CHAPTER 2-5
BRYOPHYTA - SPHAGNOPSIDA

Class Sphagnopsida – the peat mosses

The class Sphagnopsida is very different from other members of Bryophyta (sensu stricto). It certainly is worthy of its own class, and some agree with Crum (2004) that it is likewise worthy of its own phylum, the Sphagnophyta. Certainly its morphological differences play a major role in its unusual ecology. Until recently it was composed of only one genus (Sphagnum; Figure 1), but now the family Ambuchananiaceae (one genus, Ambuchanania) has been described from Tasmania, and possesses rhizoids. The only other member of Sphagnopsida with rhizoids is Sphagnum (=Flatbergium) novo-caledoniae (Figure 2-Figure 4), an epiphyte (Iwatsuki 1986; plants that grow on another plant without deriving nutrients from it) that grows in or near rivers (IUCN 2013).
Sphagnaceae

Of all the Bryobiota, *Sphagnum* is best known to the layperson because of its formation of peat and use in horticulture. The class Sphagnopsida is distinguished by leaves that are one cell thick and mostly possessing two types of cells – photosynthetic cells that possess chloroplasts and that form a network arrangement, and hyaline (colorless) cells that are dead at maturity, have one or more pores (giving access to the environment), and hold water (Figure 44). These hyaline cells form transparent patches among the network formed by the photosynthetic cells and may be equal in height to those cells or may surround them on the top (inner leaf surface) or on both surfaces. This arrangement seems to correlate well with the ability to avoid desiccation because the hyaline cells provide a reservoir of water to the photosynthetic cells. Those species typically occupying drier habitats generally have more of the hyaline cell surrounding the photosynthetic cell. These hyaline cells are usually strengthened by bar-like thickenings (fibrillae, Figure 44) in the cell walls, making them look superficially like many cells instead of the single long cell that they are. These leaves never possess a costa (moss version of a midrib).

The branches in Sphagnopsida occur in fascicles (bunches) along the stem, usually with some descending branches close to the stem (helping in capillary movement of water) and some extending outward. The stems have a wood-like cylinder that may be brittle or soft. The most readily distinctive feature is the arrangement of young branches in a tight capitulum (Figure 45), the result of branch production and elongation without the elongation of the stem. As older portions of the stem elongate, new branches form and the capitulum is maintained. This gametophyte can reproduce by fragmentation, often bifurcating at the apex to produce two capitula.

This large genus can be divided into two groups based on the large, succulent-looking leaves vs the small leaves on more narrow branches. But this grouping did not work well phylogenetically, so instead nine sections were recognized. These were recently reorganized into subgenera based on 11,704 nucleotide sequences from the nuclear, plastid, and mitochondrial genomes (Shaw et al. 2010):

**Subgenus Sphagnum** is characterized by tightly or loosely imbricate, hood-shaped (cucullate) branch leaves and large, tongue-shaped (lingulate) or fan-shaped stem leaves (> 1 mm long) (Figure 5-Figure 12).

**Subgenus Rigida** is the other group with cucullate branch leaves but is separated by small (< 1 mm long), triangular stem leaves and somewhat (or not) squarrose (spreading at right angles) branch leaves (Figure 13-Figure 14).

**Subgenus Cuspidata** has a pronounced difference between hanging branches and spreading branches, usually with hanging branches longer and more slender than spreading branches; stem leaves are much smaller than branch leaves and usually hang downward on the stem; colors vary but are never red; they are typical in wet mineral-rich depressions, submerged or near the water level (Figure 15-Figure 24).

**Subgenus Subsecunda** has flexuose hanging and spreading branches that are very similar, about the same length, or with few no branches; stem leaves are much smaller than branch leaves and usually hang downward on stems; plants are various colors but never red (branches and stems sometimes pinkish) (Figure 25-Figure 29).

**Subgenus Squarrosa** has distinctly squarrose branch leaves and large (1-1.5 mm long) lingulate stem leaves (Figure 30-Figure 31).

**Subgenus Acutifolia**

Section *Acutifolia*, like Subgenus *Cuspidata*, has a pronounced difference between hanging branches and spreading branches, usually with hanging branches longer and more slender than spreading branches; they differ from *Cuspidata* in having stem leaves nearly the same size as branch leaves or larger and usually upright on stems; plants are various shades of green, brown, or red (Figure 32-Figure 41F).

Section *Polyclada* is monotypic and lacks the cucullate leaf structure, being distinguished by having six or more branches per fascicle and a dense, rounded capitulum (Figure 42).

