to be knocked down by fogging. Mites, in particular, are missed when the fogging method is used for sampling.

Loss of organisms could be especially problematic in streams where the escapees are quickly washed downstream. On the other hand, these stream bryophyte-dwelling organisms are adapted to clinging to the bryophytes against the drag of stream flow, so it appears that few escape. I tested this occasionally during my own research by putting a collection net downstream as I used hand grabs to sample. Few organisms, compared to the large number present, actually escaped, so I abandoned the downstream nets.

Suren (1993) was more cautious in his mountain stream sampling. He placed a **Surber sampler** (area = 10x10 cm, 100 µm mesh) (Figure 41) around the bryophyte clump to be sampled. A Surber sampler has a square frame that must be placed on the bottom of the stream, and a net extends downstream from that, usually about 50 cm or more. Suren used a razor blade to dislodge the bryophytes, but one could use a knife or scalpel. I used my hands – fortunately, I have strong fingernails. Its disadvantage is that it is often difficult to make the entire frame touch the substrate, and the stream may be too deep to reach from substrate to surface, hence permitting some organisms to float away and others to escape along the bottom. It is, perhaps, better than a simple hand grab, except that one can clasp the hand around the mosses, seemingly preventing many escapes.

Figure 41. Surber sampler, showing the investigator removing a rock from the sampling area. The opening of the net faces upstream and the net catches organisms dislodged during sampling. Photo by Ray Drenner, with permission.

A modification of Suren's method is to use a screen with handles. This device usually has a wooden support or pole on each end with the mesh extended between them. The base is placed as snugly as possible against the stream substrate and bryophytes are dislodged to flow into the screen. The ones I have used are made of metal window screening, giving them rigidity, but perhaps one with a fine cloth mesh would work, permitting a closer fit around rocks in the streambed and capturing smaller organisms. The big disadvantage of the window screening is that the mesh size is large enough for mites and others of the smallest organisms to go right through the mesh, creating a sampling bias toward larger organisms. Furthermore, for collecting bryophyte communities, both the screening and fine cloth mesh samplers would require two people, one to hold the device and one to dislodge the moss.

Extraction

There are extraction techniques that are usable to get estimates of various groups if you are willing to live with their biases. The Winkler technique is still useful (Nadkarni & Longino 1990), but relies on the movement of the arthropods away from heat or light, thus creating a bias against less mobile organisms. Trägårdh (1929) recognized the limitations of this method to small soil invertebrates such as mites that are sensitive to evaporation. He found that if the moss dries too quickly they are likely to die before they can escape the heat. Instead, he chose to use a warm water funnel such as that used by chemists to filter colloidal matter. He covered this with sieves of different mesh sizes, depending on the material to be sampled.

Andrew and Rodgers (1999) used multiple extraction techniques to sample small invertebrates living among bryophytes in Tasmania. They used Tullgren Funnels and sugar flotation (Pask & Costa 1971), but also tried a new method using kerosene phase separation (Andrew & Rodgers 1999). They determined that the phase separation freed more total individuals and more **Acari** (mites) and **Collembola** (springtails) in particular. The technique works because the kerosene attaches to the cuticles of insects, causing the insects to float. Their procedure is to "pickle" the insects and their moss housing for two weeks in 95% ethanol. This mix is then put into a

test tube, filling it to 3/4 full. This is topped off with 1 cm of kerosene and shaken vigorously until the solutions are fully mixed. After the mix settles for 10-15 minutes, the tube is rolled to release trapped bubbles from the sides and bottom. The insects and other arthropods collect on the interface between the alcohol and kerosene. The kerosene must be removed with a pipette, then the remaining kerosene plus interface can be removed. To get the arthropods from the sides of the test tube, they washed the sides with 95% ethanol and repipetted to collect the arthropods. The entire process should be repeated to increase the efficiency (about 16% more). A fume hood should be used to examine the organisms safely. Brantley and Shepherd (2004) used heptane flotation to avoid the desiccation problems caused by alcohol and other flotation media.

Taxonomic Difficulties

Bryologists are very familiar with the difficulties of making determinations in the field. The myriad of arthropod species creates even greater taxonomic problems, particularly when dealing with the tiny organisms living among bryophytes. It is rare to find a person with taxonomic expertise in both groups (spanning two kingdoms!), and within the huge group of arthropods, scientists typically are experts in only one class or for insects, only one order. In 1996, Walter *et al.* estimated that the 45,000 species described represented only 5% of the number of species actually **extant**. Among those 95% of undescribed, unnamed species, the bryophyte dwellers may represent an even higher percentage of undescribed members. Instead, crop and other economic pests are usually the first taxa to be investigated.

Such taxonomic challenges explain in large part the lack of detailed information about the faunal arthropod communities among bryophytes. Facing this challenge, Oliver and Beattie (1993) suggested another method that would permit an assessment of biodiversity without requiring taxonomic expertise, large expenditures of time, or high cost. They compared the estimates of species richness (number of species) made by both experts and technicians. The technicians were trained for only a few hours so that they could separate organisms into **recognizable taxon units (RTUs)**.

Using the same sampling methods, the specialists for each taxonomic group of spiders, ants, polychaetes, and mosses identified and separated the taxa to species (Oliver & Beattie 1993). Interestingly, for the three animal groups the experts determined there to be 147 taxa, whereas the technicians separated their organisms into 165 groups. Among the ants and spiders, the technicians had an error rate of 13% or less. When 13 undergraduate students repeated the procedure, the average error was only 14.4%. Some of the differences arose from splitting or lumping by the experts – taxonomic concepts that will continue to plague the ecologists trying to describe ecosystems and communicate their findings. It seems that the results for mosses were more difficult to interpret. The results in numbers had greater similarity between experts and technicians, but splitting and lumping of taxa made the comparisons more difficult.

Such methods as that of Oliver and Beattie (1993) are useful for rapid assessment of biodiversity, but they do not

tell us about community shifts. When comparing two ecosystems, the composition of the species may tell us more than the numbers of species. Further problems arise due to differences in sexes and juvenile vs adult life forms, perhaps accounting for some of the greater diversity reported by the technicians. We have thus far no reason to expect that these age and sex-related within-species morphological differences are habitat related, and they do have significance in assessing functional groups. On the other hand, as we will see for amphibian taxa, various color morphs of adults can indeed relate to habitat and niche differences. Technicians are not likely to be aware of these variations, and even the experts disagree over whether to consider some of them to be different species.

Summary

Bryophytes form a habitat for many kinds of arthropods. They serve this function well by providing moisture, cover, protection from UV exposure, temperature modification, and a habitat for smaller invertebrates that serve as food. Even the soil habitat is enhanced when covered by bryophytes. They provide a refuge under some conditions and are suitable egg-laying sites for some arthropods, but are unsuitable for habitation at others. In winter they provide insulation and protection. In their role as a habitat or a refuge, they can greatly enhance species richness. This amplifies the food source for predators such as birds.

Despite the presence of secondary compounds (antifeedants, antibiotics) in many bryophytes, some still serve as food and are able to contribute protein and dry mass. Smaller organisms living there serve as food items, and the fauna serve as nutrient cyclers, moving nutrients back toward the soil.

The arthropods often form gradations of communities from soil to treetops, with mosses being present in each of those habitat zones. These ranges reflect differences in temperature, light, and humidity preferences. Disturbance of the epiphytic communities can impact food sources for non-migrating birds, especially in winter.

In dry habitats such as prairies, mosses in cryptogamic crusts provide a refuge from the sun and desiccation. These arthropods in turn contribute to soil nutrient cycling.

In streams bryophytes provide a safe site against predators that don't like the taste of the bryophytes, but these bryophytes are also a safe site against the rapid flow of streams and rivers. Furthermore, they provide this habitat during winter when tracheophytes disappear from the streams. They furthermore increase surface area that collects periphyton and detritus, suitable food sources for many arthropods, a role most likely much more important than the role of the bryophyte itself as a food source.

Sphagnum sites are particularly rich in species, sometimes having double the number of species found in forested areas. Lycosids are common. Spiders have unique niches within the peatlands and often characterize biotopes there. Nevertheless, the low pH and need for basic compounds to harden the cuticle make the peatlands inhospitable for many taxa.

In the Antarctic, water content in and under bryophyte cover is important, but in some cases the bryophytes are important for providing suitable temperatures. This can be especially important for overwintering of eggs and larvae, as well as some adults. Nevertheless, higher altitudes in New Zealand do not seem to influence species richness.

Bryophytes in many habitats can provide refuge from the heat of summer, but upper layers of mosses such as *Sphagnum* or *Bryum argenteum* can reach temperatures 10°C or more above ambient. A further protection by bryophytes is the chemical defense that discourages larger predators and protects the microarthropods hiding among the bryophytes.

Disturbance and fragmentation seems to have little effect on the microarthropod fauna remaining in the bryophyte islands. Recolonization can occur by passive transport.

Acrocarpous cushions can house more arthropods than pleurocarpous mosses, perhaps due to greater moisture-holding capacity in the former. But cushions also hold much more soil. And cushions generally afford more protection from UV light and heat of the sun.

Secondary compounds that prevent herbivory may also defend the small inhabitants living among the bryophytes. Crayfish and Canada Geese tend to avoid feeding on bryophyte inhabitants.

Collecting and extracting is somewhat problematic because not all arthropods can be collected and extracted by the same techniques. Collection includes fogging, hand grabs, Surber samplers, and kick nets. One can accomplish extraction with a Tullgren funnel, sugar flotation, or kerosene phase separation, as well as hand picking. Once the arthropods are extracted, the difficult task of identification begins. For purposes of assessing diversity, morphotypes will suffice, but for comparing actual community composition, species names are important.

Acknowledgments

My sister, Eileen Dumire, reviewed the chapter for readability and grammatical/spelling errors. Larry Williams made suggestions for improvement and caught several technical errors. CHAPTER 7-2

ARTHROPODS: ARACHNIDA – SPIDER BIOLOGY

Figure 1. *Arctosa cf. alpigena* female on moss, showing disruptive coloration that makes it more difficult to see. It has been reported from mosses in more than one study (Harvey *et al.* 2002; Almquist 2005). Photo by Walter Pfliegler, with permission.

SUBPHYLUM CHELICERATA

The subphylum **Chelicerata** includes the spiders and mites, both having members associated with bryophytes. Both spiders and mites are in the class **Arachnida**, along with scorpions, harvestmen, ticks, and Solifugae. The **Chelicerata** are characterized by four pairs of walking legs, a pair of chelicerae, and a pair of pedipalps. Although the arachnids are not as small as many of the organisms in preceding chapters, many are small enough that the bryophytes still provide sufficient space for many of these taxa to navigate easily among the stems and leaves. Hence, we should expect to find the bryophytes to be a suitable habitat for a number of these.

Following the concept of a niche, bryophytes can provide a number of important "resources" for arachnids. The most obvious of these are shelter and protection. With **disruptive coloration** on their backs, spiders and other small arachnids can hide among the bryophytes undetected by would-be predators such as birds. This shelter may provide a safe site when an arachnid is being chased or provide a protected niche for an egg case during incubation. The protection also extends to anchorage and shelter from wind, diffusion of raindrops (avoiding the impact of a free-fallen drop), temperature buffering, and retention of humidity. Further possibilities include having

a place to lie in wait for a walking meal to meander by, or perhaps even eating the bryophyte itself, a menu item that is poorly documented (and unlikely) for spiders.

But bryophytes may also extend their benefits to those arachnids not living among the branches. Bryophytes help to keep the soil beneath humid, soft, and pliable for longer periods than that experienced by bare soil. They permit an arachnid to emerge from a burrow and look around while remaining hidden beneath a canopy of loose bryophytes. Even those arachnids traversing the surface of bryophytes may benefit from the disruptive coloring of mosses that make the disruptive colors of arachnid backs less conspicuous. Or they may simply add a place where humidity is greater, helping arachnids to travel greater distances before risk of drying. And who knows if these arachnids might take advantage of the early morning dew captured by bryophyte leaves to gain a drink of water.

With all these possibilities, we would expect some arthropods to have distinct adaptations to that bryophytic habitat. Indeed some do, but I feel certain many stories remain to be discovered.

Class Arachnida

The arachnids include the spiders (order **Araneae**), mites (subclass **Acarina**), ticks (subclass **Acarina**), and harvestman or daddy-long-legs (order **Opiliones**). These are creatures that somewhat resemble insects, but as adults they have eight legs. They have one or two main body regions, not three as in insects. Among these, the mites are fairly common residents in moss clones. Although the other arachnids are not very common among bryophytes, there are, nevertheless, some interesting stories about all of these inhabitant groups.

Arachnid Trapping Limitations

Little quantitative work exists for any arachnids except that for the moss-dwelling mites. One limitation that might suggest that bryophytes are unimportant is the typical sampling method used for forest floor arthropods, including arachnids. Pitfall traps are typically used for those arthropods that are active above the surface during some part of the 24-hour cycle (Curtis 1980). But if arthropods spend most of their time within the bryophyte mat rather than on the surface, they are not likely to fall into such traps.

Curtis found that responses of spider species to four pitfall trapping methods differed, causing distortions in the community species frequency curves. Hence, we should expect even greater differences among a wider range of methods. For example, Komposch (2000) studied the spiders in wetlands of Austria using pitfall traps, light traps, soil sifters, and hand collections. As will be seen in studies cited in this chapter, this broader set of methods gets better representation of groups like the **Linyphiidae**, a very species-rich family of small spiders with many species living among bryophytes.

Pitfall traps are sunken into the ground with water or other liquid to trap the fallen arthropods. The top is covered with a wide mesh screen to keep out debris and possesses a second raised cover to keep rain out. The container can be simple, like a cereal bowl (Figure 2) or can (Figure 3). Although bait is shown in the diagrams, it

is not necessary and may introduce a bias if the study is quantitative.

Figure 2. Pitfall trap with cereal bowl holding alcohol. The bait will bring the organisms to the trap, but most will fall into the alcohol before reaching the wire that gives them access. Drawing from USDA website.

Figure 3. Pitfall trap using a can with water to trap arthropods. Drawing from USDA website.

In the tropics, fogging with pesticides (Pyrethrin) can reveal a number of canopy arthropod fauna. However,

most of the bryophyte dwellers remain trapped within the bryophyte clumps (Yanoviak *et al.* 2003). The smaller ones, like the **Linyphiidae**, are the least likely to drop from the canopy into the collecting containers, giving a biased representation of the community and even missing some species entirely.

Such trapping limitations tend to limit the habitat descriptions of spider fauna. For example, Koponen (1999) described the fauna of the Finnish taiga, but only mentioned the mosses *Pleurozium schreberi*, *Dicranum*, and *Hylocomium splendens* as the dominant ground cover without relating the spider locations to them.

Sieving might be a somewhat better technique for bryophyte dwellers, but for many species that live among the branches of the mosses, only hand picking is likely to uncover some of the species sufficiently to represent their abundance. We need to examine the efficacy of typical trapping and other sampling methods on enumeration of bryophyte-dwelling arthropods.

Order Araneae – Spiders

"Once upon a time Anansi the Spider was walking, walking, walking through the forest when something caught his eye. It was a strange moss-covered rock. "How interesting!" Anansi said. "Isn't this a strange moss-covered rock!" (Kimmel 1988).

Kimmel (1988) uses mosses and a spider to build a children's story. In this story, a spider uses "strange moss-covered rock" to trick the other animals, but Little Bush Deer decides the spider needs to learn a lesson.

Spiders in nature use mosses to provide cover and camouflage against predation. Rocks with mosses are indeed interesting, although not quite in the way of trickery that Anansi used them. They house many kinds of arthropods, spiders among them.

Nomenclature for spiders follows Platnick (2000-2013).

Spider Biology

There are approximately 40,000 species of spiders in the world (Wikipedia 2012a; InsectIdentification 2013). Spiders are 8-legged creatures that have chitinous coverings and two body regions, the **cephalothorax** (head and thorax as one external unit) and abdomen. Unlike the insects, they lack antennae. Instead, they have various hairs that penetrate their chitinous covering (Wikipedia 2010d). Some of these may be sensitive to the slightest movement, such as that of wind. Others are sensitive to chemicals, thus achieving the role of insect antennae and our noses and tongues.

The legs originate on the underside of the cephalothorax. Instead of muscles, they use hydraulic pressure to extend their legs, although they have muscles to flex them. This explains why dead spiders always have the legs drawn in – no pressure to extend them. And any puncture to the chitin of the cephalothorax causes loss of water pressure and certain death.

Spiders have chelicerae (claws) with fangs that they use to inject venom into their forthcoming dinner. Most of these poisons are not serious dangers for humans, although they can cause itching or painful swelling locally. Only one herbivorous spider is known (Meehan *et al.* 2009), all others being predators. Therefore, we should not expect them to consume bryophytes.

Spiders excrete uric acid, a very concentrated form of nitrogen waste, thus permitting them to conserve water for long periods of time. This reduction of need for water may help to explain their reticence to live among mosses where humidity is often high, but there are at least some spiders that live in the water, so one would expect some to be adapted to the higher humidity of bryophytes in other habitats.

While bogs probably host the majority of spider species associated with bryophytes, many spiders live among bryophytes also in drier habitats. Humid forests are often rich in bryophytes. But dry habitats such as coastal dunes may also have a high coverage of bryophytes serving as habitats for spiders, even though these bryophytes are dried up much of the time.

Although at times the Linyphiidae may be somewhat numerous, in other cases spiders are a minor component of the bryophyte habitat. In the epiphyte mats of Costa Rican cloud forests, where bryophytes are only one component, Yanoviak *et al.* (2007) found spiders among the lowest in representation among 10 groups of arthropods, occupying about 1% of the fauna in the cloud forests in the wet season and 1-2% in the dry season.

Growth Forms and Life Forms

Bryophytes are often lumped together as if they are all the same to their animal communities, but growth and life forms can make quite a difference to the living space within. Gimingham and Birse (1957) related growth form response to decreasing levels of moisture, from dendroid and thaloid mats in high moisture to short turfs and cushions in low moisture. Vilde (1991) showed that differences in life form can reduce evaporative rate by 5.3-46 times, depending on the species and site conditions.

The two terms of **life form** and **growth form** have been confused in the literature (La Farge 1996), as discussed in Chapter 4-5. To reiterate briefly here, **growth form** is a purely morphological term and although genetically determined, it can be modified by the environment, as opposed to **life form**, which is more encompassing and describes the result of life conditions, including growth form, influence of environment, and assemblage of individuals (Warming 1896; Mägdefrau 1982). La Farge-England (pers. comm. 1996) sums it up by stating that **life form** is the **assemblage** of individual shoots, branching pattern, and directions of growth as modified by the habitat, whereas **growth form** is a property of an **individual**, the structures of the shoots, direction of growth, length, frequency and position of branches.

Mägdefrau (1969) defined the following **life forms**, to which I have added examples and habitats:

annuals: *Phasium*, *Riccia* – disturbed habitats

short turf: *Trichostomum brachydontium*, *Barbula* – epiphytes; tundra

tail: *Prionodon densus*, *Leucodon*

cushion: *Leucobryum* – deciduous & conifer forests; epiphytes; alpine; desert

mat: *Hypnum*; *Plagiothecium* – moist forests; conifer forests; epiphytes; alpine; tundra

fan: *Neckeropsis* – humid tropical forests; epiphytes

tall turf: *Dicranum* spp.; *Polytrichum* – conifer forests; alpine; tundra

weft: *Hylocomium*, *Pleurozium* – conifer & deciduous forests; desert; alpine; tundra
dendroid: *Climacium*, *Hypnodendron* –
pendant: *Meteoriaceae* – humid tropical forests; epiphytes

Sphagnum does not fit well into these categories because of its loose interior with an expanded apex. It perhaps most closely fits into the tall turf.

A comparison of these categories as spider habitats may provide interesting relationships. However, few studies address the moisture benefits of various life forms to the bryophytes and none seem to address this question experimentally for the spiders. Therefore, we can only theorize. Life forms will be mentioned occasionally throughout this chapter, but they should be viewed with some caution because the vocabulary used seems to be primarily confined to mat vs cushion.

Bryophytes as Cover

As early as 1896, Banks recognized the importance of mosses for spiders, including the **Linyphiidae** *Eridantes* (as *Lophocarenum*) *erigonoides*, *Islandiana flaveola* (as *Tmeticus flaveolus*), and *Scylaceus* (as *Tmeticus*) *pallidus* in moss on Long Island, NY, USA. Bryophytes form important cover for many kinds of spiders. Es'kov (1981) found that an abundant moss cover is important for spider populations in the Russian taiga; Vilbaste (1981) likewise found spider fauna in mires of Estonia. Diverse invertebrate bryophyte communities similar to those found in the soil are common in the tundra (Chernov 1964), so it is possible that the bryophyte habitat is an important feeding area for spiders there. Bonte *et al.* (2003) found a significant correlation between spiders and moss cover in the coastal grey dunes along the North Sea. Larrivée *et al.* (2005) found a correlation between spiders and moss/lichen cover in burned areas, but not in clearcut areas, suggesting that the two types of deforestation elicit very different responses from the spider populations.

