Interaction between the carbon nanotube (CNT) and deoxyribonucleic acid (DNA) has been a subject of interest for almost two decades1–9 ever since it was known that CNTs possess many interesting properties. For example, applications of the CNT-DNA conjugates as DNA transporters,10 biosensors,11 and field effect transistors12 (FET) have been reported. DNA has also been used as an agent for dispersion and sorting of CNTs in solution.13,14 These results instigated further investigations for a detailed understanding of the interaction of CNTs with inorganic and organic moieties. There is also an increasing interest in the usage of functionalized CNTs as biosensing devices. The experimental fact that the BNNTs, within a large background current masks relatively small changes in current due to the biomolecular adsorption. The results therefore suggest the suitability of BNNTs for biosensing applications. © 2013 AIP Publishing LLC. [http://dx.doi.org/10.1063/1.4801442]

The effect of molecular adsorption on the transport properties of single walled carbon and boron nitride nanotubes (CNTs and BNNTs) is investigated using density functional theory and non-equilibrium Green’s function methods. The calculated I-V characteristics predict noticeable changes in the conductivity of semiconducting BNNTs due to physisorption of nucleic acid base molecules. Specifically, guanine which binds to the side wall of BNNT significantly enhances its conductivity by introducing conduction channels near the Fermi energy of the bioconjugated system. For metallic CNTs, a large background current masks relatively small changes in current due to the biomolecular adsorption. The results therefore suggest the suitability of BNNTs for biosensing applications.

In this letter, we consider nucleobases of DNA and RNA (i.e., guanine, adenine, cytosine, thymine, and uracil) interacting with single-walled CNT and BNNT. Our focus will be to understand how the adsorption of the nucleobases affects the electrical transport properties of metallic CNTs and semiconducting BNNTs and, thereby, their applicability as biosensing devices. The experimental fact that the response of the device does not change for the DNA-conjugated CNT device relative to that of the pristine CNT device will be used to benchmark the modeling elements of our computational method.

The electronic structure calculations were first performed on the bioconjugated complex consisting of a nucleobase adsorbed on a tubular configuration of either CNT or BNNT. We employed the plane-wave pseudopotential approach within the local density approximation (LDA)25 of density functional theory (DFT).25,26 The Vienna Ab Initio Simulation Package (VASP) was used27,28 with an energy cutoff of 850 eV and 0.03 eV/A for the Hellmann-Feynman force convergence criteria. The periodically repeated system images were separated by 15 Å of vacuum to avoid interaction between them. The (1 × 1 × 3) Monkhorst-Pack grid29 was used for k-point sampling of the Brillouin zone. In order to simulate an electronic environment resembling more closely the situation in DNA and RNA, the C atom of the base molecules linked to the sugar ring in nucleic acid was terminated with a methyl group. Because of the complexity of system, the optimization process was performed in four steps as discussed in our previous studies.18,22

It is worth noting that the LDA functional by its semilocal nature is not the best choice for investigating interactions where vdW forces dominate. However, higher-level methods such as many-body perturbation theory, which are more capable for describing long-range forces, are too expensive to apply to complex systems as considered here. Previous studies\textsuperscript{50,31} have shown that while the generalized gradient approximation (GGA)\textsuperscript{32} does not satisfactorily describe long-range interactions, LDA provides reasonably good description of the system. Also, a recent work\textsuperscript{33} studying the adsorption of adenine on graphite suggests that the potential energy surface obtained by using LDA and GGA with a modified version of the London dispersion formula for vdW interactions is, in practice, indistinguishable. Moreover, the LDA equilibrium distance between adenine and graphene is found to be equal to that obtained using the GGA + vdW level of theory. Based on the above facts, we believe that the LDA functional adopted in the present study is able to render reasonably accurate results in describing the nucleobase-CNT/BNNT interactions.

The bias-dependent electron transmission and current are calculated using the non-equilibrium Green’s function (NEGF) method based on the Keldysh formalism, as implemented in the SMEAGOL program.\textsuperscript{34,38} The current via the gold-connected nanotubes can be obtained as

\[ I = \frac{e}{\hbar} \int_{-\infty}^{\infty} dE T(E,V)\left[f(E-\mu_1) - f(E-\mu_2)\right], \]

where \( \mu_1 \) and \( \mu_2 \) are the electrochemical potentials in the two contacts under an external bias \( V \) and \( f(E) \) is the Fermi-Dirac distribution function. The transmission function, \( T(E,V) \) is an important intrinsic factor describing the average quantum mechanical transmission probabilities multiplied by the number of electron conduction channels for electrons. The semi-infinite effect of the left (right) electrode is taken into account by introducing the self-energy \( \Sigma_L (\Sigma_R) \) in the effective Hamiltonian which was obtained by performing the self-consistent LDA-DFT calculations on the bulk gold with the \( k \)-space sampling of \( 2 \times 2 \times 100 \) grid. The complex part of the integral leading to the charge density is computed using 300 energy points on the complex semi-circle, 300 points along the line parallel to the real axis, and 30 poles. The integral over real energies necessary at finite bias is evaluated over 1500 points. It is worth noting that the transmission depends on both the electron energy \( E \) and the applied external bias \( V \).