Section *Insulosa* has toothed branch leaves and pores in hyaline cell ends (Figure 43).

Chapter 2-5: Bryophyta – Sphagnopsida

2-5-10

Figure 45. *Sphagnum fimbriatum* showing capitulum where archegonia will arise. Photo by Janice Glime.

The **antheridia** are nearly globose (Figure 46) and are nestled among the leaves near the tips of the capitulum branches, usually endowing those tips with a reddish color (Figure 47). The **archegonia** are terminal on short branches near the center of the capitulum.

Figure 46. Globose *Sphagnum* antheridia nestled among the leaves of a capitulum branch. Photos by Janice Glime (top) and Yenhung Li (bottom), with permission.

Jennings (1915) and Bryan (1915 in Jennings 1915) recognized the unique character of *Sphagnum*. They described a globose antheridial head that began development in August, before the September initiation of the archegonia. They discovered that some of the oldest archegonia matured by 25 October, whereas others did not mature until spring. But the uniqueness was the structures. The archegonia have a stalk, thick venter, and a narrow, twisted neck, all characteristic of mosses. But their inactive cover cell, intercalary growth of the archegonia, and the small number of canal cells (8-9) are characteristic of liverworts.

Figure 47. Antheridial branches in the capitulum of *Sphagnum*. Red coloration is from the antheridia. Photo by Janice Glime.

*Sphagnum capsules* (Figure 48), or sporangia, are rarely seen in many of the species, but some fruit abundantly. Nevertheless, one must be lucky to see them because they, like the liverwort sporophytes, are **short-lived**. They develop from fertilized eggs (zygotes) in the capitulum (Figure 45). As these develop embryos, they likewise form a **foot**, **stalk**, and **capsule** (Figure 48), but the stalk does not elongate. Instead, it remains with its foot, embedded in gametophyte tissue. *Sphagnum* is much like the liverworts in that its stalk matures after the capsule is mature, but in *Sphagnum*, this watery stalk (**pseudopodium**, pl. **pseudopodia**) is part of the gametophyte generation, not the sporophyte (Figure 48). It soon disintegrates, as do the liverwort stalks.

The capsule does not split as in liverworts and the **Takakiopsida**, **Andreaeopsida**, and **Andreaeobryopsida** in the **Bryophyta**, but instead possesses an operculum (lid; top part of capsule of mosses that comes off for spore dispersal) that is shed prior to spore dispersal (Figure 48), as in the **Bryophyta** classes **Bryopsida** and **Polytrichopsida**. However, unlike most members of the latter two classes, it lacks a peristome (set of teeth-like appendages around the opening of capsule; Figure 48). The **columella** (Figure 48), that central mass of sterile tissue that is like a column in **Bryopsida** and **Polytrichopsida**, is globose in *Sphagnum*, protruding like a knob into the center of the capsule without reaching its top. **Elaters are lacking**, a characteristic shared with all other *Bryophyta* (**sensu stricto**).

Within the capsule, meiosis occurs, producing the spores. When the spores are mature, the **operculum** (Figure 48) is shed explosively when the capsule shrinks and compresses the gases, dispersing nearly all the spores in one blast of 4-6 atmospheres of pressure (Crum 2004; see Chapter 4-9). In fact, bryological folklore claims that one can hear the explosions when the sun and moisture are
just right to cause the capsules to explode. No extant sphagnologist seems to have actually heard this, but following a *Sphagnum* field trip at an international meeting in Great Britain, one of the bryologists was startled to hear ping...ping-ping...ping-ping-ping while he was sitting in bed reading. He had put his *Sphagnum* with capsules under the bed lamp to dry, and so it had, with capsules shrinking and exploding. The pings were opercula hitting the metal shade on the lamp!

It appears that *Sphagnum* is prolific in its spore production, ranging 8-90 million among six species examined by Sundberg (2005). And these spores seem to disperse quite well, with only 2-14% of those dispersed remaining within the parent colony. Being large helps. The larger capsules dispersed a greater percentage of spores, had a smaller percentage trapped within the parent colony, and thus dispersed more spores to greater distances.

In the presence of moisture and light, and at least some nutrients, particularly phosphates (see Sundberg & Rydin 2002; Claeyss 2017), the spores germinate to form a short thread. This thread soon, however, divides in more than one direction to form a thalloid protonema (Figure 48), as in most liverworts. A similar thalloid protonema is present also in other bryophytes such as *Andreaea* (Bryophyta class Andreaeopsida) and would be more appropriately called a sporeling. Like the liverworts, and unlike the other mosses, each protonema produces only one bud, thus only one mature gametophyte.