Pearce *et al.* (2004) compared the microhabitats of spiders in boreal forests of northwestern Ontario, Canada. They found that among the four stand types, spiders did not view mosses as simply mosses. Rather, *Agyneta olivacea* (see Figure 4; **Linyphiidae**) and *Pardosa uintana* (see Figure 22; **Lycosidae**) occupied microhabitats associated with feather mosses (wefts; Figure 5) rather than those of *Sphagnum* (tall turf; Figure 6), suggesting the possibility that life or growth form may be important.

Figure 4. Male *Agyneta ramosa* on a moss, giving one an idea of its small size. Photo by Jørgen Lissner, with permission.

Figure 5. *Hylocomium splendens*, a weft-forming feather moss. Photo by Michael Lüth, with permission.

Figure 6. *Sphagnum russowii*, where a variety of spiders might take advantage of the humidity. Photo by Michael Lüth, with permission.

Among the few studies to consider the bryophyte habitat specifically, that of Biström and Pajunen (1989) compares the fauna in two forest locations in southern Finland. In these forests, they considered the fauna on *Polytrichum commune* (Figure 7) and several species of *Sphagnum* (Figure 6). They found seven generalist spiders, all **Linyphiidae** [*Centromerus arcanus* (Figure 16), *Dicymbium tibiale* (Figure 8), *Semljicola faustus* (as *Latithorax faustus*; Figure 9), *Lepthyphantes alacris* (Figure 10), *Minyriolus pusillus* (Figure 11-Figure 12), *Tapinocyba pallens* (Figure 13), and *Walckenaeria cuspidata* (Figure 14)], that occurred with these mosses at all five of the main collecting sites during the May to October collecting season.

Drozd *et al.* (2009) sampled under moss "cushions" and in litter, obtaining 55,000 invertebrate specimens. They found that the arthropod association, including spiders, reflects interaction between presence of mosses (*Polytrichum commune*, *Polytrichastrum formosum*, *Sphagnum teres*, *Bazzania trilobata*, *Pleurozium schreberi*, *Eurhynchium angustirete*, *Oligotrichum hercynicum*) and other features of the microhabitat. Moss presence, moss species, and moisture are very important characters for both total arthropod abundance and abundance of various arthropod groups. On the other hand,

the total arthropod abundance and that of most groups is actually higher in the litter than in moss cushions ($p = 0.0003$). Although the surface activity is considerable, the dense moss cushion prevents them from moving effectively or with due speed. Hence the larger arthropod taxa avoid the dense interior by staying on the surface.

Trampling

Few studies on trampling effects on bryophytes or on spiders exist. Nevertheless, one can imagine that anything that squashes the spaces where spiders move about in search of food would have a negative impact on the spider community. Duffey (1975) studied the effects of trampling on invertebrates in grassland litter and found that the air space dropped from 63% to 38% as a result of 10 treads per month. Although there was little difference in the invertebrate fauna between two levels of trampling, there was significant reduction in the spider fauna. Furthermore, spiders were sensitive at a much lower trampling level than the vegetation itself. It is possible that spiders living among bryophytes would suffer similarly from compaction. On the other hand, it could be that the bryophytes would spring back, offering patches of refuge following trampling of other vegetation. This would make an interesting study.

Abundance, Richness, and Specificity

Quantitative studies are not as common as species richness studies, but one can, nevertheless, find a number of studies with species numbers. For our purposes, however, it is difficult to identify which of those species is associated directly with bryophytes rather than just occurring in a habitat that has bryophytes.

In the study by Biström and Pajunen (1989) in two forest locations in southern Finland, there were 23 species that occurred in at least one of the main sites with a density of at least one individual per square meter. At Borgå they found approximately 57 species associated with *Polytrichum commune* (Figure 7), some of which were juveniles and could not be identified to species. In association with *Sphagnum girgensohnii* (Figure 15) they found only 43 species. *Centromerus arcanus* (Figure 16) and *Erigoninae* juveniles were among the most abundant at both sites. The most abundant of bryophyte-associated species, *Centromerus arcanus* (Figure 16), is only 1.5-2.6 mm long (Roberts 1987) and exhibited mean densities of 8.7-24.4 individuals per square meter (Biström & Pajunen 1989). Somewhat less abundant were *Dicymbium tibiale* (1.8-11.9 mm; Figure 8) and *Lepthyphantes alacris* (0.7-2.0 mm; Figure 10).

Figure 15. *Sphagnum girgensohnii*, a common woodland species. Photo by Michael Lüth, with permission.

Figure 16. *Centromerus arcanus*, the most abundant spider associated with *Sphagnum* in a Finnish study. Photo by Jørgen Lissner, with permission.

I found the greater number of species associated with *Polytrichum commune* (Figure 7) (Biström & Pajunen 1989) to be somewhat surprising because the *Polytrichum* species do not have the high moisture-holding capacity available with species of *Sphagnum* (Figure 15). Perhaps the *Polytrichum commune* is too dry for some spiders, as suggested by the moisture data of Biström and Pajunen (1989), but for others some of the wetter mosses are less desirable. Too much water can affect the ability to exchange gasses through the tiny spider tracheae, causing the spiders to drown. *Polytrichum commune* provides a high spot out of the wet environment. It would be interesting to monitor the behavior of the spiders as water levels change in the bog and fen ecosystems. Such moisture and morphological differences are not exclusionary for most of the generalist spiders, but may be of importance in the distributions of rarer species.

I also wonder which of these mosses provides a habitat where maneuverability is greater. It would appear to me that it would be easier to move among *Sphagnum* stems (Figure 15) than among those of *Polytrichum commune* (Figure 7), but perhaps the spider does not perceive it that way. It would be interesting to experiment with the environmental variables vs the morphological characters that differ among these species to see just what factors are important to the location of the spiders. One must also consider the possibility of sampling bias. Although the sieve technique used by the researchers in this study seems to be the most appropriate for bryophytes, it may have differed in effectiveness between moss genera.

No spider species seemed to be especially abundant on just one bryophyte species and rare on the others, suggesting that they either had relatively wide tolerances for the conditions available or that they were sufficiently mobile to be found in the range of species locations due to transit between preferred sites. For example, some species of the *Linyphiidae* subfamily *Erigoninae* may be numerous in an area one day and gone the next (Wikipedia 2010b). This lack of specificity is consistent with observations by Graves and Graves (1969) in North Carolina, USA. They found no habitat specificity for the spiders among mosses, fungi, *Rhododendron* leaf litter, and other microhabitats.

Isaia *et al.* (2009) present us with a very useful study from the Abruzzo Apennines in Central Italy. They used a Berlese apparatus to extract spiders from "wet" mosses.

Not surprisingly, the **Linyphiidae** were the most prominent family. This is a large family of tiny spiders and was represented by 22 of the 38 species.

In all, Isaia and coworkers (2009) found 494 spiders among wet mosses from the Apennines in Central Italy, representing 38 species in 36 genera and 14 families, an interesting distribution where lack of multiple species in the same genus suggests niche separation. Some were more generalists, occurring in mosses and elsewhere [*Robertus lividus* (Figure 17-Figure 18; **Theridiidae**), *Caracladus leberti* (**Linyphiidae**), *Diplocephalus arnoi* (cf. Figure 19; **Linyphiidae**), and *Antistea elegans* (Figure 20; **Hahniidae**)]. Juveniles of *Lepthyphantes* (Figure 10), *Parachtes*, *Cryphoea* (Figure 21), *Pardosa* (Figure 22), *Pirata* (Figure 23), and *Xysticus* (Figure 24), all rather common genera, likewise included the mosses among their habitats.

Figure 24. *Xysticus cristatus* (ground crab spiders), member of a genus known from mosses. Photo by Trevor & Dilys Pendleton <www.eakringbirds.com>, with permission.

Parachtes sicutus (**Dysderidae**) prefers wet places, so mosses proved to be a suitable place for this species (Isaia *et al.* 2009). Not surprisingly, they found a new species of **Linyphiidae** (*Diplocephalus arnoi*) from wet mosses, with 96 out of 103 specimens from mosses associated with the film of water on rocks (**petrimadiculous** mosses). *Mecopisthes latinus* (**Linyphiidae**) also occurred among these mosses. The **Hahniidae** in wet mosses were represented by *Antistea elegans* (Figure 20), the most abundant, followed by immature members of *Cryphoeca* (Figure 21). One male of *Cryphoeca silvicola* (Figure 21) could be identified, and one male of *Hahn timer onidum* (Figure 25), known elsewhere from mosses, as well as *Ozyptila claveata* (or possibly *O. trux*?) (see Figure 26; **Thomisidae**) from wet mosses. This small number of males may be an artifact due to their smaller size and greater difficulty of finding them.

Moisture Relationships

Many spiders are particularly prone to desiccation, whereas some species from arid climates are able to survive without water for months and even years. Entling *et al.* (2007) found that spider β -diversity was strikingly higher in open habitats than in forests, suggesting that they have either behavioral or physiological means to protect them from desiccation. Many spiders are night-active, permitting them to enter more exposed areas without the danger of desiccation from daytime sun. Anyone who has put a living spider in a jar knows that spiders easily dehydrate, leading to their death. Their legs contract due to the loss of hydrostatic pressure.

But in a study of five species of spiders from various habitats, Vollmer and MacMahon (1974) could find no relationship with habitat. Likewise, Gajdo and Toft (2000), using pitfall traps, found no relationship between epigeic spiders and moisture in a heathland-marsh gradient in Denmark. In the latter case, the habitat ranged from 100% cover of mosses to near zero.

Rather, body size seemed to be a better determinant of the rate of water loss (Vollmer & MacMahon 1974), with small spiders losing moisture more rapidly due to their larger surface area to volume ratio. This water loss leads to reduced survivorship in smaller individuals (Vincent 1993).

One adaptation for survival of these small species and individuals is behavioral – living among bryophytes or taking periodic refuge there. As will be seen in many of the examples in this chapter, bryophyte-dwelling spiders are frequently small.

On the other hand, the critical activity point does correlate with the moisture of the habitat (Vollmer & MacMahon 1974), suggesting that bryophytes may permit spiders, especially small ones, to be more active.

Nonetheless, DeVito *et al.* (2004) found that within the spider genus *Pardosa*, distribution did indeed follow a moisture gradient related to a stream. But even these were not restricted by proximity to the shoreline. Bruun and Toft (2004) were able to demonstrate a moisture gradient in two Danish peat bogs, with *Pardosa sphagnicola* (Figure 27-Figure 29) and *Oedothorax gibbosus* (Figure 30) at the moist end of the gradient and *Haplodrassus signifer* (Figure 31) and *Zelotes* spp. (Figure 32) at the dry end. They concluded that moisture and vegetation density were the determining factors for community composition.

Once we understood the mechanisms of water loss by spiders, size became a logical explanation. The **tracheae** are the respiratory organs where oxygen enters the body (Davies & Edney 1952). Thus they are also exit points for water, but also cause drowning if too much water is present to block them. Humphreys (1975) pointed out that water loss is influenced by the size of the spider, temperature, saturation deficit, and by relative humidity per se. Davies and Edney demonstrated that up to 30°C the rates of water

loss in $\text{mg cm}^{-3} \text{ hr}^{-1}$ were low, never more than 1.6 (dead spiders with free spiracles) and usually <0.6 .

Figure 32. *Zelotes latreillei*. Photo by Trevor and Dilys Pendleton <www.eakringbirds.com>, with permission.

Hence, temperature is also important in conserving moisture. Animals exposed at 2°C intervals from $40\text{--}50^{\circ}\text{C}$ show a steep rise in water loss starting at 42°C (Davies & Edney 1952). The species are ordered by critical temperatures (lowest to highest): *Zygiella* (as *Zilla*) *atraca* [outsides of houses (Emerton 1902); woodlands (Elton 1928)], *Pardosa amentata* (Figure 45; **Lycosidae**; bogs), *Metellina segmentata* (as *Meta*) [Figure 33; **Tetragnathidae**; some species in breaks in blanket bogs (Cherrett 1964)]; *Tegenaria domestica* (as *T. derhami*) [wooded areas, deserts, coastal areas, grassy fields, inside man-made structures (Hunt 2012)]. *Zygiella* (as *Zilla*) *x-notata* [outsides of houses (Emerton 1902); woodlands (Elton 1928)] shows a less defined critical temperature and a lower rate of evaporation than any other study species at higher temperatures. Experiments with dusting caused a six-fold increase in the evaporation rate of *Pardosa amentata*, causing Davies and Edney (1952) to conclude that a wax layer might be present in the cuticle. Since living organisms lost water more slowly than dead ones, it is likely that this cuticle is secreted by living organisms. There are no experimental data on bryophyte-dwelling spiders and any cuticular relationship relative to temperature.

Figure 33. *Metellina segmentata*. Photo by Trevor and Dilys Pendleton <www.eakringbirds.com>, with permission.

In the Morr House National Nature Reserve, Westmorland, GB, Cherrett (1964) found *Metellina* (as *Meta*) *merianae* (Figure 34; **Tetragnathidae**) and *Larinioides* (as *Araneus*) *cornutus* (Figure 35-Figure 36; **Araneidae**) only in breaks in the blanket bog (Cherrett 1964). *Metellina merianae* was mostly in peat overhangs, suggesting that it was avoiding either sun (heat, light) or finding a moist site that was open enough for easy movement. Cherrett attributed this distribution to avoidance of light. Four other species, however, were distributed in a way suggesting they had the ability to withstand desiccation.

I don't know of any direct observations of spiders drinking water from mosses, but I consider it likely that it occurs. The water in soil capillary spaces provides a source of water, even for the larger Lycosidae. Parry (1954) experimented with *Alopecosa* (as *Tarentula*) *barbipes* (Sundevall), a species of heathlands and one of the larger British lycosids, and *Hogna* (as *Lycosa*) *radiata*. Parry demonstrated that when these spiders had lost about 10% of their normal weight, they would nearly always take advantage of an opportunity to drink from these capillary spaces. It would seem that water adhering in the capillary spaces of bryophytes would be even easier to obtain than that within the soil and may be an important source of water in places such as sand dunes. *Alopecosa barbipes* occurs on calcareous coastal dunes in Flanders, Belgium, where the ground cover is predominately mosses (*Syntrichia ruralis*, *Hypnum cupressiforme* var. *lacunosum*), low grasses, and low herbs (Bonte *et al.* 2000). The mosses in this habitat may be important as a source of drinking water.

Importance of Temperature

We have seen the importance that temperature holds for two lycosid spiders living on and in the *Sphagnum* mat. In geothermal areas, bryophytes often form the dominant vegetation. Studies of spiders living there may produce new records, or at the very least, range extensions, but a search with Google Scholar produced nothing on this relationship.

But spiders also inhabit cool areas. Růžicka and Hajer (1996) found that spiders in North Bohemia lived on mountain tops and peat bogs as well as on the lower edges of boulders where the air stream created "an exceedingly cold microclimate." They found *Diplocentria bidentata* (Figure 37; **Linyphiidae**) in pitfall traps laid among mosses at the edge of the stony debris. *Semljicola* (as *Latithorax*) *faustus* (Figure 9; **Linyphiidae**), a species known previously only from peat bogs, and *Theonoe minutissima* (Figure 38; **Theridiidae**), also a known bog dweller, occurred in moss at the lower edge of the debris.

Figure 37. *Diplocentria bidentata* on moss. Photo by Jørgen Lissner, with permission.

Figure 38. *Theonoe minutissima* female on moss. Photo by Jørgen Lissner, with permission.

Temperature can be important at the microclimate scale for nest and web site selection. Riechert and Tracy (1975) showed that there was an 8-fold increase in obtaining energy for *Agelenopsis aperta* (**Agelenidae**), a desert spider, from selection of a favorable thermal environment, compared to only 2-fold for selecting for greater numbers of prey. This is at least partly due to the increased spider activity in more favorable temperatures. Riechert (1985) suggested that shade might provide a cue to sites with favorable temperatures, whereas olfactory and vibratory cues help them to locate prey.

Humphreys (1975) showed that for *Geolycosa godeffroyi* (**Lycosidae**) water loss was a function of temperature. Humphreys suggested that this burrowing spider might be able to obtain water in the soil when it was greater than 11% by using heat differentials as a source of water, even though the spider was unable to extract it from near-saturated air. This heat differential extraction would seem to be a possibility among mosses as well.

The need for temperature optimization can cause spiders to select certain vegetational attributes. In a sagebrush community, spiders selected the most dense foliage form that had been experimentally modified by tying the branches together (Hatley & Macmahon 1980). The species diversity and number of **guilds** (any groups of species that exploit same resources, or that exploit different resources in related ways) were greater there. Should we expect a similar relationship for the scaled down community of small spiders that live among bryophytes? If

so, we might expect the communities to differ based on bryophyte life forms.

Hygrolycosa rubrofasciata (**Lycosidae**; Figure 39), a forest species, may choose its habitat for conditions conducive to attracting a mate. The male makes its mating "call" by drumming its abdomen on dry leaves, hence making the bog habitat unsuitable (Kotiaho *et al.* 2000). Kotiaho and coworkers found a positive correlation between dry leaves and presence of spiders. Furthermore, the drumming rate and both male and female mobility were correlated with temperature.

Figure 39. *Hygrolycosa rubrofasciata* on moss. Photo by Arno Grabolle, with permission.

Food Sources

If you have wondered how those spiders in your cellar find food to survive the winter, perhaps they don't need any, at least for a long time. Forster and Kavale (1989) found that the Australian redback spider (*Latrodectus hasselti*) can survive more than 300 days as adults with no food. Their longevity is greatest at 10°C, making your cellar or cool attic a suitable place to wait out the low food period. This suggests that within a bryophyte mat such spiders could survive a long winter without danger of death by starvation. Apparently most spiders can recover after 2-3 months with no food.

Reports on bryophytes as food for arachnids are relatively rare, although some recent studies have demonstrated that at least some mite taxa consume them (See Chapt 9-1). One suggestion that appears frequently in the literature is that bryophytes either have too little nutritional value, or that it is too difficult to extract that nutritional value from cells that have a large ratio of cell wall (cellulose) to cell contents. But for the arachnids, both the mouth parts and the digestive systems are adapted to eating animal prey.

Spiders may trap their prey or actively hunt for them. Many have poisons that anaesthetize or kill the prey. For example, the **Thomisidae** have their first two pairs of legs modified for grabbing the prey (Lissner 2011a). Their third and fourth legs help to anchor the spider to its substrate during the ensuing, but short, struggle. Once the spider has the opportunity to bite the prey, the prey dies within seconds from the highly potent venom. The longer first two pairs of legs permit the spider to walk sideways like a crab, albeit slowly (Stewart 2001).

Prey size is important to spiders. Whereas they are able to eat captured prey that is larger than they are, this is not necessarily their preferred prey size. Nentwig and Wissel (1986) found that the preferred size ranged 50-80% the size of the spider. Only two of the thirteen spiders in the experiments accepted prey (crickets) that were double their size. Nentwig (1989) found that season had little or no effect on prey size selection. Rather, the important influences were properties of the web, microhabitat, physiological, and behavioral differences among the spider species.

Hunting spiders can be **polyphagous**, feeding on a wide range of prey, or **oligophagous**, specializing on few kinds of organisms (Nentwig 1986). The **monophagous** species are rare, but their single food choice is usually a selection from only a few prey taxa – ants, bees, termites, and other spiders.

Despite the size relationships, the relationship between predator and prey may be unimportant in habitat choice. In one dune system, the relationship between dwarf spiders and their **Collembola** (springtail) prey seems to be a matter of common microhabitat preferences (Bonte & Mertens 2003). In this habitat that experiences severe microclimate fluctuations, both predator and prey aggregate. Both groups are negatively affected by grass coverage, but rather aggregate as a function of moss coverage and not of soil moisture.

Some spiders choose to live among the mosses in trees. When Miller *et al.* (2007, 2008) found a correlation between bryophytes, **Collembola** (springtails), and spiders in Maine, USA, they suggested that spiders depended on the **Collembola** living among the bryophytes for food. When the bryophytes were lost due to gap harvesting of the forest, the arthropod communities were affected, with various responses among the members. Height on the tree influenced the communities (Wagner *et al.* 2007). Bryophytes were most abundant near the tree base. At that level they primarily housed **Acari** (mites), **Araneae** (spiders), and **Collembola**, whereas at 2 m the Diptera (flies) were the most abundant. Loss of trees, and consequent loss of tree-base mosses, resulted in loss of **Collembola** and subsequent reduction in food for spiders.