For the equilibrium configurations, the separation between nucleobases and the tubular surface falls in the range from 2.6 to 3.0 Å, which is in agreement with an earlier calculation for biomolecules adsorbed on BNNTs\textsuperscript{22,23} and CNTs.\textsuperscript{18} It reaffirms the validity of our approach, used to obtain the equilibrium configuration of the bioconjugated complexes and also the level of accuracy employed in the calculations. The other geometric parameters and electronic properties in the nucleobase-conjugated BNNT/CNT systems are also in excellent agreement with the earlier theoretical studies.\textsuperscript{18,22} We shall now focus on the effect of the adsorption of nucleobases on the transport properties of the metallic CNT and semiconducting BNNT.

![FIG. 2. The transmission functions of the pristine BNNT and CNT at the applied bias = 0 V.](image)
channel. Thus, the transmission predicted for BNNT falls into the tunneling region of the electron transport. We note that the electrostatic force microscopy and scanned gate microscopy measurements have reported the resistance of a CNT bundle consisting of a few ~1 nm diameter metallic tubes. The measured resistance was 40 KΩ which compares well with the predicted resistance of 34.6 KΩ (determined by the ratio of voltage to current at 0.25 V) for the pristine CNT (Figure 3).

In order to compare the response of both BNNTs and CNTs on the same footing, we plot the variation of the normalized current $\Delta I$ with the applied voltage in Figure 4. Here, the normalized $\Delta I$ is defined as $((I_{NT+G} - I_{NT})/I_{NT})$, i.e., $\Delta I$ is the relative current change of guanine-conjugated BNNT (or CNT) with respect to the pristine BNNT (or CNT). In the considered bias range, the guanine-conjugated BNNT renders a larger increase of current ($\Delta I$) as compared to the guanine-conjugated CNT. This difference in response of BNNTs and CNTs can be understood by examining the underlying transmission functions shown in Figure 5 where the normalized transmission function $\Delta T$ is defined as $((T_{NT+G} - T_{NT})/T_{NT})$. The guanine-conjugation induces an ultra-high peak at about $-0.08$ eV for BNNT, while it induces only small peaks for CNT. Note that the current is calculated by summing up the contribution from all the transmission channels in the energy window (i.e., an applied bias of $x$ V corresponds to the energy window of $-x/2$ to $x/2$ eV). Furthermore, a comparison of the underlying transmission functions of BNNT and its conjugated complexes show that guanine offers an additional conduction channel near the Fermi energy unlike the other nucleobases. It is worth noting here that the distinct adsorption feature of guanine-conjugated BNNT was reported in a previous theoretical study. A higher degree of hybridization of the electronic wave function of guanine and BNNT was argued to be responsible for a higher binding energy and a dramatically decreased energy gap compared with other nucleobase-conjugated complexes.

As far as the comparison between the effects of the molecular adsorption of nucleobases on transport properties are concerned, it might be concluded that semiconducting BNNTs are relatively sensitive to the attachment of molecules. This is consistent with the results of a previous theoretical study where weak attachment of trinitrotoluene, benzaldehyde, and benzoic acid was found to affect the current in their conjugated systems with BNNT. One can therefore argue that it is the high background current associated with the metallic CNT which makes the small variation in the current due to the molecular adsorption difficult to detect, unlike the semiconducting BNNTs where the background current is relatively small ($I_{CNT}/I_{BNNT} \approx 10^5$). Adsorption of molecules, e.g., molecules of different polarities, on BNNTs with a much wider variation in binding strengths might be anticipated to have more conspicuous effect on the transport properties of BNNTs.

In summary, the I-V characteristics of nucleobase-conjugated BNNT sandwiched between gold electrodes are studied using the LDA-DFT method together with the non-equilibrium Green’s function method. The calculated results show a direct relationship between the strength of binding of the molecules adsorbed on BNNTs and their effect on the transport properties of the conjugated system. Guanine leads to a higher current in the conjugated BNNTs due to opening of new conduction channels near the Fermi energy of the bioconjugated system.

Helpful discussions with Haiying He are acknowledged. The work at Michigan Technological University was performed under support by the Army Research Office through Contract No. W911NF-09-1-0221.