Figure 48. *Sphagnum* life cycle stages. Upper left photo by Zen Iwatsuki; others by Janice Glime. Protonema drawing by Margaret Minahan and Noris Salazar Allen, with permission.
Flatbergiaceae (= Sphagnaceae?)

Shaw (in Shaw et al. 2010) separated this family morphologically from Sphagnaceae by its efibrillose leaves. It is currently monotypic, with only the species Flatbergium sericeum. Currently, however, both Tropicos and The Plant List (Kew) consider this genus to belong in the Sphagnaceae. A second species is implicated for the family (Devos et al. 2016), based on molecular data. This would transfer Sphagnum novo-caledoniae to Flatbergium novo-caledoniae (Figure 49).

Ambuchananiaceae

Not many of us get to describe a new order. And certainly no one was expecting one in the Sphagnopsida! (Buchanan 2008). But this organism, this moss, was certainly something new! – Ambuchanania leucobryoides (Figure 50).

Excerpts from correspondence with Rod Seppelt

"We knew it from two localities in south western Tasmania. Alex Buchanan found it in acid gravelly sand outwash near the coast. Heathy vegetation, very low nutrient status soils. The plants were mostly buried in the sand, only the top few mm showing."

"When I first saw the material I kept trying to put it in Leucobryaceae. Same habit, hence the epithet. Initially I thought I saw a peristome. The leaves did not fit anything in Leucobryaceae. Then the penny dropped – it had no peristome. The position of the archegonia also started to ring bells."...

"So, no protonema is, as yet, known. We have a second locality, inland, from acid, low nutrient, peat amongst button grass moorland (Gymnoschoenus, which is a tussock sedge, not a grass). Alex spotted it amongst the base of some Isolepis material (pressed) that had been brought into the Tasmanian Herbarium for incorporation."

"Leaf morphology. Yes, it does have chlorophyllose cells and hyaline cells. The thickenings on the walls of the hyaline cells are a bit weird... Norton Miller first asked me if I thought of describing it as a second genus in Sphagnaceae."

"Ultimately, Howard Crum wrote to say that he was so convinced that it was so different from Sphagnum, but within the Sphagnales, that it required a separate genus Ambuchanania, new family Ambuchananiaceae. Incidentally, Jon Shaw has managed to get some DNA sequencing (incomplete) but he concurs that it is not Sphagnum, although (I believe) happy to see it remain in the Sphagnales."

An endemic of Tasmania, Ambuchanania leucobryoides occurs in sandy washes known as "daisy pans" derived from Precambrian quartzite (Johnson et al. 2008). Ambuchanania has been collected at two relatively inaccessible, high elevation localities in western Tasmania (Yamaguchi et al. 1990).

Now, this strange, yet somewhat familiar genus resides not just in a new family, but a new order, the Ambuchaniales. It differs from Sphagnum in lacking fascicles, being sparsely branched, and lacking the "wood" cylinder of the stem. Its leaves are partially bistratose but have those telltale hyaline and photosynthetic cells (Figure 51-Figure 52). It is anchored by rhizoids, a character found in Sphagnum only in one epiphytic species. Its archegonia are located terminally on stems and its capsules are cylindrical, and likewise perched on an elevated pseudopodium.

Figure 51. Ambuchanania leucobryoides leaf showing hyaline and photosynthetic cells. Photo by Lynette Cave, with permission.
the Sphagnum sporophyte is a deliquescent extension of the gametophyte (pseudopodium) and it develops after the capsule is mature. Sphagnopsida lack teeth in the capsule but have an operculum, which the capsule sheds explosively.

The life cycle involves a protonema that develops from the germinating spore, becoming thalloid in Sphagnum, whereas it becomes a branched thread in true mosses. The protonema produces one bud that develops into a leafy gametophore.

Acknowledgments

I appreciate the comments and suggestions of Karla Werner, who offered a beginner's perspective. Noris Salazar Allen offered constructive criticisms on the taxonomic descriptions and helped with the proof reading. I appreciate Rod Seppel's correspondence that added human interest to this story. Louis Thouvenot took pictures of Flatbergium (=Sphagnum novo-caledoniae) for me so I could illustrate rhizoids. Lynette Cave answered my call for pictures of Ambuchanania and notified me of an error in the text. Jon Shaw helped me update the nomenclature and classification for the Sphagnopsida. Blanka Shaw provided me with images of Eosphagnum.