Other organisms housed among bryophytes are also important as spider food. Among these are **earthworms**. Although predation of spiders on **earthworms** has rarely been observed (Figure 40), it appears that those spiders that do choose these as part of their diet are the ones that live on the ground in leaf litter, moss-covered patches, and under stones and logs (Nyffeler *et al.* 2001). These **earthworms** have a high protein content (~60-70%, dry weight) (MacDonald 1983; Lee 1985) that complements the typical insect diet of spiders. In the non-web-building genus *Xysticus* (Figure 41; **Thomisidae**), a crab spider only 7 mm long was able to consume parts of an **earthworm** of 2 cm length (Nyffeler 1982). This was no doubt possible because of the powerful front legs and a potent venom. Even web-building spiders feed on earthworms (Nyffeler *et al.* 2001). These include those making sheet webs (*e.g.* **Amaurobius** – **Amaurobiidae**) and silk tubes (*e.g.* **Atypus** – **Atypidae**) (Nyffeler *et al.* 2001), both bryophyte dwellers (Blackwell 1857).

By reviewing the literature, Nyffeler *et al.* (2001) found that members of eleven different families of spiders

are known to feed on other spiders. As you might expect, these predators belong mostly to larger species (>10.0 mm) that live near the ground in woodlands and grasslands. Among these are species that live in and under clumps of mosses.

Reproduction

Spider mating can be hazardous for the males. Females are usually larger than males, sometimes much larger (Wikipedia 2012a). Hence, males are easily overcome and can serve as dinner for the female. Males, on the other hand, express a number of complex courtship rituals that help them avoid predation by the females. They usually manage to have several matings, being limited by their short two-year life span (but much longer in some species like the tarantula).

Most spiders build nests where they deposit their eggs (Figure 42), often numbering around 1000 (Biodiversity Explorer 2012). When the eggs are expelled, they become surrounded in a viscous liquid that cements the eggs together when they dry (Figure 43). The female provides them with a fluffy silk that covers and insulates them, and she attaches this to vegetation or includes it in her web.

This cocoon also serves as protection against ant predation. Eggs laid in summer usually hatch in 1-2 weeks, whereas those laid at the end of summer will over-winter and hatch the following spring or summer. **Lycosidae** (wolf spiders) carry the cocoon attached to the rear of the abdomen (Figure 44) and later carry their young around on their backs (Figure 45), presumably providing further protection.

Figure 42. *Xysticus ulmi* (Thomisidae) female with eggs among mosses. Photo by Jørgen Lissner, with permission.

Figure 45. *Pardosa amentata* female with spiderlings. Photo by James K. Lindsey, with permission.

In the **Thomisidae**, no webs or retreats are used for oviposition (Figure 42; Lissner 2011c). The males are much smaller and darker than the females. During courtship, males touch the female in a way that causes her to recognize him as a male spider and she assumes a submissive posture. Once eggs are produced, the female guards the egg sack. Members of the genus *Xysticus* (Figure 41) are known from bryophytes (Isaia *et al.* 2009).

Some spiders use mosses as the substrate for depositing their cocoons. Hajer *et al.* (2009) found that *Theridiosoma gemmosum* (Figure 46; **Theridiosomatidae**) maintained its egg sac (Figure 47) on *Hypnum cupressiforme* (Figure 48) during their study. Alexander (2003) found this spider species among fen vegetation in Cornwall, UK, where it presumably deposits its cocoons. This species has a rather unusual mating behavior. The male releases silken threads between successive copulations (Hajer *et al.* 2009, 2011). The females unwind these draglines, then roll them into a bundle which they ingest before copulating again. Hence this nuptial gift transfers nutrients from the male to the female. Barrows (1918) reported that this species can "always" be found among wet mosses on cliff faces and other wet situations in deep woods.

Figure 46. *Theridiosoma gemmosum* adult male on moss. Photo by Jørgen Lissner, with permission.

At least some members of the **Linyphiidae** are known to care for their young by providing food (Willey & Coyle 1992). On the other hand, they may eat their own eggs, at

least in captivity – a phenomenon that has rarely been reported for spiders and may not exist in nature. The even smaller size of the young may dictate the need for a more protective environment, *i.e.*, buffered against temperature and moisture fluctuations, during the "child-rearing" period of their lives.

Figure 47. *Theridiosoma gemmosum* egg cocoon. Photo by Jørgen Lissner, with permission.

Figure 48. *Hypnum cupressiforme*. Photo by David Holyoak, with permission.

Scotina celans (Figure 49; **Liocranidae**) lives in both mosses and detritus in woodlands, where it makes a funnel tube for its nest, lying in wait there for prey (Harvey *et al.* 2002). Females regurgitate food to feed the young.

Figure 49. *Scotina celans* (**Liocranidae**) on mosses. Photo by Morten D. D. Hansen, with permission.

Nests and Webs

Among the potential uses of bryophytes, some spiders may choose them as a nesting site. This can be a home for the adult who, in most families, lies in wait for its prey. The spider has a unique set of structures called **spinnerets** that produce the silken thread used for making the webs and nests (Figure 50). These webs can be funnels (Figure 51), 3-d structures (Figure 52), or the more commonly figured sheet structures (Figure 53) such as those seen in Halloween decorations. The common moss dwellers in the **Linyphiidae** make horizontal doily webs, sometimes covering large areas (Figure 54-Figure 55). **Frontinella**, (**Linyphiidae**) the bowl and doily spider, makes an upper bowl-shaped web and a lower, flattened web (Figure 56). The spider rests under the bowl (Figure 57), above the doily, to await prey. **Eresus sandaliatus** (Figure 58; **Eresidae**) is one of those that will at least at times use mosses as a location for its food web (Figure 59).

In the genus *Arctosa* (Figure 1; Arctosidae), these medium to large spiders make burrows in mosses, sand, detritus, or under stones (Figure 63) (Lissner 2011c). But some spiders do not make any sort of retreat (Lissner 2011c). The **Thomisidae** make no webs or retreats for any purpose.

Figure 63. *Arctosa cinerea* (Lycosidae) digging burrow, which members of the genus sometimes do among mosses. Photo copyright by Evan Jones, Spider Recording Scheme/British Arachnological Society (2012) Website and on-line database facility <<http://srs.britishspiders.org.uk>>.

Hahniidae live close to the ground and construct their small sheet webs among mosses as well as other areas that exhibit small depressions (Lissner 2011b). *Hahnina nava* (Figure 64), a sheet-web maker, places its nets in mosses and other low plant forms (Harvey *et al.* 2002). *Hahnina helveola* even makes its webs in pine needles, as well as leaf litter, mosses, and low plant forms.

On the southern Appalachian peaks, USA, the tiny size (3-4 mm) of the endangered spruce-fir moss spider *Microhexura montivaga* (Figure 65; Dipluridae) permits it to live in flattened tube webs under mosses and litter mats of the spruce-fir forests (Coyle 1985). *Microhexura montivaga*, the smallest of the tarantulas, was first discovered in North Carolina (USFWS 2012). It lives in high elevation remnants of Fraser fir and red spruce forests on shaded boulders exclusively within mats of damp, well-drained mosses and liverworts (Geatz 1994). Its 2-3 mm

size permits it to move easily among the branches. Springtails within the moss mats may serve as a primary food source (USFWS 2012). The spider is endangered because its spruce-fir habitat is being destroyed by the balsam woolly adelgid (Hemiptera) (Geatz 1994; Tarter & Nelson 1995; Smith & Nicholas 1998). This canopy destruction results in drying of the mosses, making them unsuitable for this spider.

Spiders that live above ground typically produce a security thread by which they can relocate to their webs. It would be interesting to see if this is done among bryophyte-dwelling spiders.

In some cases, the bryophyte seems to play an important role that cannot be served as well as the tracheophyte counterparts. This role is in helping to form the trap door of the trapdoor spiders (Moggridge 1873) including **Ctenizidae** and **Liphistiidae** (Wikipedia 2014) and the lesser known **Cytraucheniidae** (Eiseman & Charney 2010). *Cyclocosmia torreyi*, known primarily from Guatemala, Thailand, and China, builds burrows in moss banks along the Apalachicola River in Florida, USA (Wikipedia 2014). *Stasimopus mandelai* (Ctenizidae; see Figure 66), in the Eastern Cape Province of South Africa, makes its trap door of silk and soil with a very light covering of moss (Hendrixson & Bond 2004).

Figure 66. *Stasimopus robertsi* at the entrance of its burrow. Another spider in this genus, *S. mandelai* incorporates mosses in a trapdoor that covers its burrow. Fritz Geller-Grimm through Creative Commons.

Bits of bryophytes are often added to the door as camouflage (Cloudsley-Thompson 1989), but based on images on the web, growing mosses often comprise part of the lid and appear to help in holding the lid together (Figure 67-Figure 69). The spider hides beneath the lid, and when it sees a prey organism, it darts out from the protective lid to grab the prey. It would seem that a tracheophyte would be too heavy to serve as a network to hold this door together.

Dormant Stages

One might find a greater site selectivity for the immobile dormant or egg stages. For spiders whose cocoons are not incorporated into the web constructed for trapping prey, the web/feeding site may have very different characteristics from that of the oviposition site (Suter *et al.* 1987). Suter *et al.* (1987) examined the site selection of the linyphiid *Frontinella communis* (as *F. pyramitela*) (Figure 56, Figure 70-Figure 71). This species, as far as I know, does not typically use mosses, but the female deposits her eggs in a loosely woven cocoon on or near the soil, whereas many members of this family deposit their eggs aerially where the humidity is usually much lower. It appears that the *Frontinella communis* cocoon loses water at approximately double the rate lost by three common aerial species (*Achaeranea tepidariorum*, *Argyrodes trigonum*, and *Uloborus glomosus*). Fritz and Morse (1985) contend that selection of the oviposition site is "one of the most important decisions made" by organisms that deposit eggs externally. Hieber (1985) demonstrated this same importance in the cocoon-carrying *Argiope aurantia*, where the outer cocoon layer provides the air space that does most of the insulating.

Figure 70. *Frontinella communis* (Linyphiidae), a spider that deposits her eggs near the soil where water loss is less than at the aerial position of her food web. Here she is on the underside of the web. Photo by William DuPree, with permission.

Figure 71. *Frontinella communis* (Linyphiidae), the bowl and doily spider, on its web. This species makes a double web, hence its common name. Photo by Robert Klips, with permission.

Hence, we should look at moss-dwelling species for differences in the ability of their cocoons to maintain adequate moisture levels and to prevent excess moisture compared to aerial species. We know that *Hickmanapis minuta* (Anapidae) will attach its egg sacs to mosses (Hickman 1943). It is likely that a number of others do the same.

Overwintering

Spiders typically live only about two years, so it would not seem expedient for their overwintering strategy to be a strong evolutionary driver. Nevertheless, they must survive at least one winter, and strategies vary. In the **Thomisidae**, there seems to be no special overwintering structure – no web or burrow (Lissner 2011c).

But for some spiders, mosses are essential to winter survival. *Larinia jeskovi* (Araneidae), living among the sedge *Carex rostrata*, is rare in Europe (Kupryjanowicz 2003). It builds no winter retreat, but females overwinter in areas with a thick, loose layer of mosses. When the moss layer is absent, the abundance of this species is low. In peatlands, *Sitticus floricola* (Figure 72-Figure 73; Salticidae) overwinters deep in the *Sphagnum* (Harvey *et al.* 2002).

Spider Guilds

Root (1967) defined a guild as "a group of species that exploit the same class of environmental resources in a similar way." This uses terminology familiar from the niche concept, but confines members of a guild to a class of resources rather than all of them.

The concept of guild may be useful in describing the spider communities of bryophytes, but such a description has not yet been constructed. Cardoso *et al.* (2011) defined spider guilds in large scale view for the first time. They used foraging strategy (type of web and method of active hunting), prey range (narrow or wide diversity), vertical stratification (ground or vegetation) and circadian activity (diurnal or nocturnal). This resulted in eight guilds, based on feeding strategy: (1) sensing weavers; (2) sheet weavers; (3) space weavers; (4) orb web weavers; (5) specialists; (6) ambush; (7) ground; and (8) other hunters. Using this classification, Cardoso and coworkers found that the correlation of guild richness or abundances was generally higher than the correlation of family richness or abundances. Nevertheless, guilds tended to include related species because among spiders the web-building strategy and form of the feeding apparatus are the basis of higher classification. Therefore, it is not surprising that families serve as good surrogates, forming similar groupings.

If we attempt to describe the predominant spider guilds among bryophytes, it might provide a framework for examining the habitats where they live. Certainly the **ground-hunting guild** is common on the surface of bryophytes in bogs and open habitats such as sand dunes and grasslands or meadows. Cardoso *et al.* (2011) found that **ground hunters** formed the largest guild (number of families) worldwide. The **sheet-weavers** and **other hunters**, including the **Linyphiidae**, are predominant among bryophytes in most habitats. Surprisingly, the **ground hunters** have the largest family representation among the bryophytes, but the number of species is not large, and representation differs with habitat. Each of the guilds is represented by one or more families among the bryophytes:

Sensing web: Atypidae

Sheet web: Amaurobiidae, Dipluridae, Eresidae, Hahniidae, Linyphiidae (Linyphiinae, Micronetinae)

Space web: Dictynidae (Dictyninae),
Micropholcommatidae
Orb web: Anapidae, Araneidae, Symphytognathidae
Specialist: Mimetidae
Ground hunters: Corinnidae, Gnaphosidae,
Lio cranidae, Lycosidae, Zoridae
Other hunters: Clubionidae, Linyphiidae (Erigoninae),
Philodromidae, Salticidae
Ambush hunters: Thomisidae

I have omitted the **Cybaeidae** because the one species (*Argyroneta aquatica*) reported herein uses an underwater nest and darts out to catch prey, not catching them with a web as used for the guild classification.

Adaptations to Bryophytes

For spiders, living among bryophytes seems to be mostly an advantage for the spiders, not the bryophytes. The provision of cover and moisture by the bryophyte is complemented by providing avoidance of larger predators. Loss of water would result in loss of hydrostatic pressure in the legs, making it impossible to extend their legs, hence making them unable to escape. The moisture within a moss mat should therefore make mobility easier than in a drier location.

In other groups of animals, color patterns have presented good adaptations. There seems to be little discussion of this as an adaptation for bryophyte-living, and certainly green spiders are rare. However, coloring of spiders is often disruptive, as seen for *Sitticus floricola* (Figure 72-Figure 73; **Salticidae**) and the disruptive pattern of the spider in Figure 74.

But to live among bryophytes can be somewhat demanding on the construction of the spider. Bryophytes do not provide an easy landscape for navigation for larger spiders. Within the protective cover, jumping is usually not an option. The higher moisture content could save energy that might be needed to provide a thicker cuticle for spiders living in drier habitats. But being small is an important adaptation, permitting easy navigation and being compensated by the higher moisture levels available. The moss furthermore buffers the rain so that it does not easily dislodge the spider, and spiders are able to move about sufficiently to avoid drowning in areas of water collection such as leaf bases.

Figure 74. This spider blends well as it traverses the moss *Didymodon cordatus* in Europe. Photo by Michael Lüth, with permission.

Several families stand out among bryophyte dwellers. The one with the greatest number of bryophyte-dwelling species is the **Linyphiidae**, a family of spiders generally less than 2 mm long. Bryophyte-dwelling spiders are also found within many other spider families, especially including the **Gnaphosidae** (ground spiders), **Clubionidae** (foliage spiders), and **Theridiidae** (comb-footed spiders), some of which are considerably larger. In New Zealand, the **Micropholcommatidae** have a number of bryophyte-dwelling species.

Anapidae

The **Anapidae** are orb weavers, often with webs less than 3 cm. Given the small size (mostly less than 2 mm) and habits (Wikipedia 2010a) of this family, we should look for heretofore unknown species among the bryophytes. Kropf (1997) has shown that one member, *Comaroma simoni* (Figure 75), a member of the **Anapidae**, is born without a hardened covering, a characteristic that likely applies to other species as well. Such species are thus subject to greater desiccation than adults (Kropf 1997), a problem that could be ameliorated by bryophytes. Nonetheless, this species is a soil dweller in Austria and in the scree areas of mountains in Europe, it occurs exclusively in association with bare rock (Růžicka & Klimeš 2005). Kropf suggests that in the beech (*Fagus sylvatica*) forests of Austria this species most likely undergoes vertical migration to reach the best moisture and temperature conditions. In many habitats, such behavior could make the bryophyte an important part of a daily and seasonal cycle for some taxa, even if only to increase the soil moisture.

The **Anapidae** live primarily in tropical rainforests of New Zealand, Australia, and Africa, with scattered occurrences on other continents, where bryophytes (and leaf litter) commonly provide them a home on the ground (Wikipedia 2013). *Pseudanapis aloha* (**Anapidae**), is known from mosses in the mountains of Hawaii, USA.

Figure 75. *Comaroma simoni*. Photo ©Pierre Oger, with permission.

Clubionidae (Sac or Tube Spiders)

These spiders make tubes where they hang out during the day. These tubes are located under stones, loose bark, between moss, and between leaves. At night they are hunters. On Mount Kilimanjaro, Denis (1950) found the 12 mm *Clubiona abbajensis kibonotensis* under moss [(see *C. reclusa* (Figure 76-Figure 78) and *C. pallida* (Figure 79)].

Figure 79. *Clubiona pallidula*, a generic relative of *Clubiona abbajensis kibonotensis* that lives under mosses on Mount Kilimanjaro. Photo by Trevor and Dilys Pendleton <www.eakringbirds.com>, with permission.

Gnaphosidae (Ground Spiders)

The **Gnaphosidae** (Figure 80) form a worldwide family with over 2000 species (Wikipedia 2012c). They do not construct a web for capturing prey, but instead are night-active hunters. They spend the daylight hours in a silken retreat. The females guard their thick-walled eggs until the spiderlings hatch.

Figure 80. *Gnaphosa muscorum* (Gnaphosidae) on leaf. Photo by Tom Murray, with permission.

Linyphiidae (Sheet Spiders)

If any family may be considered adapted to living among bryophytes, it is the **Linyphiidae**. This is the largest family of spiders [more than 4,300 described species in 578 genera worldwide (Wikipedia 2012b)], so it is not surprising that its species comprise the majority of bryophyte dwellers. Their tiny size (1-10 mm) makes them difficult to find and identify. Hence, there are likely many more species than those already described.

The shape of the **Linyphiidae** is somewhat different from that in many other spider families. The thorax is reduced relative to the abdomen, and the abdomen is humped or globular, making it the conspicuous part of the spider (Figure 81). Is this an adaptation that permits a relatively large amount of the body to be available for

reproduction while making a smaller size possible for the animal overall?

Figure 81. *Linyphia triangularis* showing body shape. Photo by James K. Lindsey, with permission.

Linyphiidae build sheet or dome-shaped webs (Figure 82), hence the common names of sheet weavers or sheet spiders, with no retreat, and spend their time hanging upside down on the underside of the sheet (Nieuwenhuys 2010). Flying insects become ensnared by the web and fall to its lowest point where the awaiting spider bites it through the net (Lissner 2011c). In Jutland, Denmark, the female shadow hammock spider, *Labulla thoracica* (Figure 83), is known to weave her web under a moss mat (Hormiga & Scharff 2005).

Figure 82. Horizontal webs at Shiretoko Goko, Japan, such as those manufactured by members of the **Linyphiidae**. Photos by Janice Glime.

Figure 83. *Labulla thoracica*, a spider that weaves webs beneath moss mats. Photo by Ondřej Machač, with permission.

Dispersal in the **Linyphiidae** is often accomplished by **ballooning**, a phenomenon in which the spider ascends to something taller, like a fence, points the spinnerets upward, then secretes a thread (Pratt 1935; Lissner 2011c). It jumps or is blown with the thread serving as an anchor. On a good wind, it can accomplish a greater distance. For these small spiders, this is more than could be accomplished by walking, and the thread provides an anchor so that they don't get too far from their current suitable habitat. It is a lot like bungee jumping, except a lot of their travel is horizontal. These spent bungee cords can actually be noticeable when many spiders balloon in a short period of time, as may occur in late summer. Individuals will also keep trying if they are unsuccessful in travelling very far, contributing to the accumulation of threads on the ground.

Within the **Linyphiidae**, the subfamily **Erigoninae** is a group of small spiders that are mostly less than 3 mm long. In some members of *Walckenaeria*, including a number of moss dwellers, eyes of males are located on a pedestal or turret (Figure 84-Figure 85), creating a periscope. But this would-be periscope provides little visual contribution. Rather, it serves a sexual function, possibly secreting sexual pheromones (Millidge 1983). There is some evidence that the female grabs it during courtship or mating, as known in the linyphiid *Hypomma bituberculatum*.

Figure 84. *Walckenaeria acuminata* male on a moss, showing the stalk that houses the eyes. Photo by Jørgen Lissner, with permission.

