Soricomorpha

Soricidae – Shrews

In 25 bogs and ombrotrophic mires of Poland, Ciechanowski et al. (2012) found that shrews dominated among the mammals captured in pitfall traps. The traps produced 598 individuals distributed among 12 mammal species. Typical wetland species included Neomys fodiens (Eurasian water shrew; Figure 2), Neomys anomalus (Mediterranean water shrew; Figure 3), and Microtus oeconomus (tundra vole; Figure 4). The most numerous species was the Eurasian pigmy shrew (Sorex minutus; Figure 5), and it was sometimes the only rodent present in the habitat. It was most common in undisturbed, treeless parts of bogs where Sphagnum (Figure 6) dominated.
Sorex cinereus – Long-tailed Shrew

The long-tailed shrew (Sorex cinereus; Figure 7) occurs from Alaska, USA, east to Labrador/Newfoundland, Canada, south in the USA to Washington, Utah, New Mexico, Northern Great Plains, southern Indiana and Ohio, through the Appalachian Mountains to northern Georgia and western South Carolina, and on the east coast to New Jersey and northern Maryland, where it commonly occurs with mosses (Youngman 1975; Whitaker 2004). It seems often to be present in traps set for lemmings. Hamilton (1941) found Sorex cinereus near the summit of Big Black Mountain in Harlan County, Kentucky, USA, at ~1220 m. Of these, six of the seven specimens were taken from runways at the sides of moss-covered logs in damp, deciduous thickets. In the thickets of Maine and New Hampshire, USA, traps set for lemmings also captured shrews (Clough & Albright 1987). These included Blarina brevicauda (northern short-tailed shrew; Figure 8) and Sorex cinereus. Groves and Yesen (1989) likewise found species of Sorex in lemming traps in a Sphagnum "bog" in Idaho, USA (Figure 9), as did Pearson (1991) in Glacier National Park and Reichel and Beckstrom (1993) in western Montana.

Sciuromorpha

Sciuridae

Records indicating that squirrels use mosses to line their nests are old (Tripp 1888).

*Tamias merriami* – Merriam Chipmunk

The Merriam chipmunk (*Tamias merriami*) has a small distribution in central and southern California, USA (Harvey & Polite 1999). There seems to be little documentation of chipmunks eating or using mosses. Imagine the surprise when Brent Mishler and his team (Mishler & Hamilton 2002) caught a chipmunk (Figure 10-Figure 11) grabbing a chunk of the moss *Syntrichia princeps* (Figure 12-Figure 13) from the very middle of their field of view (Figure 12) through a CAMcorder (see Grant *et al.* 2006 for setup). Mishler (pers. comm. 12 January 2008) suggests that the Merriam chipmunk (*Tamias merriami*; Figure 10-Figure 11) may have been after the water adhering to the moss (*Syntrichia princeps*), as it had just been moistened earlier in the day for an experiment; the surroundings were dry.

Figure 13. *Syntrichia princeps* with capsules. Photo by F. Guana, Modoc National Forest.

*Tamiasciurus hudsonicus* – American Red Squirrel

The American red squirrel (*Tamiasciurus hudsonicus*; Figure 14) seems to eat just about anything. It is more tame than most squirrels, and I have even had a confused squirrel climb my leg! It also seems to like decorating its
abode, using paper, moss, and other local objects it can find (Hanrahan 2012).

Figure 14. *Tamiasciurus hudsonicus* (American red squirrel) uses mosses to decorate its home. Photo by Cephas, through Creative Commons.

**Sciurus vulgaris** – Eurasian Red Squirrel

The Eurasian red squirrel (*Sciurus vulgaris*; Figure 15-Figure 16) is distributed across the northern parts of Europe (Greene 1887). It makes a nest in the fork of a tree. This nest is an interwoven structure of twigs, leaves, and mosses.

Figure 15. *Sciurus vulgaris*, a species that uses pleurocarpous mosses in its nest boxes. Photo from Saxifraga – Mark Zekhuis, with online permission.