Figure 85. *Walckenaeria cucullata* male on moss, providing a front view of the stalk with eyes. Photo by Jørgen Lissner, with permission.

Lycosidae (Wolf Spiders)

Contrasting with these small species, the larger *Pardosa maisa*, a wolf spider (cf. Figure 86), lives in a poor pine fen where there is a "rich" *Sphagnum* layer (Itaemies & Jarva 1983). Peatlands and mires have their unique fauna of spiders (Vilbaste 1981). Villepoux (1990) found that ground-level spiders in a French peat bog formed several representative groups, each helping to define a biotope. In fact, he felt that only a few species of spiders were sufficient to estimate the diversity of the plant communities in this habitat. In bog and fen habitats, several members of this family are dominant, running about on the surface rather than within the mat, and no doubt taking advantage of the moist mosses to retain their moisture in the drying rays of the sun. Other sunny habitats for moss inhabitants of this family include the open tundra (Dondale *et al.* 1997), sand dunes (Merkens 2000), and as invaders after fires (Larrivée *et al.* 2005).

Figure 86. *Pardosa amentata* female with egg sac, a wolf spider related to the *Sphagnum* spider *P. maisa*. Photo by James K. Lindsey, through Wikimedia Commons.

Symphytognathidae and Micropholcommatidae

The family includes some very small spiders, some of which are known moss-dwellers. The Samoan moss spider

(*Patu marplei*; **Symphytognathidae**) is often considered to be the world's smallest spider (Alphonse 2010), having a leg span of only 0.5 mm (King 2004). However, in other members of this genus only the female is known. Since the male is typically smaller, it is possible that other species may be smaller, in particular *Patu digua* (Wikipedia 2010c) that is often designated as the smallest. *Patu marplei* is known from mosses in New Zealand (Forster 1959). The family **Micropholcommatidae** is a segregate of **Symphytognathidae** and includes *Textricella* a genus with a number of known moss dwellers. *Textricella nigra* (**Micropholcommatidae**) is known from moss on tree trunks at 1000 m asl and the type is known from moss, both in New Zealand; *T. propinqua*, *T. pusilla*, *T. salmoni*, *T. scuta*, *T. signata*, *T. tropica*, *T. vulgaris* (many records), *Micropholcomma bryophilum*, *Parapua punctata*, *Pua novaezealandiae*, *Zealanapis australis* (as *Chasmocephalon armatum*), all members of **Micropholcommatidae**, occur among mosses in New Zealand. *Patu woodwardi* (as *Mismena woodwardi*; **Symphytognathidae**) from New Guinea and *Textricella hickmani* and *T. parva* from Tasmania are known from mosses.

Theridiidae (Tangle-web Spiders, Cobweb Spiders, and Comb-footed Spiders)

This family (Figure 87) is likewise among the larger families with over 2200 species (Wikipedia 2012d). The females often build a tangle web (3-d) instead of a simpler sheet. Their web construction uses a sticky silk to capture prey instead of the more common woolly silk. Many other theridiids trap ants and other ground-dwelling insects with their elastic sticky silk trap lines that lead to the soil surface. It would be worth searching for these traplines among bryophytes. The family includes the well-known widow spiders. The largest genus is *Theridion*, which includes some members among mosses (Logunov *et al.* 1998).

Figure 87. *Robertus pumilus*, member of a genus in which some members inhabit bryophytes. Photo by Tom Murray, through Creative Commons.

Summary

Spiders are in the subphylum **Chelicerata**, Class **Arachnida**, Order **Araneae**. Spiders have eight legs attached ventrally to the **cephalothorax**. Some occur on the surface of moss beds where mosses provide moisture, but others live within moss beds and cushions. Because of their tiny size and habit of living within moss mats or cushions, some, perhaps many, spiders never go near pitfall traps commonly used for collecting. More diversity is likely if one uses a combination of pitfall traps, light traps, soil sifters (sieving), and hand collections. Because of widespread use of only pitfall traps, our knowledge of bryophyte-dwelling spiders most likely underestimates the importance of the bryophyte habitat for diversity. Spiders considered rare are likely to occur among bryophytes, in part due to inadequate sampling, and in other cases due to rarity of a particular habitat.

The growth form of bryophytes may play a role in the choice of habitat, but no study specifically tests this hypothesis, although different spider communities have been found on different growth forms. Small members of **Linyphiidae** have the most moss-dwelling species in most habitats, with **Lycosidae** having more biomass in open habitats of bogs, tundra, dunes, and sites after fire.

Spiders are susceptible to water loss and may use bryophytes as a moist retreat as well as a hideaway from predators. The bryophyte cover also protects them from the heat and UV rays of the sun, with higher temperatures causing a greater water loss. Bryophytes serve as sites for reproduction, nests, and food webs. Some spiders use mosses as a winter refuge. Spiders will locate their nests to optimize temperature, thus optimizing energy gain.

Spiders use claws with fangs to inject venom into their prey. Some use webs to trap and others hunt their prey. Spiders are carnivores and most likely never eat bryophytes. However, bryophytes can serve as a source of food by harboring food organisms, including other spiders, insects (esp Collembola), and earthworms.

The most common spider families to be found associated with bryophytes are Anapidae, Clubionidae (sac or tube spiders), Gnaphosidae (ground spiders), Linyphiidae (sheet spiders), Lycosidae (wolf spiders), Symphytognathidae, Micropholcomatidae, Theridiidae (tangle-web spiders, cobweb spiders, and comb-footed spiders). All eight spider guilds are present among mosses. The adaptations of spiders to living among bryophytes may include disruptive coloration and small size, with maneuverability limiting larger spiders. Bryophytes are the sites for webs of some species and for placing eggs for others. They provide buffered temperature and humidity locations for dormant stages, including overwintering. Some members of the **Linyphiidae**, the most species-rich family among bryophytes, care for their young by providing food, but most young spiderlings are on their own.

Dispersal in large spiders is typically accomplished by running, but in the tiny **Linyphiidae**, ballooning and bungee jumping can help them to get to greater distances than is feasible for their tiny legs.

Acknowledgments

My gratitude goes to numerous arachnologists who contributed information and many images that helped to make this chapter more interesting. My co-author for parts of this chapter, Jörgen Lissner, actually collected data and took numerous photographs to help make this chapter more complete. Then he served as a reviewer for this sub-chapter as well as the other spider sub-chapters. Thank you to Jorge Cuvertino for sending me the web address of the reference that verified *Patu marplei* as a moss dweller. I appreciate all those photographers who have placed their images in the public domain, saving me time in illustrating the spiders. I will be forever grateful to the scientific community for being so willing to share and to all the members of Bryonet who forebear my frequent questions and requests.

CHAPTER 7-3

ARTHROPODS: ARACHNIDA -

SPIDER HABITATS

Figure 1. *Gnaphosa nigerrima* (Gnaphosidae) male on moss. Photo by Jørgen Lissner, with permission.

Habitats

Although the smallest spiders are somewhat common among bryophytes, this habitat is one that has not been studied extensively. Because these small spiders are not very mobile, they are often missed by pitfall traps, and even those that do fall into the traps cannot be specifically associated with the bryophytes. It is likely that in most habitats one can find new or rare spider species among the bryophytes.

Pommeresche (2002) used pitfall traps to examine spiders in fifty different sites in the Geitaknottane Nature Reserve in western Norway, including open forests, shady pine forests, humid deciduous forests, and dry deciduous forests. He found a good correlation between the spider communities and the plant communities. The bog and forest habitats of the Nature Reserve had a number of species varying from 21 to 51 per site. They identified five groups of spider communities on the reserve: wet, open areas; open forests; shady pine forests; humid deciduous

forests. The communities correlated well with vegetation, having significant correlations with productivity of wood, soil humidity, tree cover, bush cover, and heat index. As will be seen later, vegetation type is likewise important in determining the spider fauna of bogs and fens (subchapters 7-3, 7-4).

Oliger (2004) used studies from northwest Russia to assert that species such as *Arctosa alpigena* (as *Tricca alpigena*; Lycosidae; Figure 2), *Antistea elegans* (Hahniidae; Figure 3), and *Gnaphosa nigerrima* (Gnaphosidae; Figure 1, Figure 4) were common in bogs but rare in forests, whereas *Agroeca brunnea* (Liocranidae; Figure 5; a leaf litter species), *Hygrolycosa rubrofasciata* (Lycosidae; Figure 6), *Pirata hygrophilus* (Lycosidae; Figure 7), *Trochosa spinipalpis* (Lycosidae; Figure 8), and *T. terricola* (Figure 127) were 5-10 times more abundant in forests than in bogs. Nevertheless, *Trochosa spinipalpis* occurs almost exclusively in bogs in

Great Britain (Boyce 2004) and Pommeresche (2002) reported *T. terricola* to be among the five most active spiders in the bog at Geitaknottane Nature Reserve, western Norway. Clearly the relationships of spiders to habitat are complex. Hence, we might expect the presence of bryophytes to make a difference in the spider diversity of the ecosystem and their presence or absence might influence the type of spider fauna there.

On the other hand, Graves and Graves (1969) found that the spiders collected from mosses and other substrata on the forest floor in a high-rainfall area at 1300 m in the southern Appalachian Mountains, USA, were mostly generalists, occupying several types of humid forest microcommunities. Habitat specificity seems to be lacking for many of the bryophyte dwellers.

Forests, Heaths, and Meadows in Denmark (observations by Jørgen Lissner)

Bryophytes have adapted to nearly all types of habitats and apart from forming the dominant ground cover in bogs, they are also often dominant (at least locally) in forests, heaths, and meadows. Coniferous forests frequently possess a thick layer of bryophytes on the forest floor as well as on stems and branches of bushes and trees. Some moss species are acting as pioneer plants on heaths, such as the invasive moss *Campylopus introflexus* (Figure 9), which may increase significantly after burning or other management practices that expose raw humus. Other moss species such as *Hypnum cupressiforme* (Figure 10) may increase in abundance as the heath grows older and provides shadier and moister conditions suitable for the moss underneath the heather. Mosses may also serve as habitat for spiders in wet heathland and various types of grassland, including unimproved grasslands, e.g. *Molinia* meadows on calcareous, peaty or clayey-silt-laden soils. Even cultivated lawns may have a dense coverage of mosses such as *Brachythecium rutabulum* (Figure 11) and *Rhytidiadelphus squarrosus* (Figure 12).

Figure 11. *Brachythecium rutabulum* in Europe. Photo by Michael Lüth, with permission.

Figure 12. *Rhytidiadelphus squarrosus* in Europe. Photo by Michael Lüth, with permission.

Just a few samples of spiders inhabiting mosses in these habitats are shown here. *Haplodrassus moderatus* (Figure 13; **Gnaphosidae**) uses mosses as hiding places during the day and perhaps also hunts its prey among mosses during the night. *Gnaphosa leporina* (Figure 14-Figure 15; **Gnaphosidae**) is frequent on wet heathland whereas *Scotina celans* (Figure 16; **Liocranidae**) is sometimes found in mosses of dry heathland. *Scotina*

celans also lives in both mosses and detritus in woodlands, where it makes a funnel tube for its nest. *Asthenargus paganus* (Figure 17; **Linyphiidae**) is found rather rarely among mosses of moist open coniferous forest. Arne Grabolle (pers. Comm. 1 November 2012) told me of finding this species deep within mosses in Germany. *Agyneta ramosa* (Figure 19; **Linyphiidae**) has been recorded from a variety of habitats, often from mosses. *Ceratinella brevipes* (Figure 20; **Linyphiidae**) and its close relative *Ceratinella brevis* (Figure 21) are found in a wide array of habitats, including wet woodland with *Sphagnum* (Figure 45) and various types of grasslands and meadows.

Figure 13. The nocturnal ground spider, *Haplodrassus moderatus* (7 mm; **Gnaphosidae**), has been recorded from a range of damp habitats, ranging from moist meadows and fairly dry *Sphagnum* bogs, such as degraded raised bogs. Photo by Jørgen Lissner, with permission.

Figure 14. The ground spider, *Gnaphosa leporina* (8 mm; **Gnaphosidae**), shown here on the invasive moss *Campylopus introflexus*, is common in damp heathlands of Northern Europe. During the daytime this nocturnal species can be found in cracks and cavities underneath *Campylopus introflexus* mats, an introduced and invasive moss that has now become widely distributed in heathland and dunes in many parts of Europe. Photo by Jørgen Lissner, with permission.

Figure 15. *Gnaphosa leporina* (**Gnaphosidae**) submale on mosses. Photo by Jørgen Lissner, with permission.

Figure 16. *Scotina celans* belongs to the spider family **Liocranidae** (spiny-legged sac spiders). The female shown here measures ca 4.5 mm. Specimens may be found by sifting dense mats of *Hypnum cupressiforme/jutlandicum* moss on *Calluna* heathland, but it may also be found among leaf litter. Photo by Jørgen Lissner, with permission.

Figure 17. The Palearctic line-weaving spider, *Asthenargus paganus* (1.6 mm; **Linyphiidae**), is sometimes found rather abundantly in dense mats of red-stemmed feather moss (*Pleurozium schreberi*, Figure 18). This moss is very common in the ground layer of moist, open coniferous forest of Northern Europe, such as in the transition zones between forests and wet heathland. Photo by Rudolf Macek, with permission.

Figure 18. *Pleurozium schreberi*. Photo by John Hribljan, with permission.

Figure 19. *Agyneta ramosa* (Linyphiidae), here a male measuring 2.2 mm. This Palearctic species is mainly found in mosses of damp areas such as deciduous woodland and among leaf litter and mosses in forested edges of raised bogs. Photo by Jørgen Lissner, with permission.

Figure 20. *Ceratinella brevipes* (Linyphiidae) on moss. Photo by Jørgen Lissner, with permission.

Figure 21. *Ceratinella brevis* is a small species of the line-weaving spiders (Linyphiidae) with rather short legs and globular, coriaceous abdomen. The female shown here measures slightly less than 2 mm. It occurs in similar situations to those of the smaller congener, *Ceratinella brevipes* (Figure 20). Both species may be collected from mosses in a wide array of habitats. Photo by Jørgen Lissner, with permission.

Forests and Woodlands

Often we learn about organisms and their reliance on microhabitat features following a disturbance by examining what has disappeared and what correlates with that disappearance. Huber *et al.* (2007) did just that following clear-cutting of a Norway spruce forest (*Picea abies*) in Germany. They found that the control, uncut forest, spider fauna was dominated by one species, *Coelotes terrestris* (49% of the spider fauna) (Figure 22-Figure 23; Amaurobiidae), a species noted by Sereda *et al.* (2012) to be positively related to moss cover and negatively related to litter cover on the forest floor. They did not demonstrate what this relationship entailed, so it could be a matter of both preferring similar environmental conditions. In Denmark *C. terrestris* (8-15 mm) is found under large, rotten wood in very dark, moist places, but this primarily woodland species sometimes also occurs in mossy banks (Harvey *et al.* 2002; Nieuwenhuys 2011).

Figure 22. *Coelotes terrestris* (Amaurobiidae), a forest species that correlates positively with moss cover. Photo by Ed Nieuwenhuys, with permission.

Figure 23. *Coelotes terrestris* retreat among mosses and litter. Photo by James K. Lindsey, with permission.

During the two years following cutting, the families **Linyphiidae**, **Amaurobiidae**, **Agelenidae**, and **Clubionidae** all decreased drastically (Huber *et al.* 2007). These were replaced by the wolf spider family, the **Lycosidae** – large spiders that hunt their food. The disappearing species were characterized by those that were small (<3.0 mm) and large (>10.5) web builders with a preference for hygrophilic to medium moisture. These disappearing species typically live below ground or associated with the moss layer. As expected, the spiders that prefer open habitat increased in number. Huber and co-workers specifically pointed out that individuals that preferred a humus layer with mosses decreased. They interpreted this decrease to be the result of a higher light intensity.

On the other hand, some forest spiders seem to avoid bryophytes. Sereda *et al.* (2012) found that *Tenuiphantes zimmermanni* (Figure 24; **Linyphiidae**), a spider known from mosses elsewhere (Holm 1980), and *Tapinocyba insecta* (Figure 25; **Linyphiidae**) were negatively related to cover of mosses on the forest floor in a *Fagus sylvatica* forest in Europe, whereas Arne Grabolle (pers. comm. 1 November 2012) found *Tapinocyba pallens* (Figure 26) deep among mosses in Germany. *Tapinocyba insecta* was also negatively correlated with availability of prey, which could account for its negative correlation with mosses. Sereda and coworkers concluded that a patchy habitat was important in increasing the diversity of spiders on the forest floor.

Figure 24. *Tenuiphantes zimmermanni* female. Photo by Jørgen Lissner, with permission.

Figure 25. *Tapinocyba insecta* (**Linyphiidae**) female. This species is negatively correlated with bryophytes in a *Fagus sylvatica* forest. Photo by Jørgen Lissner, with permission.

Figure 26. *Tapinocyba pallens* male, a species that may occur deep within mosses. Photo by Jørgen Lissner, with permission.

By comparing interiors and edges of old-growth forest and managed forests in southern Finland, Pajunen *et al.* (1995) were able to describe some of the specific habitats of spiders. They concluded that there were no habitat specialists among these forest species, with no species being strictly an old-growth species. Rather, differences in tree canopy cover accounted for differences in species assemblages. The **Lycosidae** (wolf spiders – hunters) and **Gnaphosidae** benefitted from clear-cutting, whereas small species, especially **Linyphiidae**, decreased from the greater exposure in plantations and open forests.

Nevertheless, a few species may be moss specialists. Jackson (1906) reported two members of **Theridiidae** [*Theonoe minutissima* (as *Onesinda minutissima*; Figure 27), *Robertus neglectus*] and three of **Linyphiidae** [*Palliduphantes pallidus* (as *Lepthyphantes pallidus*; Figure 28), and *Saaristoa firma* (as *Tmeticus firmus*; Figure 29) as species of mosses in woods of the Tyne Valley, but mentioned no other habitat for them. *Minyriolus pusillus* (Figure 30; **Linyphiidae**) only seemed to occur among mosses in damp woods.

Figure 27. *Theonoe minutissima* (Linyphiidae). Photo by Jørgen Lissner, with permission.

Figure 29. *Saaristoa firma* (Linyphiidae) on moss. Photo by Arno Grabolle <www.arnograbolle.de>, with permission.

Among the moss-dwelling spiders in Yukon forests, Dondale *et al.* (1997) found *Hackmania prominula* (Dictynidae) in moss and litter in coniferous woods. This family is seldom recorded from mosses, but is known from tundra mosses (Koponen 1992; Logunov *et al.* 1998).

Atypidae

The **Atypidae** is not typically a moss-dwelling family. Nevertheless, when Jonsson (1998) used a sieving technique to distinguish the actual locations of the spiders in the Skärålid Gorge, southern Sweden, a forested location with a microclimate affected by the gorge, he found that mosses could be used by this spider. He found *Atypus affinis* (Figure 31) in its tube beneath the soil with its opening extending into the leaf litter, soil, stones, and mosses of the gorge. However, in British heathland this species tends to avoid soil covered by mosses (Dallas 1938) and it is not usually considered a bryophyte dweller elsewhere. Hence, it appears that some spiders, such as this one, are facultative bryophyte dwellers.

Figure 31. *Atypus affinis* (Atypidae) male exoskeleton; the insides have been eaten by a female of the species. Photo by Jørgen Lissner, with permission.

Clubionidae (Sac Spiders)

The sac spiders (**Clubionidae**) are represented by only one genus among the forest mosses. *Clubiona lutescens* (Figure 32) lives in a broad range of habitats and has been collected from mosses and litter of woodlands in the UK (Crocker & Daws 1996).

Figure 32. *Clubiona lutescens* on moss. Photo by Ed Nieuwenhuys, with permission.

Gnaphosidae (Ground Spiders)

This family has a wide range of sizes, as small as 3 mm and as large as 16 mm or more. Of the 2000 species, few are known from mosses. Two **Gnaphosidae** occurred among forest mosses at the Lesni Lom Quarry (Hula & Šťastná 2010). *Micaria pulicaria* (Figure 33), another non-specialist of warm, dry places, occurred among both grass and mosses in more open habitats of forest edges, clearings, and mountain corries (cirques). *Zelotes clivicola* (Figure 34), another abundant spider, can be found in pine and birch forests under stones and among mosses at the quarry. In the Arctic Yukon, Dondale *et al.* (1997) found *Gnaphosa microps* (Figure 35) in litter and moss in coniferous woods.

Figure 33. *Micaria pulicaria* (**Gnaphosidae**), one of the ant mimics. Photo by Arno Grabolle <www.arnograbolle.de>, with permission.

Figure 35. *Gnaphosa microps* (**Gnaphosidae**). Photo by Glenn Halvor Morka, with permission.

Hahniidae (Dwarf Sheet Spiders)

The **Hahniidae**, a family of small spiders of about 2 mm, also can be found among woodland mosses. *Hahn timer helveola* (Figure 36) builds its webs in mosses in woodlands and a variety of other UK habitats (Harvey *et al.* 2002). It lives at the roots of conifers, among needles, or concealed among the mosses, whereas *Hahn timer montana* (Figure 37) lives among dead leaves and mosses (Jackson 1906;), where it also lives in the mountain forests of Tatra National Park, southern Poland (Svatoň & Kovalčík 2006); it places its small sheet web close to the ground among the mosses or under stones. *Hahn timer ononidum* (as *H. H. mengei*) (Figure 38) occurred in association with *Vaccinium myrtillus*, *V. vitis-idaea*, and *Empetrum* sp. in a range of 100-400 m asl in Norway and used the cover of leaf litter as well as mosses (Hauge 1969). This species was active in Norway for the relatively long period of May to September.

Figure 39. *Cryphoea silvicola* (Hahniidae) on bark. Photo by Rudolf Macek, with permission.

Figure 37. *Hahnia montana* (Hahniidae). Photo by Jørgen Lissner, with permission.

In the Czech Republic, *Cryphoea silvicola* (Figure 39; Hahniidae) lives in forest litter, mosses, and stone rubble, but it mainly occurs on lichens on tree bark (Szymkowiak & Górski 2004). We might find it among epiphytic bryophytes there as well.

Figure 38. *Hahnia ononidum* (Hahniidae) female. Photo by Glenn Halvor Morka, with permission.

Linyphiidae

There are several subfamilies common among mosses in the species-rich Linyphiidae: **Erigoninae**, **Linyphiinae**, and **Micronetinae**. In the moist older forests, Huhta (1971) found that the typically smaller **Erigoninae** spiders occupied deeper positions in smaller cavities among mosses and humus than the somewhat larger **Linyphiinae** spiders.

The **Linyphiidae**, the largest spider family with moss-dwelling members, enjoys large numbers in moist, closed forests, especially where there is a well-developed cover of the moss *Dicranum majus* (Figure 40) (Pajunen *et al.* 1995). They also found that the smaller members in the subfamily **Erigoninae** are able to penetrate the smaller cavities deeper in the moss layer, the primary home of this subfamily. Small spiders such as **Linyphiidae** are able to attach their webs between the stems of mosses. The well-established mosses in older forests provide suitable websites for linyphiid species such as those of *Lepthyphantes* (possibly now in *Palliduphantes*) and *Macrargus rufus* (Figure 41). As the canopy declines, larger (medium-sized) members of the **Linyphiidae** are able to take advantage of the improved growth of mosses. *Porrhomma convexum* (Figure 42) is a widespread linyphiid spider that commonly occurs in moss and in ground vegetation in woods (Agnarsson 1996).

Figure 41. *Macrargus rufus* (Linyphiidae) male on moss. Photo by James K. Lindsey, with permission.

Figure 42. *Porrhomma convexum* (Linyphiidae). Photo by Tom Murray, with permission.

In the Finnish forest study on spiders of the mosses *Polytrichum* (Figure 43-Figure 44) and *Sphagnum* (Figure 45), the **Linyphiidae** had the most species represented – far more than any other family (Biström & Pajunen 1989). Because of the large number of species in this family, and the small size of most members of the family, this high representation is predictable.

Figure 43. *Polytrichum* in bog at Azuma Yama, Japan. Photo by Janice Glime.

Figure 44. *Polytrichum strictum* cushion. Photo by Michael Lüth, with permission.

Figure 45. *Sphagnum* sp. in birch-hemlock forest, Michigan, USA. Photo by Janice Glime.

Several **Linyphiidae** were typical of both leaf litter and mosses in the Tyne Valley woodlands: *Microneta viaria* (Figure 46; more typical of dry leaves and sandy places where it escapes some predators by mimicking ants), *Porrhomma cambridgei* (as *Porrhomma oblongum*), *Centromerus dilutus* (as *Sintula diluta*), and *Tapinocyba praecox* (Figure 47). Several other species of Linyphiidae were present among both mosses and grasses in woodlands there: *Dicymbium tibiale* (damp areas; Figure 48), *Micrargus herbigradus* (as *Lophomma herbigradum*; Figure 49), and *Agyneta cauta* (as *Microneta cauta*).

Figure 46. *Microneta viaria* (Linyphiidae) male. Photo by Glenn Halvor Morka, with permission.

Figure 49. *Micrargus herbigradus* (Linyphiidae) male on moss. Photo by Jørgen Lissner, with permission.

Figure 48. *Dicymbium tibiale* male on bryophytes. Photo by Jørgen Lissner, with permission.

Figure 50. *Diplocentria rectangulata* female. Photo by Glenn Halvor Morka, with permission.

Maelfait *et al.* (1990) found *Eriogonella hiemalis* and *Minyriolus pusillus* in wet woodlands where they were associated with a well-developed moss layer. They were abundant in wet Douglas fir (*Pseudotsuga menziesii*) stands.

In a study in Norway, Hauge (1969) found several linyphiid spiders that seemed to prefer mosses. The small (ca 1.38 mm) *Diplocentria rectangulata* (as *Microcentria pusilla*; Figure 50; Linyphiidae) occurred June – September, when it was "very abundant" in mosses, occurring only in mosses and in association with *Vaccinium myrtillus*, *V. vitis-idaea*, and *Empetrum* sp. as the dominant plants in the birch forests at 150-350 m asl. *Macrargus multesimus* occurred as ground dwellers in mosses and among dead leaves in birch forests at 150-300 m asl.

The small (<2 mm) *Lepthyphantes antroniensis* (as *L. exiguus*) seemed somewhat seasonal in Norway, appearing in collections June – September 1967 and June – August 1968 (Hauge 1969). It likewise occurred in mosses and

among dead leaves on the forest floor of birch at 150-250 m asl. The somewhat larger (ca 4 mm) *Tmeticus nigriceps* (as *Gongylidium nigriceps*; **Linyphiidae**) occurred at lower elevations (10-200 m asl) and was likewise collected in the summer months of June – August in mosses and among dead leaves in the birch forest. Hauge (1976) reported three new species of spiders in Norway. One of these, *Meioneta saxatilis* (**Linyphiidae**), occurred in moss cover in mixed deciduous and pine forests. Arne Grabolle (pers. comm. 1 November 2012) often finds *Meioneta mossica* (Figure 51) deep within mosses in Germany.

Figure 51. *Meioneta mossica*, a deep moss dweller in Germany. Photo by Marko Mutanen, University of Oulu, through Creative Commons.

A large number of species of the linyphiid genus *Walckenaeria* are known from mosses in a variety of habitats, and the forest is no exception. *Walckenaeria cuspidata* (Figure 52) occurs among mosses in a wide range of habitats, including woods (Harvey *et al.* 2002). Jackson (1906) found *W. cuspidata* (as *Cornicularia cuspidata*; Figure 52) not only among mosses and grass in woods, but also in fields and marshes in the Tyne Valley of northern England. Jackson listed *Walckenaeria dysderoides* (as *Wideria fugax*; Figure 53) from mosses, but no habitat was given. *Walckenaeria dysderoides* (Figure 53) likewise was abundant in moss and detritus at the Lesni Lom Quarry in the Czech Republic, where it preferred humid habitats (Hula & Štátná 2010).

However, in Flanders, Belgium, *W. dysderoides* was rare in forested sites, but occurred in well-developed moss carpets (Maelfait *et al.* 1990). *Walckenaeria nodosa* (Figure 54) seems to have a smaller range of habitats, but lives among mosses in woods (Harvey *et al.* 2002). In the Tyne Valley, UK, Jackson (1906) found *W. obtusa* (Figure 55) only from mosses, but Harvey *et al.* (2002) reported *W. obtusa* from mosses and grass in broad-leaved forests of the UK (Harvey *et al.* 2002). In addition to these UK species, Millidge (1983) reported species from Arctic and North American forested sites: *W. anceps* from mosses and conifer litter; *W. communis* (Figure 56) from moss in fir woods and also from a frog's stomach in Alaska (this

species was one of only three **Linyphiidae** from mosses in the Arctic Yukon forests); *W. faceta* from moss on logs and deciduous litter; *W. tricornis* from mosses in high ground of the northeastern USA and in the Northwest Territories.

Figure 56. *Walckenaeria communis*, one of many moss-dwelling *Walckenaeria* species. Photo by Tom Murray, through Creative Commons.

Logs can be important as habitats for both bryophytes and spiders. In some cases, these mosses serve as home for the spiders. Such is the case for *Eremaeus stiktos*, an inhabitant of moss-covered logs in Washington, USA (Higgins 1962).

At the Lesní Lom Quarry in the Czech Republic, Hula and Štátná (2010) found that the linyphiid *Centromerus sylvaticus* (Figure 57) was especially abundant in autumn and early spring, living among mosses and detritus in both open and forested sites. Jackson (1906) found this species among mosses, grasses, and leaf litter in the Tyne Valley of England.

In other locations, although the Linyphiidae usually predominate, species differ from the above studies. This is not surprising for animals with a short life span and limited dispersal ability. Pickavance and Dondale (2005) reported three Holarctic linyphiid spider species from Newfoundland, where they lived among mosses. *Carorita limnaea* (Figure 58) occurred in mixed coniferous woods as well as peatlands. *Hilaira canaliculata* lived among litter and mosses in shrub thickets. *Sciastes dubius* lived in damp mosses in mixed coniferous woods.

Figure 57. *Centromerus sylvaticus* (Linyphiidae) female. Photo by Jørgen Lissner, with permission.

Figure 58. *Carorita limnaea* (Linyphiidae) male on moss. Photo by Jørgen Lissner, with permission.

The linyphiid *Diplocephalus latifrons* (Figure 59) is a dominant species in the forests in the moist, shaded bottom of the Skärälid Gorge, southern Sweden, where it occurs among mosses in that dark habitat (Jonsson 1998). Accompanying it in this area is another linyphiid, *Monocephalus castaneipes*, living among mosses on south-facing slopes, as well as on trees and ground.

Figure 59. *Diplocephalus latifrons* (Linyphiidae) male crossing a bryophyte. Photo by Jørgen Lissner, with permission.

The linyphiid *Thyreosthenius parasiticus* (Figure 60) is common in the northern hemisphere temperate region, occurring in mosses of woodlands and litter of old beech forests (Szymkowiak & Górski 2004). In the Geitaknottane Nature Reserve, western Norway, *Gonatium rubellum*

(Figure 61) is typically found among mosses in the bilberry-pine and deciduous forests (Pommeresche 2002).

Figure 60. *Thyreosthenius parasiticus* female on thallose liverwort. Photo by Jørgen Lissner, with permission.

Figure 61. *Gonatium rubellum* on moss. Photo by Arno Grabolle <www.arnograbolle.de>, with permission.

The Palaearctic linyphiid *Centromerus arcanus* (Figure 62) occurs among moss, grass, and leaf litter in coniferous forests and in acid bogs, especially in mountainous areas of the UK (Harvey *et al.* 2002). *Diplocentria bidentata* (Figure 63-Figure 64) is likewise a species of northern climates and is rare in lowland areas south of 59°N. It occurs in moss, as well as in grass, under stones, and in woodland litter (Locket & Millidge 1953; Harvey *et al.* 2002; Lissner 2011). It was common among mosses in the colder portions of the Skärälid Gorge, southern Sweden at 56°N, 13°E (Jonsson 1998). In their study of spiders of the scree slopes in the Czech Republic, Růžička and Klimeš (2005) found this species to be an exclusive inhabitant of mosses, and it never occurred in deep layers. Růžička (2011) likewise found it to occur exclusively among mosses on lower margins of scree slopes that had a permafrost-like microclimate at the mid altitudes (300-550 m asl) in the Czech Republic.

It is interesting that in their study of Arctic Yukon forests, Dondale *et al.* (1997) found only three members of **Linyphiidae**. *Ceratinopsis stativa* lives there in moss in deciduous or mixed woods. *Lepthyphantes alpinus* lives in moss in coniferous and birch woods. The third linyphiid species was the more widely known moss-dweller,

Walckenaeria communis (Figure 56) on moss and litter in moist coniferous woods.

Neotropical and South American Forests

Tropical communities, even in higher elevations, are quite different from those at higher latitudes. Like other forests, forests in South America have their share of **Linyphiidae**, but these are not well studied. In general, the species reported from one tropical area differ from those in another. This is in part due to limited collecting and insufficient communication and observation among collecting groups, but it also speaks to the dispersal limitations between higher mountain areas in the tropical areas.

Miller (2007) reviewed the records of Neotropical erigonine spiders, providing many records of spiders among mosses in forests there. These included *Scolecuroa propinqua* in the humid mossy Chaco forest, Argentina, eastern Bolivia, and Paraguay, but its relationship to the mosses there is not clear. *Intecymbium antarcticum* and *Sphecozone bicolor* have been found in disturbed forests in Chile, where they live among mosses (Miller & Hormiga 2004; Miller 2007). The latter species was also found in dung traps in *Sphagnum* (Miller 2007). *Millidgella* (as *Valdiviella*) *trisetosa* occurs in mossy forest floor litter of *Nothofagus* and *Araucaria* forests at 1250 m in Chile, as well as litter from moss on the forest floor at 460 m and in wet forest moss at 500 m. *Onychembolus anceps* occurs in moss on logs in Chile.

Sphagnum in forests has its own unique species, including *Microplanus odin* from the cloud forest of western Panama at 1860 m, whereas *Microplanus mollis* was found by sifting mosses at 3450-3650 m asl at Laguna Iguaque, Colombia (Miller 2007). Also at Laguna Iguaque, Miller reports *Gonatoraphis lysistrata* and *Triplogyna major* from mosses. *Labicymbium sturmi* occurred on mosses and tracheophytes at 3600 m in the Cordillera Oriental region of Colombia.

In the far south, including southern Chile and South Georgian Islands, mosses shelter additional unique bryophyte-dwelling spiders. These include *Notiomaso australis* (Figure 65) in association with leaf litter, debris, and rocks, as well as among and under mosses (Miller 2007). *Onychembolus subalpinus* occurs in central and southern Chile and adjacent Argentina on the mossy forest floor among the litter, low shrubs, and moss near Chorio Hermoso at 350 m asl. Pitfall traps revealed that *Neomaso claggi* is widespread in this region, occurring among mosses that live in the shade among the tussock grass and from mosses on a wet streambank, as well as among low shrubs.

Figure 65. *Notiomaso australis* (possibly) from South Georgia. Photo by Roger S. Key, with permission.

Lycosidae

This family seems to be poorly represented among forest mosses, preferring sunny locations. Pajunen *et al.* (1995) report *Pardosa riparia* (Figure 66) as numerous in *Polytrichum commune* (Figure 67) in swampy forests, but it appears that in drier forests this family is not typically a moss dweller.

Figure 66. *Pardosa riparia* female on moss. Photo by Walter Pfliegl, with permission.

Figure 67. *Polytrichum commune* var *commune*. Photo by David T. Holyoak, with permission.

But the forest following cutting in the Yukon Arctic region seems to be an exception, perhaps due to the greater light penetration, having a species-rich representation of the family. Dondale *et al.* (1997) found eight species of this family on or in mosses:

- Arctosa alpigena* on moss in spruce woods
- Pardosa concinna* in moss in coniferous woods
- Pardosa furcifera* in moss in coniferous woods
- Pardosa hyperborea* in moss in coniferous woods
- Pardosa mackenziana* in moss in coniferous woods, more rarely in deciduous woods
- Pardosa moesta* on moss in mixed woods
- Pardosa uintana* in moss in coniferous woods
- Pardosa xerampelina* somewhat rarely on moss in coniferous woods.

Malkaridae

This is a family of small spiders (Figure 68) that live mostly in leaf litter and mosses in temperate and tropical wet forests in Australia and New Zealand (Hormiga & Scharff 2020). Little is known about their life history. They are rarely observed in their natural habitat, so bryologists can contribute to our knowledge of their natural history.

Figure 68. *Tingotingo tokorera* (Malkaridae) male, member of a family of tiny spiders that live in leaf litter and mosses. Photo by S. E. Thorpe, through public domain.

Salticidae

Nieuwenhuys (2009) reports that *Pseudicius encarpatus* (Figure 69; Salticidae) can occur among mosses and leaf litter in forests of northwest Europe, although it typically occurs under bark. In the Tyne Valley of northern England, Jackson (1906) reported mosses from various substrata, demonstrating that most bryophyte-dwelling spiders are not bryophyte specialists. It is likely that the spiders treat the mosses in the same way many soil biologists do – as part of the litter layer. Hence, many species are common to both litter and mosses. *Neon reticulatus* (Figure 70), also in the Salticidae, lived among pine needles and mosses. In Iran, Logunov *et al.* (2006) found *Chinattus caucasicus* among mosses and liverworts in moist forest.

Figure 69. *Pseudicius encarpatus*, a spider that occurs mostly on bark but can also occur among mosses and leaf litter in woodlands. Photo by Arno Grabolle <www.arnograbolle.de>, with permission.

Figure 70. *Neon reticulatus* (Linyphiidae) male on moss. Photo by Jørgen Lissner, with permission.

Theridiidae

Robertus lividus (Figure 71), a member of the Theridiidae, occurred among both mosses and stones; this genus occurs among mosses in a variety of habitats, but thus far the known species are different among the habitats. Hauge (1969) reported *Robertus lyriker* (Theridiidae) from 150-350 m asl in Norway, only in mosses and in association with *Vaccinium myrtillus*, *V. vitis-idaea*, and *Empetrum* sp. as the dominant plants.

Figure 71. *Robertus lividus* (Theridiidae) female on moss. Photo by Jørgen Lissner, with permission.

Thomisidae

This family is not common among forest mosses. But in the Arctic Yukon three members are known (Dondale *et al.* 1997). *Ozyptila sincera* occurs in moss in coniferous woods. *Xysticus britcheri* occurs in moss in coniferous woods, whereas it occurred among lichens on the tundra. *Xysticus emertoni* (Figure 72) occurs in moss and litter under shrubs and trees.

Figure 72. *Xysticus emertoni* (Thomsiidae) female. Photo by John Sloan, with permission.

Rock Outcrops

Some forest spiders find their refuge among mosses on rock outcrops, and these may represent different families from the usual forest moss dwellers. *Microhexura montivaga* (Figure 73), in the **Dipluridae**, lives in moss mats that are damp but well drained in well-shaded areas of North Carolina, USA, forests (Coyle 1981, 1997, 1999; Harp 1992; Tarter & Nelson 1995; USFWS 2012). If the moss mat is too dry, the spider suffers desiccation, and if it is too wet, the large drops of water can interfere with absorption of air through the spiracles (USFWS 2012). Springtails (Collembola) are abundant in these moss mats and are the most likely food source (Coyle 1981, Harp 1992).

Figure 73. *Microhexura montivaga*. Photo by Joel Harp, US Fish and Wildlife Service, through public domain.

Epiphytic Bryophytes

Epiphytic bryophytes have their spider fauna as well. In Hungary, Horváth and Szinetár (2002) used trunk-traps at 3 m height to compare the fauna in forest and urban habitats. They found that these mountain forest biotopes had a characteristic fauna, influenced by higher prey density, warmer climate, and lower predation in towns. Epiphytic moss fauna included *Phrurolithus festivus*

(Figure 74; **Corinnidae**) and *Clubiona comta* (**Clubionidae**), but these species are not restricted to bryophyte habitats. It is likely that other spiders use the dense moss cover in the canopy of parts of the tropical rainforest and cloud forest, but these remain to be studied.

Figure 74. *Phrurolithus festivus*. Photo by Trevor and Dilys Pendleton <<http://www.eakringbirds.com/>>, with permission.

Epiphytes reach their greatest density in the rain forests, including the tropics. Tropical spiders seem to have finer resource partitioning than those in the temperate regions, with both species and family diversity being higher in the tropics (Cardoso *et al.* 2011). Nevertheless, functional diversity there is also influenced by altitude and habitat structure. This finer niche partitioning is undoubtedly at least in part the result of the greater number of niches, coupled with the greater variety of both predator and prey organisms. Bryophytes in that region therefore might provide opportunities for greater specialization and diversity.

Peck and Moldenke (1999) have been concerned about invertebrates being spread to new areas in harvested mosses. In their study of these invertebrate communities, they found that the microspiders, **Micryphantidae** (**Linyphiidae**, *e.g.* Figure 46-Figure 50), were among the most abundant invertebrates in moss mats at the tips of shrub branches. The other abundant group was the springtail *Sminthurus* (Figure 75), a food item for spiders.

Figure 75. *Sminthurinus aureus forma maculata*, a moss dweller that is spider food. Photo by Jan van Duinen, with permission.