Nest boxes used by the Eurasian red squirrel (*Sciurus vulgaris*; Figure 15-Figure 16) displayed pleurocarpous mosses (van Laar & Dirkse 2010). Two of these were ground species [*Hypnum cupressiforme* (Figure 17), *Homalothecium sericeum* (Figure 18)]. The Eurasian red squirrel used only one epiphytic species (*Orthotrichum* sp.; Figure 19), but van Laar and Dirkse suggested that all of the mosses may have been collected from a nearby tree. The nest included ~470 g spruce twigs and ~180 g of these mosses. In addition, the squirrel had included insulation material from the roof of a nearby house. Quinton (1997) reported finding a nest under *Sphagnum* (Figure 6) in the boreal forest of North America.

Figure 18. *Homalothecium sericeum*, a moss used in nests of *Sciurus vulgaris*. Photo by Michael Lüth, with permission.
Pulliainen and Raatikainen (1996) studied the effect of various nesting materials on nest temperature of the red squirrel in Finland. The wind speed had a large effect on differences between inside and outside the nest. During windless times, the temperature difference could be as much as 30°C in nests made of mosses, proving mosses to be superior insulators to the beard lichen (*Usnea*; Figure 20). Juniper bark provided the poorest insulation among the materials tested. A plastic plate under grass greatly increased the inside temperature by restricting the air current throughout the nest.

TalkTalk (2011) describes the nest of the red squirrel as having a layer of twigs with a layer of moss or bark fragments. It is likely that availability is a major influence on the nest materials used.

**Sciurus carolinensis – Grey Squirrel**

The grey squirrel (*Sciurus carolinensis*; Figure 21-Figure 22) lives in the eastern USA, but is an invasive in Europe (Steele et al. 1996; Goheen & Swihart 2003). It builds a nest the size of a football (YPTE 2011). It is comprised of twigs, often with their leaves remaining attached, and is perched high in a tree. The squirrels line the nest with dry grass, shredded bark, moss, and feathers. The summer nest is typically flimsy and located among small branches.

**Spermophilus parryii – Arctic Ground Squirrels**

Like the pikas, it appears that Arctic ground squirrels (*Spermophilus parryii*; Figure 23-Figure 24) survive winter in the "warmth" of hibernacula (Barnes 1989). These rodents can wake up and run around when their core temperature is as low as -2.9°C. Temperatures much lower than that can be lethal for such small homeotherms. Maintenance of a temperature as low as -3°C could save up to ten times as much energy as maintenance of a body temperature above 0°C. It is quite possible that for the pikas, the mosses permit the maintenance of sufficiently "warm" temperatures to survive.
Chapter 17-3: Rodents and Bats – Non-Muroidea

Figure 24. *Spermophilus parryii*, Arctic ground squirrel, a species that seems to benefit from the insulating ability of mosses in the nest. Photo Jim McCarthy, through public domain.

Arctic ground squirrels actually cache bryophytes. They preferentially decapsulate bryaceous mosses and store the capsules in their nests for winter food reserves (Zazula et al. 2006).

Nest materials for these Arctic ground squirrels in the Yukon include mosses and lichens and these are the most common materials found in the pouches of females (Gillis et al. 2005). Carrying these materials was most common prior to and during lactation. These mosses and lichens are absent in male pouches.

**Glaucomys – Flying Squirrels**

*Glaucomys* are active all year, but have little resistance to cold (Marchand 2001). Instead, they keep warm by huddling together in tree cavities lined with grass, moss, or bark. The nests can be as much as 30º warmer than the surrounding air outside the nest. These huddles typically have about 10 squirrels, but there may be as may as 50.

*Glaucomys sabrinus* – Northern Flying Squirrel

The northern flying squirrels (*Glaucomys sabrinus*; Figure 25) has a wide distribution throughout northern North America from Alaska, across Canada to the eastern provinces, with several extensions into northern USA. Like the southern flying squirrel, this squirrel is nocturnal (IUCN 2017).

Figure 25. Northern flying squirrel, *Glaucomys sabrinus*, a species that uses mosses in its nests. Photo by Phil Myers, through Creative Commons.

The northern flying squirrel (*Glaucomys sabrinus*; Figure 25) builds a cavity nest, using various mosses (Patterson et al. 2007). Patterson and coworkers found trace amounts of peat moss (*Sphagnum*; Figure 6), dried grasses, cedar leaves, and twigs in the nests in southern Ontario.