Heath and Heather

Heathlands (Figure 76) are dominated by *Erica* and *Calluna*, among other shrubs, but they may also have a dense cover of mosses, including *Sphagnum* (Figure 45). These mosses can have their own fauna of spiders. In northwestern Europe, these habitats seem to be losing their ability to support their typical fauna. At the nature reserve Lüneburger Heide, Germany, the ladybird spider, *Eresus kollari* (Figure 77; *Eresidae*) (often included in *Eresus cinnaberinus*), is one of these diminishing species (Krause *et al.* 2011). This species, a native of southern Europe, usually lives under rocks or in mosses (Wikipedia 2012a) where it requires a balance between exposure and warming (Krause *et al.* 2011). Krause *et al.* (2011) found that they could not separate the effects of *Calluna* cover from that of the moss layer in determining the suitability of the habitat. Both sexes dig their burrows in the organic layer, and the heat of insolation needs to penetrate to 10 cm (Krause *et al.* 2011). This spider subsists on millipedes (Figure 78) and beetles, and the successful male moves into the nest with the female and shares in eating the prey (Wikipedia 2012a).

Gajdo and Toft (2000) used pitfall traps to examine spider fauna on a moisture transect from heathland to marsh in Denmark. They could find no clear relationship between vegetation structure or soil moisture and the pattern of spider species composition. This habitat extended from 100% moss cover to areas that had next to no mosses. But the mobility, especially of larger spiders, could easily make it difficult to detect preferences by using pitfall traps. This lack of relationship could even be the result of day-night migrations to optimize moisture, at least for the larger species.

Hauge (2000) used pitfall traps in a coastal heathland in western Norway to examine habitat distribution. The area included variation from plant associations dominated by the shrub *Calluna vulgaris* with several moss species to areas with a continuous, humid *Sphagnum* (Figure 45) mat and little *Calluna*. During an especially dry spring and early summer, the spiders, and particularly the *Linyphiidae*, diminished drastically toward mid-summer in the *Calluna vulgaris* area. In that habitat, linyphiids *Minyriolus pusillus* (Figure 30; already reported from forests), *Erigonella hiemalis* (Figure 79), *Gongylidiellum latebricola* (Figure 80), and *G. vivum* (Figure 81) comprised 59% of the spider fauna. *Gongylidiellum* and *Gonatium rubens* (Figure 82) occurred among the *Calluna* habitat in damp places among moss, grass, and leaf litter (Bengtson & Hauge 1979; Holm 1980).

Figure 79. *Erigonella hiemalis* on moss. Photo by Jørgen Lissner, with permission.

Figure 80. *Gongyliellum latebricola* on moss. This species occurs among mosses in heathlands. Photo by Jørgen Lissner, with permission.

Figure 81. *Gongyliellum vivum* female on moss. Photo by Jørgen Lissner, with permission.

Figure 82. *Gonatium rubens* female on moss. Photo by Jørgen Lissner, with permission.

In the *Sphagnum* area of Norwegian heathlands, dominance shifted, and *Robertus arundineti* (45%; Figure 83; **Theridiidae**) and *Minyriolus pusillus* (10%; **Linyphiidae**) represented 55% of the species (Hauge 2000). Nevertheless, *Sphagnum* bogs are among the habitats that have some species in common with heathlands. In Great Britain, *Hypselistes jacksoni* (Figure 84; **Linyphiidae**) and *Trochosa spinipalpis* (Figure 8; **Lycosidae**) occur almost exclusively in bogs and wet heaths (Boyce 2004).

Figure 84. *Hypselistes jacksoni*. Photo by Jørgen Lissner, with permission.

On the Faroe Islands, several families are represented in association with mosses on the heathlands, with a new one, the **Zoridae**, present. *Zora nemoralis* (Figure 85) is found on the Faroe Islands and likewise is found among moss and heather in the UK (Harvey *et al.* 2002). *Haplodrassus signifer* (Figure 86; **Gnaphosidae**) lives among heather and moss at Kletsbrúgv, Faroe Islands, at 125 m altitude (Lissner 2011). *Hahnina montana* (Figure 37; **Hahniidae**), a spider also of woodlands, nests among mosses in the heathland (Harvey *et al.* 2002; Lissner 2011). But as usual, the **Linyphiidae** is the most diverse family among the bryophytes and is discussed below.

Figure 85. *Zora nemoralis* nymph on leaf litter. Photo by Walter Pfliegler, with permission.

Figure 86. *Haplodrassus signifer* sub-adult female on moss. Photo by Jørgen Lissner, with permission.

Clubionidae

The Clubionidae are the sac spiders, so-named because they build sac-like structures which serves as retreats. This once-large family now has only 15 genera and about 500 species. Few of these are represented on bryophytes. *Clubiona trivialis* (Figure 87) is known from mosses among heather and from moss in meadows and pastures (Schenkel, 1925; Holm 1980, Lissner 2010, 2011). Harvey *et al.* (2002) report *Clubiona norvegica* (Figure 88) from among mosses in the high moorland of the UK, a habitat similar to heathland.

Figure 88. *Clubiona norvegica* (Clubionidae) male on moss. Photo by Walter Pfliegler, with permission.

Linyphiidae

The Linyphiidae is a common family among mosses of heathlands. *Oreonetides vaginatus* (Figure 89) lives among moss in moist heaths, but it also lives in snow beds with *Salix herbacea* (Holm 1967). *Poeciloneta variegata* (Figure 90) lives under stones and among grass, moss, and heather (Brændegaard 1928). *Semljicola faustus* (Figure 91) is known from mosses and occurs on heather (Bengtson & Hauge 1979; Holm 1980), but I cannot document that it occurs on mosses in heather. Some species, such as *Sintula comigera* occurs in the wet heathlands of Flanders, Belgium, but also occurs in *Sphagnum* bogs (Maelfait *et al.* (1990).

Figure 91. *Semljicola faustus* (Linyphiidae) female. Photo by Jørgen Lissner, with permission.

In the Faroe Islands, Lissner (2011) reported *Agyneta subtilis* from similar habitats to those of *A. decora* (Figure 92) in Britain, where it lives among mosses in a variety of habitats, including mosses in heathlands. However, in Iceland *A. decora* is known only from mossy grassland and meadows, not heathlands (Agnarsson 1996). *Centromerus arcanus* (Figure 62) lives in mosses and can be found in grass and shrub heath (Bengtson & Hauge 1979; Bengtson *et al.* 2004), as well as mosses in forests. *Ceratinella brevipes* (Figure 20) was located by sweeping heather and sifting moss amongst grass on a slope (Holm 1980); it also occurs on mosses in forests and other habitats.

Figure 92. *Agyneta decora* (Linyphiidae) female on moss. Photo by Jørgen Lissner, with permission.

Mecynargus morulus (Figure 93) occurs on high ground (200-880 m) among mosses, grass, gravel, and under stones (Lissner 2011). Previously, Holm (1967) had reported this species to be common in *Hylocomium (splendens?)* (Figure 94) on moss heaths in the Faroes. It is typically a high ground species in the Faroe Islands, found at 200-880 m asl in moss, grass, gravel, and under stones (Lissner 2011). *Palliduphantes ericaeus* (Figure 95) likewise occurred in *Hylocomium*, but at altitudes below 200 m (Holm 1980). Jackson (1906) reported *P. ericaeus* (as *Lepthyphantes ericaeus*) among mosses, heather, and leaves in the Tyne Valley, UK.

Lissner (2011) found *Tiso vagans* among moss and rocks on the Faroe Islands. In Britain, it is known from a wide variety of habitats, including moss, grass and detritus in heathland (Harvey *et al.* 2002).

Improphantes complicatus (Figure 96) occurs in both Greenland (Lissner 2011) and the Yukon tundra (Dondale *et al.* 1997) in a variety of damp and dry habitats, including among moss, litter, and under stones on heaths (Figure 76). *Leptorhoptrum robustum* (Figure 97) has been found in moss among heather vegetation up to 750 m (Brændegaard 1928; Bengtson & Hauge 1979; Holm 1980).

Figure 96. *Improphantes complicatus* (Linyphiidae). Photo by Gergin Blagoev, through Creative Commons.

Figure 97. *Leptorhoptrum robustum* (Linyphiidae) male on moss. Photo by Jørgen Lissner, with permission.

Tenuiphantes mengei (Figure 98) has several habitats, including grass and moss of dry heath in Britain (Harvey *et al.* 2002). *Tenuiphantes zimmermanni* (Figure 24) has an even broader range of habitats where it is associated with bryophytes, including forests and moorland with heather (Holm 1980), where it occurs among the heather, grasses, sedges, and mosses (Harvey *et al.* 2002).

Figure 98. *Tenuiphantes mengei* (Linyphiidae) male on moss. Photo by Jørgen Lissner, with permission.

As in the woodlands, the most species-rich linyphiid moss-dweller genus in the heathlands is *Walckenaeria*. *Walckenaeria antica* (Figure 99), also in woodlands, lives below 300 m in the Faroe Islands (Holm 1980), where it is known from mosses among heather (Lissner 2011). *Walckenaeria clavicornis* (Figure 100) occurs at 50-600 m in the Faroes, living among mosses, gravel, and stones, but in Greenland it occurs among mosses in "luxuriant heaths"

(Holm 1967; Millidge 1983). *Walckenaeria karpinskii* (as *W. holmi*) lives among *Sphagnum* and other mosses in North America and Greenland, as well as under stones, in the moist dwarf-bush heath (Millidge 1983). *Walckenaeria nodosa* (Figure 54), also found in the Faroes, is known from damp heathland in southern England (Harvey *et al.* 2002). *Walckenaeria nudipalpis* (Figure 101) occurs below 300 m in the Faroes (Holm 1980), occurring among mosses in heather (Lissner 2011). Jackson (1906) reported *W. monoceros* (as *Prosopotheca monoceros*) and *W. acuminata* (Figure 102) in the Tyne Valley, UK, among moss in moorlands, a landform that can have vegetation closely related to heath. Maelfait *et al.* (1990) considered *W. dysderoides* (Figure 53) to be rare, but typical of open heath with well-developed moss carpets in Flanders, Belgium.

Marshes and Moist Meadows

Cattail marshes generally lack bryophytes, but some marshes have their own bryophyte flora. Kupryjanowicz (2003) described the spider fauna of sedge marshes and sedge-moss marshes in Poland. In these two habitats, he collected 14,566 individuals, comprising 173 species. The family mix in these Polish marshland locations is rather different from that of the previously discussed habitats, and certainly many of the species differ. Among these, *Pardosa sphagnicola* (Figure 103; Lycosidae) and *Pirata tenuitarsis* (Figure 104; Lycosidae) inhabit mosses in the sedge-moss marshes; these two species are active hunters and are able to run across the surface of water in hunt of food (Figure 105).

It is not surprising that some sphagnophilous species [*Pardosa sphagnicola* (Figure 103), *Pirata uliginosus* (Figure 106), *P. tenuitarsis* (Figure 104), and *Antistea elegans* (Figure 3; Hahniidae)] live in sedge moss marshes, along with other peat-bog related species, e.g. *Aphileta misera* (Figure 107; Linyphiidae; reported by Jackson to live only among mosses and only in marshes in the Tyne Valley of England), *Gnaphosa nigerrima* (Figure 4; Gnaphosidae), and *Neon valentulus* (Figure 108; Salticidae). *Drassyllus lutetianus* (Figure 109; Gnaphosidae) likewise occurs among mosses in marshes as well as in bogs (Koponen 2002).

Figure 109. *Drassyllus lutetianus* (Gnaphosidae), a moss-dweller in marshes and bogs. Photo by Jan Barvinek, through Creative Commons.

At one marsh site, three species dominated in the mosses: *Erigonella ignobilis* (Figure 110; Linyphiidae) (8%), *Porrhomma pygmaeum* (Figure 111; Linyphiidae) (6.7%) – also reported by Storey (2012), and *Sitticus caricis* (Figure 112; Salticidae) (9%). At another site, dominant species typical of mosses were *Ozyptila gertschi*

(Thomisidae), *Neon valentulus* [Figure 108; Salticidae (*N. reticulatus* occurs in forests on mosses)], and *Sitticus caricis* (Salticidae), species that were subdominant in the pitfall trap catches. *Larinia jeskovi* (Araneidae) is a rare species elsewhere, but survives in the marshlands by overwintering among the mosses.

Figure 112. *Sitticus caricis* (Salticidae) on moss. Photo by Jørgen Lissner, with permission.

Linyphiidae

Some of the earliest records of spiders among mosses in marshland are those of Jackson (1906) for the Tyne Valley, UK, who listed only two, both in the Linyphiidae.

Cnephalocotes obscurus (Figure 113) occurs among both mosses and rushes in marshes, whereas *Oedothorax gibbosus* (as *Gongylidium gibbosum*; Figure 114) lives among mosses and grasses in marshes.

Figure 113. *Cnephalocotes obscurus* (Linyphiidae) male on moss. Photo by Jørgen Lissner, with permission.

Figure 114. *Oedothorax gibbosus* (Linyphiidae). Photo by Morten D. D. Hansen, with permission.

Holm (1980) found a number of Linyphiidae in moist meadows of the Faroe Islands. He found *Palliduphantes ericaeus* (Figure 95) at altitudes below 200 m by sifting moss, mostly *Hylocomium* (Figure 94). *Centromerus arcanus* (Figure 62) occurred in moss in a meadow at 180-200 m altitude (Holm 1980); it is a **eurytopic** (able to tolerate a wide range of habitats and conditions) species also occurring in forests and heathland. *Leptorhoptrum robustum* (Figure 97) occurs among moss and grass in meadows up to 750 m (Holm 1980; Brændegaard 1928). Lissner (2011) reported a number of species from wet meadows there, including the linyphiid *Hypomma bituberculatum* (Figure 115) from a very wet, gently sloping meadow with abundant mosses.

The common moss-dwelling linyphiid genus *Walckenaeria* is again represented in marshes, including the Faroe Islands (Lissner 2011), with species repeating several found in the forest: *Walckenaeria cuspidata* (Figure 52) among mosses in wet meadows at 260 and 290 m altitude (Holm 1980), also in marshes of the Tyne Valley, northern England (Jackson 1906); *W. nodosa* (Figure 54) among mosses in marshes in the Faroes and in southern England (Harvey *et al.* 2002). *Walckenaeria*

nudipalpis (Figure 101), known also from heathlands elsewhere, in the Faroe Islands is mostly below 300 m among mosses in moist meadows and bogs (Holm 1980; Lissner 2011). Jackson (1906) reported *W. nudipalpis* (Figure 101) among moss in "swampy" places, which may include several habitat types. *Walckenaeria acuminata* (Figure 102) lives among moss, grass, and dead leaves in marshes and other habitats, including heathland (Jackson 1906).

Figure 115. *Hypomma bituberculatum* (Linyphiidae) female among mosses. Photo by Jørgen Lissner, with permission.

Swampy Places

The term swamp has a myriad of definitions, and I cannot pretend to understand what definition was intended by the various researchers over a century or more from all over the globe. For example, Hula and Šťastná (2010) reported that the linyphiid *Walckenaeria dysderoides* (Figure 53) occurs among mosses and detritus in "humid habitats," leaving the habitat open to some interpretation. Likewise, Maelfait *et al.* (1990) reported that *Agynera ramosa* (Figure 19) was rare in Flanders, Belgium, but it occurred in open "marshy" situations that had a thick moss layer. Therefore, I have included this section only as a place to represent those spiders from habitats identified by the researchers as swamps or swampy.

As already discussed for marshes and forests, bryophyte-dwelling spiders often occur in other habitats and on other substrata in those habitats. For example, in the Tyne Valley, UK, Jackson (1906) reported a number of Linyphiidae. *Hilaira excisa* lives among grass, rushes, and moss in swamps. Grasses often seem to provide alternative habitats to mosses, with *Bathypantes nigrinus*, *Gongylidiellum vivum* (Figure 81; also in heathland), *Tenuiphantes cristatus* (as *Lepthyphantes cristatus*; Figure 116), and *Semljicola faustus* (as *Sintula fausta*; Figure 91) among both mosses and grasses in swamps. But Jackson also reported some species only from mosses: *Diplocephalus permixtus* (Figure 117), *Drepanotylus uncatus* (as *Hilaira uncata*; Figure 118), *Erigonella ignobilis* (as *Troxochrus ignobilis*; Figure 110), *Erigonella hiemalis* (as *Troxochrus hiemalis*; Figure 79). I have found only one species thus far, *Robertus neglectus* from among moss in swamps, but also in woods, that belongs to a different family, the Theridiidae. But this may be an artifact of the way people have described or named the habitat.

Figure 118. *Drepanotylus uncatus* (Linyphiidae) male on moss. Photo by Jørgen Lissner, with permission.

Aquatic

Few spiders are aquatic, and even fewer have any known association with mosses. Pickard-Cambridge (1860) mentioned that *Argyronecta aquatica* (Figure 119-Figure 120; Cybaeidae) is an occasional spider in Southport, UK, where it can be found in moss dykes. This unique spider is the only one known to spend its entire life under water (Wikipedia 2012b). This is possible for this air breather because of unique behavior similar to that of some aquatic insects. It uses a **diving bell**. It traps air in a

bubble (or grabs an air bubble) and holds the bubble with hairs on its abdomen and legs. It is then able to exchange CO₂ with the O₂ from the bubble. The bubble loses CO₂ and gains O₂ from the water by diffusion. When the diffusion rate is unable to replace the oxygen to a sufficient amount, the spider grabs another air bubble.

Females of *Argyroneta aquatica* (Figure 119-Figure 120) go a step farther (Schütz & Taborsky 2003). They build an underwater diving bell web that they fill with air. This nest is used for molting, mating, raising offspring, and even for digesting prey. They leave the bells only to dart out to catch prey that have the misfortune of touching the bell or the threads that anchor it. The male bell is smaller, and males are more active in pursuing prey. Since their nets serve fewer purposes, the air supply lasts longer.

Figure 119. *Argyroneta aquatica* (Cybaeidae) female water spider, inhabitant of fens and bogs. Photo by Jørgen Lissner, with permission.

Figure 120. *Argyroneta aquatica* (Cybaeidae) showing air bubble on underside. Photo by Norbert Schuller, through Wikimedia Commons.

Insects often get the air for their diving bells from the photosynthetic air bubbles on plant leaves. It would be interesting to determine if the spiders that live among or near bryophytes likewise use this source of oxygenated air.

Sand Dunes

One does not usually think about sand dunes as a bryophyte habitat, but in fact, bryophytes, particularly

mosses, can be important stabilizers on the sand. For spiders, they are important refuges for moisture and cover, especially from both the heat and light of the sun.

Merkens (2000) divided inland dunes in northern Germany into four categories in an attempt to delimit habitats for spiders there: lichen cover, grass cover, herb cover, moss cover. He found that not only the type of vegetation cover (especially lichen, moss, and herbs), but also the kind of neighboring habitat, play important roles to influence the species composition of the inland dunes. Among the 286 species on the dunes, he found among the 34 species with significant ($p < 0.05$) habitat correlations, nine species were significantly correlated with moss cover. These were in families familiar from forest studies, but are mostly species not previously cited. **Salticidae:** *Aelurillus v-insignitus* (Figure 121-Figure 122); **Lycosidae:** *Alopecosa fabrilis* (Figure 123-Figure 126), *Trochosa terricola* (Figure 127); **Linyphiidae:** *Bathypantes gracilis* (Figure 129), *Centromerita concinna* (Figure 130), *Centromerus sylvaticus* (Figure 57; also occurs on mosses in forests), *Typhochrestus digitatus*; **Gnaphosidae:** *Drassyllus pusillus* (Figure 131); **Hahniidae:** *Hahnina nava* (Figure 132-Figure 133). Merken found that on these dunes, the spider community seems to follow the successional stage. Some are restricted to the initial stage of open sand and little plant cover, whereas others depend on a dense cover of mosses and herbs that represent the advanced stages of succession.

In coastal dunes of Belgium, marram grass (*Ammophila arenaria*) and mosses often dominate the dunes (Bonte *et al.* 2002). As in Germany, *Alopecosa fabrilis* (Figure 123-Figure 126; **Lycosidae**) dominated the spider fauna, particularly in areas with a dominance of lichens and mosses near the inner dune front. *Alopecosa fabrilis* was the only one of the German dune species with habitat correlations that correlated only with moss cover (Merkens 2000). On the other hand, *Oedothorax apicatus* and *Arctosa perita* had a significant negative correlation with moss cover.

In these Belgian dunes, families were similar, but fewer, than those in forests. In addition to *Alopecosa fabrilis* (**Lycosidae**), mosses served as habitat to *Micaria dives* (Figure 134; **Gnaphosidae**), *Zelotes longipes* (Figure 135; **Gnaphosidae**), and *Walckenaeria stylifrons* (Figure 136; **Linyphiidae**) – a species different from that of previously discussed habitats (Bonte *et al.* 2002). The genus *Micaria* is **diurnal** (active in daytime) and runs about rapidly in the bright sunshine, hunting for food (Lissner 2011). Bell *et al.* (1998) found a different species of *Zelotes*, the widespread European spider species *Zelotes latreillei* (Figure 137). This native of chalk and coastal areas of Europe is positively correlated with the number of plant species in sand dunes. It lives in areas with a rich, compact "thatch" of low vegetation where bare ground is partly replaced with cover of moss, debris, and other vegetation.