**Glaucomys volans** – Southern Flying Squirrel

The smaller southern flying squirrels (*Glaucomys volans*; Figure 26) occur along the southern USA north to New England (Marchand 2001). They have tiny bodies, weighing only 57-113 g. They are nocturnal, thus most people have never seen them. Nevertheless, they are the most abundant squirrel in the eastern US.

Figure 26. Southern flying squirrel, *Glaucomys volans*, a species that uses mosses in its nests. Photo by Ken Thomas, through Creative Commons.

**Lagomorpha – Hares, Rabbits, and Pikas**

**Leporidae – Rabbits and Hares**

**Lepus arcticus** – Arctic Hare

In the high Arctic, the Arctic hare (*Lepus arcticus*; Figure 1, Figure 27) seems to prefer eating developing bryophyte capsules (Catherine LaFarge, Bryonet 30 March 2016). LaFarge often found decapitated sporophytes, although the lemmings helped in the consumption.
**Oryctolagus cuniculus – European Rabbit**

The European rabbit (*Oryctolagus cuniculus*) is present in all Western European countries, Ireland and UK, Austria, Sweden, Poland, Czech Republic, Hungary, Romania, Ukraine, and Mediterranean, Croatia, and Slovakia (Smith & Boyer 2008).

Rabbits, with their noses to the ground, would seem ideally suited for nibbling on bryophytes. However, it seems they may not find them to their liking. Bhadresa (1977) reported that in a food preference test, the rabbit *Oryctolagus cuniculus* (European rabbit – the only domesticated rabbit; Figure 28) in Norfolk – actually disliked *Dicranum scoparium* (Figure 29). But then, that is only one moss. Davidson *et al.* (1990) found leaf fragments of *Mnium* (Figure 30-Figure 31), *Brachythecium* (Figure 32), *Hypnum* (Figure 17), and *Polytrichum* (Figure 36) species in feces of rabbits in southeast England, but never forming more than 5% of the plant material in a fecal pellet. Rabbits eat a mixed diet (European Rabbit 2009), and it appears that mosses may be part of it – or they are ingested accidentally.

Rabbits can have a negative impact on bryophytes. After a fire in the heathlands of Brittany, rabbits, along with roe-deer, damaged the bryophytes by scraping (Clément & Touffet 1981). The bryophytes were important as initial colonizers after the fire, so the scraped areas suffered from their loss in succeeding plant and animal colonization. The mosses *Funaria hygrometrica* (Figure 33) and *Ceratodon purpureus* (Figure 34) are important in rebuilding the organic matter following fires and their loss is unfavorable to invertebrate development. *Polytrichum* s.l. species have a strong competitive ability compared to tracheophytes in colonizing these nutrient-poor sites. In particular, *Polytrichastrum formosum* (Figure 35) and *Polytrichum commune* (Figure 36) have a higher density and growth rate and can produce 7-8 tons ha⁻¹ yr⁻¹, preventing new species from becoming established and retarding the growth of those already present. As in cases with other rodents, the rabbits may facilitate the development of these *Polytrichaceae* colonies.

But rabbits (*Oryctolagus cuniculus*: Figure 28) can also create habitat for bryophytes. Callaghan (2015) reports that some mosses thrive due to grazing activities by rabbits in the UK. A more spectacular find occurred at an old tin works in Cornwall, where the rare copper moss *Scopelophila cataractae* (Figure 37) benefits by the creation of habitats by rabbits. As succession proceeds on the exposed mineral soil, the tracheophytes replace the bryophytes. However, when the rabbits arrive, the rabbits
create a network of runways and tunnels, exposing the metal-rich soil where the copper moss thrives. These serve as refugia for this moss species that is disappearing as the more coarse vegetation develops. The entrances to burrows are clothed in a mat of protonemata (Figure 38) that have abundant gemmae (Figure 39). Callaghan speculates that the rabbits must disperse thousands of these gemmae on their fur, and the entrance to the tunnel is often the benefactor substrate.

The European rabbit has multiplied from the 24 introduced to Australia in 1859 to over 600 million in less than a century (European Rabbit 2009), suggesting that this rapid multiplier could present considerable destruction to mosses, or could favor their increase by destroying lichens. In areas where rabbits have been introduced, they often have no natural enemies. Australia is a case in point. In such cases, the virus causing myxomatosis may be their only enemy. While this has been used successfully to help control the rabbits, the ones currently remaining in Australia are now immune to it.

In an area where rabbits have been introduced, they often have no natural enemies. Australia is a case in point. In such cases, the virus causing myxomatosis may be their only enemy. While this has been used successfully to help control the rabbits, the ones currently remaining in Australia are now immune to it.

In a dune system in Wales, the advent of myxomatosis caused changes in the vegetation. This area had been the site of severe rabbit grazing. In 1954, myxomatosis began to spread to the area and Ranwell (1960) anticipated the loss to the rabbit population. In May of 1955 rabbit pellets were common and thick on the transects across turf areas. Mosses were very evident among the 1-2 cm high turf, but were much less evident in the deep turf. During the succeeding years of rabbit decline, grasses, sedges, and pleurocarpous mosses [Ditrichum flexicaule (Figure 40), Pseudoscleropodium purum (Figure 41), Rhytidiadelphus squarrosus (Figure 42), R. triquetrus (Figure 43)] increased, surviving in the ungrazed turf. Eurhynchium praelongum (Figure 44) and Plagiomnium undulatum (Figure 45) also increased during the study period. At the same time, decreases were evident in the acrocarpous mosses Bryum sp. (Figure 46), Climacium dendroides (Figure 47), Dicranum scoparium (Figure 29), Syntrichia ruralis (Figure 48). Rhodobryum roseum (Figure 49) disappeared from 1955 to 1958. Overall, the bryophyte richness remained unchanged. The greatest losses of mosses occurred only after 3-4 years of recovery from grazing.

The results of Ranwell (1960) differ somewhat from those of Watt (1957), who showed that disappearance of rabbits resulted in the decrease of mosses in ungrazed pasture over long periods of time. Watt found that mosses in the ungrazed turf are tall and mostly pleurocarpous. The small mosses seem to be unable to survive competition with taller vegetation, including competition for light. The larger mosses, on the other hand, seem to thrive in the ungrazed conditions. Watt considered these results to support the hypothesis that "in the grazed community the competitive power of the potentially taller growing plants is reduced by grazing sufficiently to allow the smaller species to survive and that in the ungrazed the unchecked growth of taller growing species eliminates or tends to eliminate the smaller, whether they are annual or perennial of varied life-forms."

Gillham (1955) also stressed the importance of rabbit grazing, considering it to be less important than exposure. This contention was supported by the abundance of mosses that are intolerant of extreme exposure, but that are able to reach their maximum in the "closely nibbled swards." Heavy grazing caused moss cover to reach 25%, mostly of the moss *Ceratodon purpureus* (Figure 34) – a moss that is not shy of sunlight. In early spring, when the rabbits were most hungry, the lanes between the grazed heather bushes were dominated by the mosses *Rhytidiadelphus squarrosus* (Figure 42) and *Hypnum cupressiforme* (Figure 17). Gillham (1954) found that bryophyte fragments were only occasionally present in the rabbit dung and concluded that they were probably only eaten when mixed with other plant material. Although the bryophytes are important components of the turf in heavily grazed inland areas, they have little importance on sea cliffs due to their exposure to wind and salt there (Gillham 1955).

Ochotonidae – Pikas

*Ochotona princeps* – American Pika

The American pika (*Ochotona princeps*; Figure 50) is distributed widely in British Columbia and the western USA (Defenders of Wildlife 2017). Mosses are often a dominant feature of their landscape.

Figure 50. *Ochotona princeps* among mosses. Photo courtesy of Mallory Lambert, through Johanna Varner.

The presence of pikas is usually a good indicator of regions with rocky, mesic, cool habitat (Figure 51) with long winters and short summers (Simpson 2009). Although
the American pikas (*Ochotona princeps*; Figure 51) are a high elevation species in western North America, in the Columbia River Gorge they live near sea level (Horsfall 1925; Varner & Dearing 2014a, b). But at low elevations in the southern part of the Columbia River Gorge, Oregon, USA, the known temperature range was extended and the long winters and typical snow accumulation were not present.