Figure 137. *Zelotes latreillei* (Gnaphosidae) on sand. Photo by James K. Lindsey, with permission.

Clubiona lutescens (Figure 32; **Clubionidae**) occurs in a wide variety of habitats, including woodlands, grasslands, marshes, gardens, waste places, and stony seashores (Crocker & Daws 1996), where it can be found among bryophytes.

For any bryophyte habitat to be suitable, it must not only provide appropriate heat, moisture, and cover, but it must be a place where there is also food available. In the coastal dunes of Belgium, Bonte and Mertens (2003) found that both spiders and springtails (family **Isotomidae**) diminish in numbers as grass coverage increases and soil

formation increases. It is their conclusion that species aggregations of both groups are driven by these changes, resulting in their aggregation in areas with high moss coverage.

Grasslands and Pastures

Although grasslands are not considered mossy habitats, close examination will often reveal species like those of *Brachythecium* (Figure 138), *Bryum* spp. (Figure 139), *Racomitrium canescens* (Figure 140), *Syntrichia ruralis* (Figure 141), and *Tortella flavovirens* (Figure 142- Figure 143) (Jun & Rozé 2005). Kajak *et al.* (2000) considered the moss and litter layers in grasslands to be important for the spider communities. They found that the soils under the mosses in the sedge-moss community of grasslands had the highest water-holding capacity and maintained a stable moisture level throughout the year.

Figure 143. *Tortella flavovirens* in its desiccated state. Photo by Michael Lüth, with permission.

Pastures are often wetter than wild grasslands, but one might consider these two habitats as a continuum, with "fields" occurring somewhere in that continuum. Nevertheless, I have found little evidence of overlapping species, albeit based on a very small sample.

Clubionidae

As mentioned earlier, *Clubiona lutescens* (Clubionidae; Figure 32) occupies a wide range of habitats in the UK and elsewhere, with mosses in grasslands among these (Harvey *et al.* 2002).

Gnaphosidae

Micaria pulicaria (Figure 33) is likewise very abundant among grass and moss in various open habitats at the Lesni Lom Quarry (Hula & Štátná 2010), but occurs in forests in the Tyne Valley of England.

Linyphiidae

This habitat has its own fauna of spiders, and some may depend on bryophytes for cover or moisture. As usual, a number of these are in the Linyphiidae. In grasslands of Essex, UK, *Cnephalocotes obscurus* (Figure 113) lives among the detritus, mosses, and other herbaceous vegetation (Spider and Harvestman Recording Scheme 2012), in addition to swampy places cited above. Roberts (1987) reported *Peponocranium ludicrum* (Figure 144) from mosses and grasses in the UK. Johnston and Cameron (2002) reported *Sintula corniger* (Figure 145) among mosses, grasses, and litter in the UK. It is not clear if these species occur among mosses in grassland.

Figure 144. *Peponocranium ludicrum* (Linyphiidae) male on moss. Photo by Jørgen Lissner, with permission.

Figure 145. *Sintula corniger* (Linyphiidae) female on moss. Photo by Jørgen Lissner, with permission.

Also in Britain, *Savignia frontata* (Figure 146), *Tenuiphantes zimmermanni* (Figure 24), and *Tiso vagans* live in grasslands and among mosses (Harvey *et al.* 2002); *T. zimmermanni* is also known from forests and heathlands, as discussed above.

Figure 146. *Savignia frontata* male. Photo by Jørgen Lissner, with permission.

Holm (1980) reports *Ceratinella brevipes* (Figure 20), a moss inhabitant in many of its habitats, from sifting mosses growing among grasses on a slope and *Gongylidiellum vivum* (Figure 81; also from heath, swampy land, and grassland) from grass heaths in the UK. *Leptorhoptrum robustum* (Figure 97) also occurred in open grass heaths, more rarely in other habitats (Bengtson & Hauge 1979).

Jackson (1906) found a number of members of Linyphiidae in the Tyne Valley, England. *Panamomops sulcifrons* (as *Panamomops bicuspis*) occurred among mosses in fields or pastures. Members of the ubiquitous *Walckenaeria* included *W. acuminata* (Figure 102) and *W. cuspidata* (Figure 52), both previously discussed from other bryophyte habitats, occurring in fields and pastures. *Walckenaeria cuspidata* (Figure 52) in Iceland prefers moist grassland and moss there as well (Agnarsson 1996).

At the Lesní Lom Quarry (Brno-Hady), a nature preserve in the Czech Republic, *Centromerus sylvaticus* (Figure 57), also on mosses in sand dunes and forests, is a very abundant species in autumn and early spring in grasslands there; it is common in open habitats (Hula & Šťastná 2010).

Grasslands in the Arctic can be quite different from those in the temperate zone. In Iceland, *Agyneta decora* (Figure 92), also known from heathlands, occurs there in mossy grasslands (Agnarsson 1996) and *A. subtilis*, likewise known from mosses in heathlands, occurs among both mosses and grasses (Harvey *et al.* 2002).

Improphantes complicatus (Figure 96) occurs over a wide range of altitudes in Iceland, where it occupies mosses and wet grasslands (Agnarsson 1996); it also occurs in heathlands in Greenland. *Porrhomma montanum* (Figure 160) occurs among grassland and moss in Iceland (Agnarsson 1996).

Sunny banks often have different vegetation and thus different spiders from the main habitat. For example, Jackson (1906) reported *Syedra gracilis* (as *Syedra pholcommoides*) as rare among mosses and grasses on sunny banks. Miller and Hormiga (2004) found *Myrmecomelix leucippus* among mosses on a xeric slope in the Neotropics in Peru.

Lycosidae

Among the bryophyte dwellers, the **Lycosidae** are most common in marshes and bogs, but they also occur in grasslands. In the Faroe Islands, *Pardosa palustris* (Figure 197) occurs among mosses and in grassy heaths (Schenkel 1925; Bengtson and Hauge 1979; Holm 1980; Lissner 2011), and most likely occurs among mosses in those heaths.

Thomisidae

The **Thomisidae** are represented by several genera. Jackson (1906) found the rare *Trichopternoides thorelli* (as *Entelecara thorelli*) and *Xysticus bifasciatus* (Figure 147) among mosses in fields or pastures of the Tyne Valley, England. *Ozyptila pullata* (Figure 148) occurs among mosses in calcareous grassland in the UK (Harvey *et al.* 2002).

Figure 147. *Xysticus bifasciatus* (Thomisidae). Photo by Ed Nieuwenhuys, with permission.

Mountains and Altitudinal Relations

Mountains create a series of climate zones in which plant communities differ. Increased elevation changes light intensity, increases UV-radiation (a problem for spiders), shortens the growing season, promotes lower temperatures, creates moisture differences, and can have different substrata. All of these differences promote differences in bryophyte communities as well, and the role of bryophytes for spiders is likely to change in consort with these differences.

Unfortunately, few studies connect substrate such as mosses with the mountain habitat or with elevational differences in climate and plant communities. In the Tyne Valley, UK, Jackson (1906) alludes to it when he states that *Ceratinella brevis* (Figure 149; **Linyphiidae**) – a species known from mosses in forests – occurs to a "considerable altitude" among grass, mosses, and dead leaves. A major contributor to altitudinal records, Lissner (2011) frequently cites altitude in his collections from the Faroe Islands.

Figure 149. *Ceratinella brevis* (Linyphiidae) male on moss. Photo by Jørgen Lissner, with permission.

Švatoň and Kovalčík (2006) provided an extensive spider study in the Tatras National Park, southern Poland, with a number of peaks over 2500 m asl, although elevational effects are not discussed. Mountain forest

mosses house *Cryphoea carpathica* (Figure 150; **Hahniidae**), *Hahnia difficilis* (**Hahniidae**), and the common moss-dweller, *Hahnia montana* (Figure 37). Other muscicolous species include *Robertus truncorum* (Figure 151; **Theridiidae**) and the rarer *Alopecosa pinetorum* (Figure 152; **Lycosidae**). Boggy areas there support *Pardosa sordidata* (**Lycosidae**) and *Robertus scoticus* (Figure 153). It is interesting that *Robertus* occurs in several different habitats described above, but each is reported as a different species.

Figure 153. *Robertus scoticus* (**Theridiidae**) female on moss. Photo by Walter Pfliegler, with permission.

Araneidae

This family is not often represented among bryophytes. However, in the Tatra Mountains Svatoň and Kovalčík (2006) found *Araneus nordmanni* (Figure 154) in a peat bog. This species is more common in the USA and Canada; it is rare in Europe.

Figure 154. *Araneus nordmanni* (**Araneidae**) on flower buds. Photo by Tom Murray, through Creative Commons.

Clubionidae

A 12 mm spider, *Clubiona abbajensis kibonotensis*, was found under moss on Mount Kilimanjaro, Africa (Denis 1950).

Gnaphosidae

The family **Gnaphosidae** is represented in many habitats among the moss dwellers. In the Faroe Islands, two species have been reported. *Micaria alpina* (Figure 155) occurs above 750 m on the Faroe Islands, likewise in mosses, but also under stones and among grasses (Holm 1980). *Haplodrassus signifer* (Figure 86) occurs at 125 m asl (Lissner 2011), and is also present among mosses in the heather. In the Yukon and elsewhere in the Arctic and alpine regions, *Gnaphosa borea* occurs primarily above 1000 m asl (Dondale *et al.* 1997).

Figure 155. *Micaria alpina* (Gnaphosidae) female. Photo by Walter Pfliegler, with permission.

Hahniidae

In Caribou Mountains Wildland Provincial Park, Canada, members of the **Hahniidae** occur in mosses and other damp places (Nordstrom & Buckle 2006). They sometimes make webs among mosses and usually hide under bits of soil at the edge of the web (Lissner 2011; Framenau 2012).

In the Tatras Mountains, Svatoň and Kovalčík (2006) likewise found **Hahniidae** to live among mosses. These included *Cryphoea carpathica* (Figure 150), *Hahnina difficilis*, and *H. montana* (Figure 37). *Hahnina montana* has been mentioned for several other habitats above.

Linyphiidae

This family comprises a strong majority among the reported Arctic and alpine moss-dwelling spiders. In the East Alps, Thaler (1999) reported three bryophyte-dwellers, all **Linyphiidae**, that were confined to cushions (mosses and other plants): *Erigone tirolensis* (Figure 156), *Walckenaeria clavicornis* (Figure 100) [also among mosses at 50-600 m in the Faroe Islands (Holm 1980; Lissner 2011) and in Britain mostly above 650 m altitude, but also in raised bogs at low elevations (Harvey *et al.* 2002), and in heathlands, grasslands, and pastures], and *Oreoneta montigena* (as *Hilaira montigena*), a species also found among mosses in the Carpathians by Svatoň and Kovalčík (2006). *Gonatium rubens* (Figure 157) occurs among mosses in the mountains of the Faroe Islands (Holm 1980), but also occurs in heathlands elsewhere.

Figure 156. *Erigone tirolensis* (Linyphiidae) male on moss. Photo by Jørgen Lissner, with permission.

Figure 157. *Gonatium rubens* (Linyphiidae) female on moss. Photo by Jørgen Lissner, with permission.

Holm (1980) and Lissner (2011), working in the Faroe Islands, are among the few to include both elevations and moss habitats in their reports. Most of those spiders reported here are in the **Linyphiidae**. For those spiders living among mosses at lower elevations, they reported the eurytopic *Centromerus arcanus* (Figure 62) [known from mosses on mountains in Britain (Harvey *et al.* 2002)]; *Hilaira nubigena* (Figure 158) [also from altitudes of 400-750 m asl in Britain (Brændegaard 1928; Bengtson & Hauge 1979; Holm 1980)]; *Walckenaeria antica* (Figure 99) below 300 m and also from heathlands elsewhere (Lissner 2011); *Walckenaeria cuspidata* (Figure 52) at 260 m and 290 m asl (Holm 1980), also occurring in the mountains of Britain (Harvey *et al.* 2002) and noted above from forests, marshes, and grassland. *Walckenaeria nudipalpis* (Figure 101) has a somewhat more intermediate distribution, being found from 45 m up to 400 m asl in the Faroes (Lissner 2011); it also occurs in heathland and marshes elsewhere.

From higher altitudes, one can find **Linyphiidae**, including *Mecynargus morulus* (Figure 93), a species also known from heathlands, which occurs from 200-880 m asl in the Faroes (Lissner 2011). *Meioneta nigripes* (Figure 159) occurs above 500 m asl in Britain, but at lower altitudes in Orkney and Shetland (Harvey *et al.* 2002). *Scotinotylus evansi* occurs at 600 m asl in the Faroe Islands (Lissner 2011) and is found in altitudes up to 1000 m asl in Iceland (Agnarsson 1996).

Figure 158. *Hilaira nubigena* (Linyphiidae). Photo by Glenn Halvor Morka, with permission.

Some moss dwellers are wide-ranging species. Among these is the linyphiid *Porrhomma convexum* (Figure 42) from 0-900 m asl in Iceland (Agnarsson 1996) and from mosses in forests elsewhere. *Porrhomma montanum* (Figure 160; also from mosses in grasslands elsewhere) occurs from sea level to the highest point in the Faroes (882 m asl at Slættaratindur) (Lissner 2011) and from 0-900 m asl in Iceland (Agnarsson 1996). As expected for a species of many habitats, *Tenuiphantes zimmemanni* (Figure 24) likewise occurs among mosses from sea level to "high levels in the mountains" (Holm 1980) and in forests, heath, and grasslands elsewhere.

Figure 159. *Meioneta nigripes* (Linyphiidae). Photo by Michael Hohner, with permission.

Snowfields provide unique communities of spider species that either tolerate or require cool temperatures and elevated moisture. Here, the Linyphiidae are likewise common (Svatoň & Kovalčík 2006), but their associations with bryophytes adjoining the snowfields are not known. In the Tatra Mountains Svatoň and Kovalčík (2006) found that the Linyphiidae is the most frequently represented.

Figure 160. *Porrhomma montanum* (Linyphiidae). Photo by Glenn Halvor Morka, with permission.

Lycosidae

In Sweden, *Arctosa alpigena* (Figure 161) is found in *Sphagnum* (Figure 162) bogs in subalpine and alpine regions (Almqvist 2005). *Arctosa alpigena* occurs above 1000 m in the mountains of the UK, where it lives both in and under the moss *Racomitrium lanuginosum* (Figure 195) (Harvey *et al.* 2002).

Figure 161. *Arctosa alpigena* (Lycosidae) on *Sphagnum*. Photo by Barbara Thaler-Knoflach, with permission.

Figure 162. *Sphagnum magellanicum* from Cape Hope. Photo from NY Botanical Garden, through public domain.

Svatoň and Kovalčík (2006) found the rare lycosid *Alopecosa pinetorum* among mosses in the Tatra Mountains, the highest range in the Carpathian Mountains. In addition, *Pardosa sordidata* occurred in boggy areas.

Tundra and Arctic

A number of spider species appear to be very tolerant of cold, but few cases of physiological adaptation are documented. In their study of Alaskan arthropods, Dunman *et al.* (2004) identified three spiders that had antifreeze proteins (AFPs). Most of the terrestrial arthropods are freeze avoiders, and this seems to include those AFP-producing species. The proteins do, however, function to prevent freezing.

Sherriffs (1934) was among the first to identify the tundra mosses where spiders were found, but he reported only two species of bryophyte dwellers. *Thanatus arcticus* (Figure 163-Figure 164; **Philodromidae**) from Greenland guards its large white flattened egg cocoon that it deposits under stones. Logunov *et al.* (1998) also reported this species from the moss-tussock-shrubby wet tundra of southern Siberia.

Dondale *et al.* (1997) have added many more species to the list of moss-dwelling tundra species. All but one (*Sisis rotundus*, **Linyphiidae**) of these also occur in litter or other habitats. Those living in bogs and fens will be discussed in the next sub-chapter.

Of those species listed for the Yukon, 57 are known to occur in or associated with mosses (Dondale *et al.* 1997). *Alopecosa* (**Lycosidae**) species, known elsewhere from mosses, were present among lichens, but not reported among mosses. The following species occur with mosses in the tundra or alpine areas of the Yukon and elsewhere: **Theridiidae** – *Robertus vigerens* (Figure 165); **Thomisidae** – *Xysticus emertoni* (Figure 166); **Salticidae** – *Phidippus borealis* (Figure 167). Additional Yukon species are discussed below with families having more representation.

Koponen (1992) found juvenile *Dictyna* (Figure 168; **Dictynidae**) among the moss *Racomitrium* in the low Arctic of the Belcher Islands, Hudson Bay, but reported no adults.

Figure 168. *Dictyna* sp. (**Dictynidae**). Photo by Christophe Quintin, through Creative Commons.

It is interesting that several species that live among mosses in forested sites live instead under stones in the open tundra (Dondale *et al.* 1997).

In their study of the tundra spiders in Tuva, South Siberia, Logunov *et al.* (1998) reported on habitats that had little prior study. These researchers compared the species found in mountain moss-tussock-shrubby wet tundra, the mountain moss tussock, and mountain moss-lichen-stony tundra. The most represented families in the wet, mossy tundra were **Gnaphosidae** (5 spp.), **Linyphiidae** (33 spp.) – they formed the highest proportion of species exclusive to the mountain moss-lichen-stony tundra and had the highest species richness in both habitats, **Lycosidae** (12 spp.), **Philodromidae** (3 spp.), **Salticidae** (6 spp.), **Theridiidae** (3 spp.), and **Thomisidae** (7 spp.), plus one other (Logunov *et al.* 1998). In the stony tundra, the most represented families were similar, with **Dictynidae** (1 sp.), **Gnaphosidae** (8 spp.), **Linyphiidae** (12 spp.), **Lycosidae** (4 spp.), **Salticidae** (3 spp.), and **Thomisidae** (2 spp.). The moss-lichen-stony tundra had the most exclusive species among the 23 habitat types studied, but the number may represent under collection, with only 14 species collected in the scree.

Logunov *et al.* (1998) demonstrated that at Tuva, differing from species at the moss-tussock shrubby tundra, the species in the mountain moss-lichen-stony tundra included: *Agyneta olivacea* (**Linyphiidae**), *Monocerellus montanus* (**Linyphiidae**), *Euophrys prozyskii* (**Salticidae**), *Talaera* sp. 2 (**Salticidae**), *Gnaphosa* species (**Gnaphosidae**), *Mongolicosa pseudoferruginea* (as *Acantholycosa triangulata*; **Lycosidae**), and *Pardosa baraan* (**Lycosidae**). This diversity of family representation seems to represent specialization of individual species and even includes large spiders (**Lycosidae**).

A surprisingly small number of Siberian species were found in both the mountain moss-lichen-stony tundra and the moss-tussock shrubby tundra habitats (Logunov *et al.* 1998): *Euophrys flavoatra* (**Salticidae**), *Parasyriscus logunovi* (**Gnaphosidae**), *Tibioplus diversus* (Figure 169; **Linyphiidae**), *Typhochrestoides baikalensis* (**Linyphiidae**), *Victorium putoranicum* (**Linyphiidae**), *Xysticus austrosibiricus* (**Thomisidae**).

Figure 169. *Tibioplus diversus* on moss. Photo by Walter Pfliegler, with permission.

Centromerus clarus (**Linyphiidae**), *Parasyriscus ulykpani* (**Gnaphosidae**), and *Thaleria sajanensis* (**Linyphiidae**) were unique to the mountain moss-tussock-shrubby wet tundra (Logunov *et al.* 1998).

On the other hand, the species in the mountain moss-tussock-shrubby wet tundra included many of the same species as the mountain moss tussock (Logunov *et al.* 1998). These were mostly members of the **Linyphiidae**: *Agyneta fuscipalpus*, *Agyphantes sajanensis* (as *Lepthyphantes sajanensis*), *Anguliphantes sibiricus* (as *Lepthyphantes sibiricus*), *Bathyphantes similimus* (Figure 170), *Bolyphantes distichus* (as *Lepthyphantes distichus*), *Ceratinella wideri*, *Decipiphantes decipiens*, *Episolder finitimus*, *Erigone atra* (Figure 171), *Hilaira herniosa* (Figure 172), *Hylyphantes nigrinus* (Figure 173-Figure 174), *Improphantes flexilis*, *Lepthyphantes luteipes* (a genus represented among mosses elsewhere by different species), *Mecynargus monticola* (Figure 175) [also in the Yukon tundra (Dondale *et al.* 1997)], *Meioneta affinisoides* (as *Agyneta affinisoides*), *Mughiphantes cornutus* (as *Lepthyphantes cornutus*), *Panamomops dybowskii* (a genus represented by different species in grasslands), *Panamomops tauricornis*, *Pelecopis dorniana* (Figure 176), *Savignia frontata* (Figure 146; also among mosses in grasslands of the UK), *Scotinotylus protervus*, *Semljicola latus*, and *Silometopus uralensis* (see Figure 177). Only *Semljicola* matched a genus also found in the Hudson Bay study (Koponen 1992).