![Figure 51. *Ochotona princeps* among the rocks and mosses of a talus slope. Photo courtesy of Johanna Varner.](image1)

Dr. Erik Beever (pers. comm.), research ecologist for the National Park Service Inventory & Monitoring program, reported to me that pikas occur at low elevations (less than 150 m) in a valley fed by a snowmelt river in the Cascade Range of western USA. The valley is cold, and he theorizes that their ability to survive the winter without their usual snow cover is due to the thick (>20 cm) moss mats that provide cover and insulation for them (Figure 52).

![Figure 52. *Ochotona princeps* emerging from tunnel covered with *Hylocomium splendens* and *Selaginella* sp. Photo courtesy of Johanna Varner.](image2)

Varner and Dearing (2014b) supported this assessment, finding that the moss cover insulates the interstices of the talus slopes from temperature fluctuations. Varner and Dearing (2014a) speculated that the mosses could cool the microclimates of the talus in the valley (Figure 51), making the climate suitable for the pikas. The pikas are able to travel long distances beneath the thick moss cover. Even their extensive moss consumption only removes about 0.002% of the moss in their home ranges in one year. Hence, unlike the lemmings, the pikas can enjoy the cover of the mosses without the danger of eliminating it.

In this unusual habitat they subsist on what is for most rodents an unusual food – mosses (Varner & Dearing 2014a, b). These mosses comprise more than 60% of the diet at the two sites studied. At this rate, the pikas consume ~7.31 g/day and 2.67 kg/year of mosses. The mosses are available all year, thus making food caches unnecessary.

Richardson (1981) considered mosses to be a difficult food for mammalian herbivores, having a high fiber content, low nitrogen, and low digestible energy compared to other food choices. Varner and Dearing (2014a) reported the same high fiber and low nitrogen (<1%) in the mosses of the Columbia River Valley. But the pikas re-ingest their fecal pellets. As a result, the *caecal pellets* (partially digested foods passed as fecal pellets, then re-ingested) of these pikas were far more nutritious, having low fiber content and high nitrogen content, thus allowing the pikas to gain greater nutritional value than that available to other herbivores that do not re-ingest their fecal material.

At high elevations, these talus dwellers forage on the surrounding vegetation (Figure 53) (Huntly *et al.* 1986). Their foraging intensity decreases with distance from the *talus* (rock fragments accumulated at base of cliff or slope), but their selectivity increases with distance, consistent with the "central place foraging theory." In this case, plant abundance increased with distance from the talus. The pikas would travel greater distances to harvest plants for caching (Figure 54) rather than for immediate consumption. For these haying forays, higher proportions of forbs and tall grasses were selected. The haypiles serve to sustain the pikas during winter (Dearing 1997a).

![Figure 53. *Ochotona princeps* eating a sedge in the Rockies, a rodent that runs around under the moss layer. Photo by Sevenstar, through public domain.](image3)
Dearing (1996) tested the hypothesis that plant secondary compounds may be higher in the winter diet either because they function as preservatives or because pikas delay consumption of these species until the toxins degrade. Dearing found little evidence suggesting that morphology excluded any plants from the winter diet, nor was plant size of importance. Even nutrient content showed only a weak relationship. On the other hand, the winter diet was significantly lower in water content and higher in total energy content, but no other nutrients had any consistent pattern. The manipulation of secondary compounds was, however, important. The winter diet contained more total phenolics and had greater astringency.

Dearing (1996) suggested that these secondary compounds helped to preserve the cache, but it also made an additional (initially toxic) food source available. In a follow-up study, Dearing (1997b) found that following 10 months of storage, the winter diet retained 20.5% more biomass with a higher level of energy while being lower in fiber and equal in nitrogen when compared to the summer diet of these pikas. Experiments demonstrated that the pikas preferred foods with a lower phenolic content compared to species with a high content, and they delayed eating those high phenolic species in the haypile until the phenolic content had decreased (due to microbial activity). This need to store a winter cache occupied almost 55% of the surface activity and the evolution of territoriality most likely relates to the need for sufficient vegetation for the winter food cache (Conner 1983).

Behavioral differences between high elevation and low elevation populations of pikas also contributed to their survival at the lower elevations (Smith 1974). At high elevations (3,400 m) the pikas were active throughout the day. At a lower altitude site (2,550 m) they were mostly active in the morning and late afternoon. During their inactive times at high temperatures, survival made it necessary for them to retreat to favorable microclimates among the rocksides. While onset of vocalization and parturition occurred about six weeks earlier at the low altitude site, as one might expect, it seems strange that the onset of hay storage likewise occurred six weeks earlier. But the timing of vocalization and haying were actually correlated with the amount of precipitation during the previous winter. When the winter was dry with little snow and spring was early, the pikas responded by earlier vocalization and haying. (Perhaps the earlier haying was to ensure more moisture or higher nutrient content of the food items?]

In warm weather, the American pikas have only short bursts of surface activity, typically less than 2.5 minutes at a time (MacArthur & Wang 1974). Instead, they remain in the cooler microclimate beneath the rocks and regulate their body temperature to only 2-3ºC below their upper lethal temperature.

The mean body temperature of a pika ranges 37.9–42.7 in an ambient temperature range of -9.3 to 24ºC (MacArthur & Wang 1973). Hyperthermia causes death after only two hours of exposure to ambient temperatures higher than 28ºC. Its ability to maintain a high body temperature through high metabolism and thick insulation permits it to survive in its high elevation habitat where food storage is limited. Climatic shifts that cause warmer temperatures put the pikas in peril of at least local extinctions (Beever et al. 2010). Such local extinctions have already occurred for the American pika living in the Great Basin (Beever et al. 2010, 2011). The survival of mosses that ameliorate the high temperatures will be critical to the survival of pikas in these habitats.

**Ochotona collaris – Collared Pika**

The collared pika (*Ochotona collaris;* Figure 55) is distributed in Alaska and the Yukon (Defenders of Wildlife 2017). They live on a diet of grasses and grass-like plants called sedges, but will include flowering plants, twigs, moss, and lichens among food items. Koju and Chalise (2014) assumed that the poor quality of food in winter caches for this species were due to predation pressure that limited their foraging radius to 10 m.

An interesting mechanism by at least some collared pikas is the selection of food that has previously experienced herbivory by caterpillars (Barrio et al. 2013). Could they be seeking food that had higher levels of secondary compounds, stimulated by the herbivore attacks? Or were these herbivore activities signals of suitable food of high quality?

**Like Ochotona principes** (Figure 50-Figure 54), *O. collaris* (Figure 55) can run across the talus slope under the moss cover (Morrison et al. 2004) in its Yukon, Canada, home (Morrison et al. 2009). This most likely reduces predation risk as well as modulating the temperatures they
experience (Morrison et al. 2004). Nevertheless, choice of food nutrition level does not seem to be dictated by predation risk. On the other hand, in experiments total amount of forage removed by the pikas was inversely related to predation risk.

**Erinaceidae – Hedgehogs**

The European hedgehog (*Erinaceus europaeus*) is a nocturnal species of Europe and Central Asia. As its name implies, it is common in hedgerows. The hedgehog (*Erinaceus europaeus*; Figure 56) is the only British mammal to have spines (Wildscreen 2010). They have fairly short tails, long legs, and small ears. They eat mostly insects, but may include other small animals, like frogs and rodents.

**Figure 56.** *Erinaceus europaeus*, a species that uses pleurocarpous mosses for nesting materials. Photo by Jörg Hempel, through Creative Commons.

When young hedgehogs are born, they have a coat with soft, white spines under the skin to protect the mother during birth. After a few hours these emerge. After about 36 hours, a second coat of dark-colored spines emerges, then later a third set emerges. By day eleven, the hedgehogs are able to curl into a ball, and finally after 14 days their eyes open. They are nocturnal, having large eyes, but they may also be active in the daytime (Wikipedia 2017a). They are solitary animals, and only the female takes care of the young.