Another Siberian spider that shares its habitat with bryophytes is *Chalcoscirtus hyperboreus* (see Figure 178; **Salticidae**), which occurs in humid moss-shrub tundra (Danilov & Logunov 1993).

Figure 178. *Chalcoscirtus alpicola*, a relative of *C. hyperboreus* that lives among bryophytes in the tundra. Photo by Barbara Thaler-Knoflach, with permission.

Clubionidae

Non-lyniid spiders include *Clubiona trivialis* (Figure 87) in moss in meadows and pastures (Schenkel

1925; Holm 1980; Lissner 2010, 2011), a species also from heathland mosses.

Gnaphosidae

The **Gnaphosidae** were represented in the Siberian tundra by *Gnaphosa borea*, *G. leporina* (Figure 15), also in wet heathland in Denmark, and *G. sticta* (Figure 179), all unique to the mountain moss-tussock-shrubby wet tundra at Tuva, South Siberia (Logunov *et al.* 1998). However, in the mountain moss-lichen-stony tundra in the same area, *G. muscorum* (Figure 180) and *G. pseudoleporina* were the species present among the mosses. Another represented genus of **Gnaphosidae** among mosses at Tuva was *Micaria*, including *M. alpina* (Figure 155), also found among mosses in the mountainous locations elsewhere and *M. viaria* (Figure 46) also known from woodland mosses elsewhere (Logunov *et al.* 1998). In the Arctic Yukon, *Micaria* is represented among mosses by *M. constricta* (Dondale *et al.* 1997). Dondale and coworkers also reported *Drassodes neglectus* (Figure 181) from the Arctic Yukon. *Zelotes potanini*, also in the **Gnaphosidae**, was present in the mountain moss-lichen-stony tundra at Tuva (Logunov *et al.* 1998).

Figure 179. *Gnaphosa sticta* (**Gnaphosidae**) female. Photo by Glenn Halvor Morka, with permission.

Figure 181. *Drassodes neglectus* (Gnaphosidae). Photo by John Sloan, with permission.

Hahniidae

The **Hahniidae**, including eurytopic *Hahnia montana* (Figure 37; also known from forest mosses elsewhere), live among mosses in the Faroes (Lissner 2011). The spiders in this family hunt on the upper side of the sheet web, unlike the Linyphiidae, and apparently have no retreat. *Hahnia* cf. *ononidum* (Figure 38) lives in the mountain moss-tussock-shrubby wet tundra of Siberia (Logunov *et al.* 1998).

Linyphiidae

Dondale *et al.* (1997) report that most of the tundra members of the **Linyphiidae** occur among mosses. Some moss-dwelling genera seem to be represented by different species in different places in the tundra as already seen at Tuva, South Siberia. One such genus is *Erigone*. In Tuva, Logunov *et al.* (1998) found *Erigone atra* (Figure 171) in the mountain moss-tussock-shrubby wet tundra as well as in the mountain moss tussock, whereas in the mountain moss-lichen-stony tundra they found *E. remota*. Sherriffs (1934) found *Erigone arctica* var. *maritima* (Figure 182) with *Polytrichum* sp. (Figure 43-Figure 44) in Iceland. And Lissner (2011) found *Erigone psychrophila* (Figure 183) among mosses on the Faroe Islands. These all differ from *Erigone tirolensis* reported from mosses in the East Alps.

Figure 182. *Erigone arctica* female on mosses. Photo by Jørgen Lissner, with permission.

Figure 183. *Erigone psychrophila* female in moss. Photo by Jørgen Lissner, with permission.

One of the **Linyphiidae**, *Scotinotylus*, is a northern latitude genus with several species endemic to North America (Millidge 1981). *Scotinotylus bicornis* is known from several specimens at only one location, at 1400 m in British Columbia, Canada, where a single female was reported from moss on a rock slide (Millidge 1981); no habitat was given for the other collections. *Scotinotylus evansi* was present among mosses on the Faroe Islands (Lissner 2011) and also in Iceland (Agnarsson 1996). The genus *Scotinotylus* was one of the more diverse genera among mosses in the South Siberian tundra (Logunov *et al.* 1998), where *Scotinotylus alpigenus*, *Scotinotylus altaicus*, and *Scotinotylus protervus* were present among mosses in both mountain moss-tussock-shrubby wet tundra and the mountain moss tussock.

Some *Walckenaeria* species in the mountain moss-lichen-stony tundra of Siberia are different from those in other habitats reported herein. Entling *et al.* (2007) considered that the niche of spiders evolved faster than the physiological or morphological characters. Based on 244 published spider communities representing 70 habitat types, they reported that the greatest variation was between species within genera. Like *Erigone* and *Scotinotylus*, the genus *Walckenaeria* supports this concept with representation among many habitats but with differences in represented species. In the tundra, this genus includes *Walckenaeria koenboutjei* and *Walckenaeria korobeinikovi* (Logunov *et al.* 1998), not reported from other habitats in this chapter. To these, Dondale *et al.* (1997) added *W. exigua*, *W. karpinskii* [as *W. holmi* – also in North America and Greenland (Millidge 1983)], and *W. spiralis* from the Yukon tundra. However, other species of this genus that are more common elsewhere also occur among mosses on the Faroe Islands (Lissner 2011): *Walckenaeria antica* (Figure 99), *W. clavicornis* [Figure 100; also among mosses in Greenland (Holm 1967)], *W. cuspidata* [Figure 52; also among mosses in Iceland (Agnarsson 1996)], *W. nodosa* (Figure 54), *W. nudipalpis* (Figure 101), and *W. obtusa* (Figure 184). Several species of *Walckenaeria* were also present among *Racomitrium* (Figure 194-Figure 195) in the low Arctic of the Belcher Islands, Hudson Bay (Koponen 1992).

Figure 184. *Walckenaeria obtusa*. Photo by Ruth Ahlburg, with permission.

Several additional linyphiid genera were present among mosses on the Faroe Islands as well as in the Siberian tundra, but the species were different. Lissner (2011) reported *Improphantes complicatus* (Figure 96), a species also found among mosses in Iceland (Agnarsson 1996), Yukon tundra (Dondale *et al.* 1997), and Greenland (Lissner 2011) in heathlands and grasslands. He also found *Ceratinella brevipes* (Figure 74; also known from mosses in forests, heath, grasslands, and mountains elsewhere) and *Semljicola faustus* (Figure 91), also known from mosses in heathland and swampy places elsewhere.

In the low Arctic of the Belcher Islands, Hudson Bay, Koponen (1992) sieved the thick *Racomitrium* moss layer (Figure 194-Figure 195). This method frequently revealed *Semljicola obtusus* (as *Latithorax obtusus*). Koponen also found *Horcotes quadricristatus* by hand-picking in the moss-lichen layer. *Diplocephalus sphagnicola* occurred on moss at the dry rock site of the moss-lichen tundra and shore in central Flaherty Island, also in the Hudson Bay.

Although the volcanic Kurile Islands in the Ring of Fire are not in the Arctic, the northernmost islands have tundra vegetation, and the volcanic activity and location create a severe climate on the islands. Most of the precipitation falls as snow, but the summers are foggy. Here one can find the linyphiid *Oreoneta kurile* in moss and meadow litter (Saaristo & Marusik 2003).

Faroe Islands

Lissner (2011) and Holm (1967) investigated the spiders of the Faroe Islands, citing many bryophyte associations. The islands are in a tundra biome, so many of these species might be considered tundra species. Most, however, have been discussed under other habitats, especially mountains and altitudinal effects, and will not be repeated here.

It appears that most of the moss dwellers are in **Linyphiidae**. Among those linyphiid genera not located in Siberia, Lissner found *Centromerita bicolor* (Figure 185), *Gonatium rubens* (Figure 157; including mosses in mountains of the Faroes and heathlands elsewhere), *Hypomma bituberculatum* (Figure 115), *Leptorhoptrum robustum* (Figure 97), *Oreoneta frigida*, *Palliduphantes ericaeus* (Figure 95; known from mosses of heathlands and moist meadows), *Poeciloneura variegata* (Figure 90), and *Porrhomma montanum* (Figure 160; also from mosses in grasslands and mountains) [also in Iceland (Agnarsson 1996)]. *Porrhomma convexum* (Figure 42) occurred at 0-900 m asl in Iceland and in the Faroe Islands (Lissner

2011). *Porrhomma egeria* occurred in Iceland tundra (Agnarsson 1996), whereas in Britain, it was often found in deeper parts of caves, less frequently outside caves within moss (Harvey *et al.* 2002).

Figure 185. *Centromerita bicolor*. Photo by Arno Grabolle <www.arnograbolle.de>, with permission.

Agyneta decora (Figure 92) is found among mosses in the Faroe Islands (Lissner 2011) and Iceland (Agnarsson 1996). *Agyneta subtilis* and *A. ramosa* (Figure 186-Figure 187) both occur in mosses in the Faroe Islands, but are also known from mosses in non-tundra habitats in Britain (Harvey *et al.* 2002). All three of these species are known from mosses outside the tundra, with *A. decora* and *A. subtilis* from heathlands and *A. ramosa* from forests. In the Yukon, this genus is represented among tundra mosses by *Agyneta olivacea* (Dondale *et al.* 1997).

Figure 186. *Agyneta ramosa* male on moss. Photo by Jørgen Lissner, with permission.

Figure 187. *Agyneta ramosa* male on moss detritus. Photo by Jørgen Lissner, with permission.

Lissner (2011) reported *Meioneta nigripes* (Figure 159) from tundra mosses of the Faroe Islands; this species is also known from mosses in the mountains of the UK. *Meioneta affinisoides* was listed earlier from the Siberian tundra. Dondale *et al.* (1997) reported *Meioneta lophophor* from tundra mosses in the Yukon. Bengtson *et al.* (1976) recognized the importance of bryophytes for the Icelandic spider fauna and suggested that more species might be found in the thick moss layer of the grass meadow. But they only specifically identified one spider, *Meioneta saxatilis* (Figure 188; **Linyphiidae**), from mosses there.

Figure 188. *Meioneta saxatilis*. Photo ©Pierre Oger, with permission.

Oreonetides vaginatus (Figure 89; also in mosses of heathlands elsewhere) occurs in the Faroes among moss in snow beds with *Salix herbacea* and other habitats (Holm 1967; Lissner 2011). This is among the few bryophyte-dwelling spiders in common with those of the Yukon tundra (Dondale *et al.* 1997), where it occurs in bogs and alpine areas. Holm (1980; Lissner 2011) found *Saaristoa abnormis* (Figure 189) among *Sphagnum* (Figure 162) and the weft-forming feather moss *Hylocomium* (Figure 94) in the Faroe Islands.

Figure 189. *Saaristoa abnormis* male on moss. Photo by Jørgen Lissner, with permission.

Centromerus arcanus (Figure 62) occurs among mosses in the Faroe Islands, but also occurs in mountainous regions of Britain (Harvey *et al.* 2002). *Diplocentria bidentata* (Figure 64), also known from forest mosses – see above, *Gongylidiellum vivum* (Figure 81), a eurytopic species discussed above for bryophytes in a number of other habitats, *Hilaira nubigena* (Figure 158), also known from bryophytes in mountains in the UK, *Savignia frontata* (Figure 146) also known from grassland mosses in the UK, *Tenuiphantes mengei* (Figure 98), *Tenuiphantes zimmermanni* (Figure 24) (both *Tenuiphantes* species occur among mosses in other habitats as well), *Tiso vagans*, and *Tmeticus affinis* (Figure 190) likewise occur among mosses in the Faroes (Lissner 2011). *Tenuiphantes zelatus* is known from mosses in the Yukon tundra and alpine areas (Dondale *et al.* 1997).

Figure 190. *Tmeticus affinis* on leaf. Photo by Jørgen Lissner, with permission.

Several species of *Mecynargus* occur among mosses in the tundra. *Mecynargus morulus* (Figure 93) occurs on the Faroe Islands (Lissner 2011), as well as among bryophytes in the heathlands and mountains elsewhere. Koponen (1992) reported *Mecynargus borealis* (as *Conigerella borealis*) from sieving the thick *Racomitrium* mat in the low Arctic of the Belcher Islands, Hudson Bay. *Mecynargus monticola* (Figure 175) occurred among mosses in Tuva, South Siberia (Logunov *et al.* 1998).

Yukon

Many of the species reported from the Yukon tundra mosses have been discussed above, but a number of species have not been reported elsewhere herein. These include *Ceraticelus alticeps*, *C. bulbosus*, *C. laticeps*, *Ceratinopsis labradorensis*, *Cnephalocotes obscurus* (Figure 113; also in the Ural Mountains and widespread in other habitats where it lives in mosses as shown above), *Hybauchenidium gibbosum* (Figure 191), *Incestophantes washingtoni* (Figure 192) also in alpine mosses), *Ivielum sibiricum*, *Macrargus multesimus* (Figure 193) also in birch forests), *Procerocymbium sibiricum* (also among alpine mosses elsewhere), and *Sisis rotundus* (Dondale *et al.* 1997).

Figure 192. *Incestophantes washingtoni*. Photo by Gergin Blagoev, through Creative Commons.

Figure 193. *Macrargus multesimus* male. Photo by John Sloan, with permission.

Lycosidae

This family of hunters is able to run across the open spaces of the tundra, and in the Yukon they are better represented than they are among most other mossy habitats. Koponen (1992) reported juveniles from sifting through the moss *Racomitrium* from hummocks (Figure 194-Figure 195). Dondale *et al.* (1997) has contributed a number of Arctic tundra records for lycosids (wolf spiders) associated with bryophytes:

<i>Arctosa alpigena</i>	Holarctic; alpine
<i>Arctosa raptor</i>	Nearctic; alpine
<i>Pardosa furcifera</i>	Nearctic; alpine
<i>Pardosa fuscula</i>	Nearctic; alpine
<i>Pardosa hyperborea</i>	Holarctic; alpine
<i>Pardosa nordicolens</i>	Arctic
<i>Pirata piraticus</i>	Holarctic; lake & stream margins

Figure 194. *Racomitrium* heath in Iceland. Photo by Janice Glime.

Figure 195. *Racomitrium lanuginosum*, a spider habitat in the tundra. Photo by Michael Lüth, with permission.

Sherriffs (1934) reported *Arctosa alpigena* (Figure 161; *Lycosidae*) among *Calliargon* sp. (Figure 196) in Iceland, a species later located by Lissner (2011) among mosses in the Faroe Islands and by Almquist (2005) in Sweden. In Iceland and other tundra locations, extensive areas are covered by the moss *Racomitrium* (Figure 194-Figure 195), where *Arctosa alpigena* also occurs in *Racomitrium* "heaths" (Harvey *et al.* 2002).

Figure 196. *Calliergon giganteum* in Europe. Photo by Michael Lüth, with permission.

Pardosa palustris (Figure 197) occurs among mosses in a wide range of habitats on the Faroe Islands, including grassy heath (Schenkel 1925; Bengtson & Hauge 1979; Holm 1980), but differs from *Pardosa baraan* found among mosses in the mountain moss-lichen-stony tundra of Siberia (Logunov *et al.* 1998).

Bryophytes vs Lichens

In many cases, such as cryptogamic crusts, lichens seem to offer many of the same benefits as bryophytes. They provide small crevices where small organisms can hide from would-be predators and escape the rays of the sun. But if it is protection from moisture loss, many kinds of lichens often do not provide the safe haven that spiders can find among the bryophytes. This is especially true for crustose lichens that would seem to offer only a disruptive coloration that makes the tiny spiders less conspicuous (Figure 198). For the Northern Hemisphere *Zygiella atrica* (Figure 199; *Araneidae*), mosses may play a role as a disruptive habitat when the spider has been disturbed from its aerial habitat, typically of bushes. When disturbed, it drops quickly to the ground (Roberts 1985), and if mosses are there, they could make it less conspicuous. However, the coloration on its abdomen suggests it might fare better among leaf litter.

Figure 198. *Zygiella atrica* female sitting on a covering of crustose lichens on bark. This lichen offers little in the way of protection and may add only a disruptive background where the spider is less conspicuous. This species apparently is not known from bryophytes (Wikipedia 2011). For spiders adapted to dry habitats, this location can be an advantage, whereas the damper and more convoluted habitat of a bryophyte might hinder rapid escape and be too damp. Photo by Jørgen Lissner, with permission.

Figure 199. *Zygiella atrica* male on bark. Photo by Jørgen Lissner, with permission.

Although it seems like mosses and lichens could offer similar habitats, in their report on Yukon bryophytes Dondale *et al.* (1997) report several spider species on lichens, but not on bryophytes, and many on bryophytes but not on lichens. When they occurred on both, the two substrates were sometimes in different habitats, suggesting possible moisture differences.

Casual Users

The list of spiders that may nest in or hide in bryophyte patches is surely a long one. Our knowledge is insufficient to know if there is any preference among these spiders, although at least a few seem to exist, but it appears that most of them are like some of the non-bryologists – they find no particular role for bryophytes vs any other short-statured substrate, including litter.

In many studies, the authors mention the presence of bryophytes and may even compare presence of spiders in mossy vs non-mossy areas at a research site. But one must guess that often the correlation of spiders with the presence of bryophytes is one of mutual need for the conditions that

promote the establishment of bryophytes, rather than a need for the bryophytes.

In any case, when bryophytes are present in the habitat, spiders will most likely traverse them from time to time. In some cases this will benefit the spider as a camouflaged background, whereas in others the bryophyte may provide a drink of water or rehydration site. But for some spiders, bryophytes are just part of the terrain and will be traversed when between the spider and its destination, hence creating the casual user.

The orb weaver spider, *Cercidia prominens* (Figure 200; **Araneidae**) is among those that can occasionally be found on mosses, but its relationship to them is poorly known and that is not its typical habitat. It is known to occur "at the base of mossy or heathery banks" along footpaths and makes orb webs among low vegetation (Roberts 1985). When disturbed, the spider drops into the litter layer, and this layer may likewise include mosses in some locations.

Figure 200. *Cercidia prominens* male, known from mosses, but most likely only as accidental visitors. Photo by Jørgen Lissner, with permission.

Amaurobius ferox (Figure 201; **Amaurobiidae**) might be one of these casual users. This unusual spider makes me glad I am not its mother! The species practices matricide (Kim & Roland 2000; Kim *et al.* 2000). That's right, the young eat their mother, and she actually encourages it! This ungrateful behavior ensures a greater survival of the young by giving them, apparently, a good nutritional start in life. But that is not all she does to ensure their success. The first generation of offspring may eat her eggs for her next set of offspring, giving the first clutch a greater chance for success, and increasing the success of matricide in that first clutch (Kim & Roland 2000). The young spiderlings can stimulate the release of the second clutch of eggs from the mother at an earlier developmental stage than usual. In experiments, survival success was greater when this first clutch had access to the eggs than when it was the second clutch that procured eggs as food. Bryophytes can occur in the neighborhood, but do not seem to provide any particular function in this spider's life.

In other cases, the spiders live in boggy areas where the moss creates the habitat needed for the trees and shrubs they inhabit. For example, *Araneus nordmannii* (Figure 202; **Araneidae**) lives in boggy areas of the Tatras

National Park, southern Poland (Svatoň & Kovalčík 2006), but typically it occurs in dense forests, making its webs between tree trunks and branches. It is more common in the USA and Canada than in Europe.

Figure 201. *Amaurobius ferox*, a casual inhabitant of mosses, seen here "in the neighborhood." However, its nest among mosses suggests that it is at least not adverse to a mossy habitat. Photo by Trevor and Dilys Pendleton <www.eakringbirds.com>, with permission.

Figure 202. *Araneus nordmannii*, a species known from boggy areas in the Tatras National Park, southern Poland, but typically from dense forests, making webs between tree trunks. Photo by Tom Murray, through Creative Commons.

The list in Table 1 includes those species I have determined as bryophyte dwellers. However, a few, as indicated, were identified by their images on bryophytes, where they may be casual visitors or even posed.

Table 1. Species of spiders known to me that occur in association with bryophytes. Most of these have been collected by methods that targeted bryophytes. None has specifically identified liverworts, although they presumably were included in some cases. The number of citations are an indication of the frequency of the species among locations, but the same is not true for genera. If only the genus was named, it has not been listed separately from a known species, albeit sometimes from a different location. + indicates species for which I have seen photographs of the spiders associated with a moss, but the association may be spurious or staged.