They rest in the daytime in nests made of twigs, leaves, grass, pine needles, and other foliage. The "other foliage" includes mosses (Figure 57), sometimes in large quantities! Fortunately, the nest is re-used by another individual. The hedgehog selects pleurocarpous mosses that are available near the nest among its nesting materials (van Laar & Dirkse 2010). The authors suggest that the mosses may be selected to maintain a suitable humidity in the nest.

**CHIROPTERA – Bats**

**Pteropidae – Flying Foxes**

*Pteropus conspicillatus* – Spectacled Flying Fox

The flying fox of Australia is really a kind of bat associated with the rainforest habitats of the Wet Tropics bioregion of northeastern Queensland, Australia (Parsons et al. 2007). The spectacled flying fox (*Pteropus conspicillatus*; Figure 58-Figure 59) seems like an unlikely candidate for eating mosses, but... this bat ingests mosses, as evidenced by feces (splat) comprised of 14% moss (Andi Cairns, pers. comm. 4 December 2004). Samples from the wet complex notophyll vine forest had the greatest occurrence of bryophytes in fecal samples (22.8% of 685 samples) (Parsons et al. 2007). The fragments represented a diversity of bryophytes (15 families of mosses, thalllose and leafy liverworts) and ranged from whole plants to detached leaves. The bryophytes evidenced effects of being eaten: highly fragmented, abraded, tightly interwoven with hair and fiber content. The bryophytes mixed with hair suggested that they may have been ingested during grooming.

The use of bryophytes as food may be accidental or at least of only minor significance. On the other hand, the flying fox appears to be an effective dispersal vector. Using material from the interior of the feces (Figure 60-Figure 61), Parsons (Figure 60) and coworkers (2007) demonstrated that 52% of 48 fragments developed rhizoids and/or shoots in culture. Seasonal effects were evident, with those collected early in the season having greater germination success (17 of 28 fragments) than those collected later in the growing season (7 of 20).

Summary

Larger rodents make use of bryophytes, particularly for nesting materials, but a few eat them. Bryophytes make habitats for some of these, especially in bogs, fens, and other wetlands, and in Arctic regions. Such common bog dwellers include shrews, The Merriam chipmunk gathers mosses, presumably for nesting material, but it could possibly be for food. The Eurasian red squirrel uses mosses in its nest, possibly to buffer the temperature, and possibly also explaining use by the Arctic ground squirrels in their hibernacula. Flying squirrels include mosses in the nest, presumably for the same purpose. The grey squirrel includes mosses to line the nest. The red squirrel uses mosses to decorate its home. Pikas use the mosses as a cool cover during hot days. Pleurocarpous mosses are often preferred for nesting.

Uses for food are less common among these larger rodents, but the Arctic ground squirrels cache moss capsules for winter food. The Arctic hare likewise consumes moss capsules. The European rabbit eats the leafy portions, but it is choosy about which species it eats. Pikas eat mosses when they are abundant. They re-ingest their feces, permitting them to obtain more nutrients from ingested mosses. Even the flying fox (actually a bat) ingests mosses, and in the process it serves as a dispersal agent.

Scraping activity by rabbits can destroy bryophytes, but this favors the growth of *Polytrichum* species and creates disturbed habitats suitable for *Funaria* and *Ceratodon*. And a rabbit burrow provided a suitable habitat (and probably dispersal) for the rare *Scopelophila cataractae*. In Australia, rabbits caused the disappearance of some species and appearance of others, maintaining similar bryophyte species richness. *Rhytidiadelphus squarrosum* benefits from grazing in England, but disappears with rabbit grazing in Australia.
Acknowledgments

This chapter has benefitted greatly from anecdotal records sent to me by bryologists and friends who observed these small rodents interacting with mosses in the field. Steve Junittka, a former plant taxonomy student of mine, sent me an excited email from Isle Royale after observing the young mouse devouring capsules of Funaria hygrometrica. Leah Vucetich, an Isle Royale researcher, provided me with the tentative identification of a juvenile Peromyscus based on the picture alone. Andi Cairns alerted me to the study on the spectacle flying fox. Johanna Varner helped me get images of pikas. Thank you to Brent Mishler for helping me to get all the information I needed regarding the CAMerger observations of the Merriam chinkmunk and to Des Callaghan for helping me retell the story of the role of rabbits in making a habitat for Scopelophila cataractae.
